Abstract

Background: Fewer Canadian seniors are vaccinated against pneumococcal disease than receive the influenza vaccine annually. Improved understanding of factors influencing pneumococcal vaccination among older adults is needed to improve vaccine uptake.

Methods: A self-administered survey measuring knowledge, attitudes, beliefs and behaviours about pneumococcal vaccination was administered to a cohort of seniors participating in a clinical trial of seasonal influenza vaccines at eight centers across Canada. Eligible participants were ambulatory adults 65 years of age or older, in good health or with stable health conditions, previously given influenza vaccine. The primary outcome was self-reported receipt of pneumococcal vaccination. Multi-variable logistic regression was used to determine factors significantly associated with pneumococcal vaccine receipt.

Results: A total of 863 participants completed questionnaires (response rate 92%); 58% indicated they had received the pneumococcal vaccine. Being offered the vaccine by a health care provider had the strongest relationship with vaccine receipt (AOR 23.4 (95% CI 13.4-40.7)). Other variables that remained significantly associated with vaccine receipt in the multivariable model included having heard of the vaccine (AOR 10.1 (95% CI 4.7-21.7)), and strongly agreeing that it is important for adults > 65 to be vaccinated against pneumococcus (AOR 3.3 (95% CI 1.2-9.2)). Participants who were < 70 years of age were less likely to be vaccinated.

Conclusions: These results indicate healthcare recommendation significantly influenced vaccine uptake in this population of older adults. Measures to encourage healthcare providers to offer the vaccine may help increase coverage.

Background

Invasive pneumococcal disease (IPD), caused by the *Streptococcus pneumoniae* bacterium, frequently results in serious outcomes including bacteremia, meningitis, bacterial pneumonia and death; vaccination is the primary means of prevention. In 2010, the incidence of IPD among adults 60 years of age and older in Canada was 23.2 per 100,000 and accounted for 48% of IPD cases reported in the country [1]. Vaccination coverage against pneumococcal disease is consistently lower than coverage for seasonal influenza among the elderly population in Canada and globally [2]. The most recent data available from the 2006 Canadian National Immunization Coverage Survey, based on self-report of vaccination status, estimated that only 39% of individuals 65 years of age and older had ever been vaccinated against pneumococcal disease whereas 70% had received the influenza vaccine that season [3]. A 2007 systematic review of the determinants of influenza and pneumococcal vaccination in the elderly, which included 14 studies from around the world, not including Canada, found the strongest predictors of pneumococcal vaccination were older age and physician recommendation [2]. Canadian studies of the knowledge and determinants of pneumococcal vaccination in older adults are lacking.

Currently, the polysaccharide pneumococcal vaccine (PPS), which covers 23 pneumococcal serotypes, is recommended and publicly funded for all adults 65 years of age and older in Canada [4] and in January 2012 the 13-valent pneumococcal conjugate vaccine was approved for use among adults over 50 years of age in Canada. The conjugate vaccine is made from purified polysaccharides of 13 different serotypes of *S. pneumoniae* individually conjugated to non-toxic diphtheria cross reactive material 197 (CRM197) protein [5]. At the current time, the 13 valent conjugate vaccine is recommended and funded for Canadian infants and in some jurisdictions for adults with specific health conditions that place them at increased risk for pneumococcal infection (e.g. immunocompromised) [6]. Because pneumococcal immunization coverage rates remain low and newer conjugate vaccines may improve vaccine performance [7], the objective of this study was to understand the knowledge, attitudes and beliefs of an older population regarding pneumococcal immunization. An improved understanding of the factors influencing pneumococcal vaccine uptake among older adults could allow development of targeted interventions to promote pneumococcal immunization in hopes of improving vaccine coverage in this higher-risk age group.

Methods

A cross-sectional survey was given to a convenience sample of adults participating in a clinical trial of seasonal influenza vaccines conducted by PCIRN (the Public

Health Agency of Canada/Canadian Institutes of Health Research Influenza Research Network, <http://pcirn.ca>) between October 6 and November 17, 2011. Eligible participants were English or French speaking ambulatory adults 65 years of age or older, in good health or with stable health conditions, who had received the influenza vaccine within the past two years. Further, all participants lived independently or in centers providing minimal support for daily living activities. Recruitment occurred in health centers in five Canadian provinces (British Columbia, Manitoba, Ontario, Quebec and Nova Scotia). The study was approved by the following research ethics boards: University of Manitoba Bannatyne Research Ethics Board, McGill University Health Centre Biomedical Department Research Ethics Board, Hamilton Health Sciences McMaster University Research Ethics Board, IWK Research Ethics Board, Mount Sinai Hospital Research Ethics Board, Ottawa Hospital Research Ethics Board, Centre Hospitalier Universitaire de Québec comité d'éthique, and the University of British Columbia, Children's & Women's Health Centre of BC Research Ethics Board. Participants were not provided with an incentive to complete the survey and all participants provided written informed consent.

Survey instrument

The self-administered questionnaire (supplemental information online) was based on the theory of planned behaviour [8] and the health belief model [9] and consisted of 25 questions. It measured the subject's knowledge of pneumococcal infection and immunization (three questions), perceived risk (three questions), personal normative beliefs (three questions), attitudes towards vaccines (six questions), facilitating conditions for vaccination (three questions) and respondent characteristics (7 questions). Of the 25 questions, ten were on a six point Likert scale with options of: "strongly disagree", "somewhat disagree", "neither agree nor disagree", "somewhat agree", "strongly agree" and "I don't know", eight questions had the option of "yes", "no" or "I don't know" and seven questions targeted demographics. Demographic information collected included sex, age, ethnicity, education level, hospitalization/emergency department/walk in clinic visit in the last year, vaccination status, and approximate annual household income. A measure of frailty was assigned to each participant by a site investigator (nurse or physician) using the previously validated Canadian Study of Health and Aging Clinical Frailty Scale which is a seven point scale ranging from "very fit" to "severely frail" [10]. The survey instrument, which was previously used in a younger population of parents and pregnant women, was pilot tested on the first ten participants at each centre to ensure clarity and comprehension; however, validity and reliability were not measured. All data collected were used in the analysis.

Research nurses trained in immunization reviewed all questionnaires for completeness and were available to offer participant clarification. If participants had questions regarding pneumococcal disease or the vaccine, these were addressed after the survey was completed and a pneumococcal information pamphlet was made available to all participants (supplemental information).

Outcome measure

The outcome variable used was self-reported receipt of the pneumococcal vaccine. All study participants were asked, "Have you ever previously had the pneumonia vaccine?" Possible responses were, "yes", "no" or "I don't know". Individuals indicating unknown vaccination status ($n = 75$, 8.75%) were excluded from the regression models. These individuals were older (29.3% > 80 years) and a larger proportion were "apparently vulnerable" (6.7%) relative to individuals who remembered their vaccination status, otherwise they were similar to the rest of the study participants.

Statistical analysis

Data analysis was performed using SAS version 9.3 for Windows (SAS Institute Inc., Cary, NC). All variables were explored descriptively with frequencies. Due to lack of dispersion across categories, all questions on the six point Likert scale were collapsed to four categories for the purpose of model building: "strongly agree", "somewhat agree", "strongly or somewhat disagree" and "I don't know" (a combination of those who responded "neither agree nor disagree" and "I don't know"). Bi-variable analyses investigating the relationships between self-reported vaccination status and all survey questions including demographics, knowledge, attitudes and beliefs variables were performed using Pearson's chi-square test and logistic regression.

A multi-variable logistical regression model was built to identify the variables that were associated with self-reported vaccination status. All survey variables with a significant crude relationship with vaccination status, with the exception of those identified as being collinear and those lacking the dispersion required, were included in the initial model. Demographic variables were included as potential confounders. A backward elimination process was used ($\alpha > 0.10$) to determine the best predictive model, this model was robust to stepwise and forward selection model building processes. The variable "centre", which represented the recruitment health centre, was retained in the model to account for similarities in the outcome status between individuals from the same centre. Model fit was assessed by examining the results of the Hosmer and Lemeshow goodness-of fit test and the Deviance residuals.

Results

Study population

Participant demographic characteristics by vaccination status are shown in Table 1. Of the 937 eligible individuals (59.3% female), 863 completed questionnaires (response rate 92%). The mean age of participants was 73.6 years with significantly more women participating than men (59%, $p < 0.01$). Almost all (98%) indicated they had a regular doctor for primary care whom they had visited in the last year (96%).

Seventy-one percent ($n = 615$) of participants stated they had heard of a vaccine that prevents pneumonia. Of those who had heard of the vaccine, 26% ($n = 157$) had not been told about it by their doctor/healthcare provider. Results from the knowledge, attitudes and beliefs questions can be found in Tables 2 and 3.

The percentage of individuals who self-identified as being in a high risk group for pneumonia varied with frailty score. Thirty seven percent of individuals who were "very fit", 40.2% who were "well", 45.3% who were "well with treated co-morbid disease" and 43.5% of those who were "apparently vulnerable" either strongly or somewhat agreed with the statement "I am at high risk of pneumonia"; 21.5%, 19.9%, 13.2% and 17.4% of the "very fit", "well", "well, with treated co-morbid disease" and "apparently vulnerable" respectively either somewhat or strongly disagreed with the same statement.

Vaccination status and bi-variable analyses

Fifty eight percent of participants ($n = 502$) indicated they had previously received the pneumonia vaccine. Those with higher unadjusted odds of vaccination included: women, individuals 70–79 years old, those with less than a university education, and individuals who were well with treated co-morbid disease relative to those who were well or very fit. Further, having been offered the pneumococcal vaccine by a health care provider, having been told by a healthcare provider about the pneumonia vaccine and believing their healthcare provider thought receipt of the vaccine was a good idea were all positively associated with vaccine receipt. As these latter three variables were highly correlated, recalling having been offered the vaccine by a health care provider was chosen for use in the multi-variable models as it was the strongest predictor of vaccination status. There was variation in distribution of vaccination status by study site. Montreal had the highest percentage of participants who reported receipt of the pneumonia vaccine (75%), 10% greater than any other study site. The majority of knowledge and attitude questions had a significant crude relationship with vaccination status (Tables 2 and 3).

*Number and percent of vaccinated individuals within each category.

Multivariable model

Variables significantly associated with receipt of vaccine in the multivariable logistic regression model are shown

in Table 4. Being offered the vaccine by a health care provider had the strongest relationship with vaccine receipt. Other variables that remained in the multivariable model included having heard of the vaccine, and strongly agreeing that it is important for adults older than 65 years to be vaccinated and age category.

Discussion

Fifty-eight percent of study participants recalled receiving the pneumococcal vaccine, a result that is 20% higher than the findings of the 2006 National Immunization Coverage Survey (NICS) which found only 39% of Canadians \geq 65 years of age recalled being immunized against pneumococcal disease [3]. This could reflect a true increased coverage among older adults in Canada, or it could be reflective of differences in our study population, which was highly compliant with annual influenza vaccination. In 2006, the national target for pneumococcal vaccine coverage was 80% among older adults. Although our results are still well below this level, the data suggest an increasing trend.

Vaccine provision by a healthcare provider is consistently found to be one of the strongest independent predictors of pneumococcal and influenza vaccine receipt among the elderly [11-14], a finding reproduced in this study. Although most participants had access to a health care provider (97% had seen their primary care provider in the past year), and therefore the opportunity to be offered the vaccine, only 52% remembered their health care provider offering them the pneumococcal vaccine at any time. This is important as approximately 9 out of 10 participants who indicated they had been offered the pneumococcal vaccine by a healthcare provider in the past also remembered being vaccinated compared to 3 out of 10 participants who did not recall being offered the vaccine by a healthcare provider. Healthcare providers should routinely offer to immunize their older patients with the pneumococcal vaccine. They have an essential role in educating their patients about the risks of IPD. In a recent meta-analysis, clinician reminders and education and patient outreach involving personal contact were all identified as factors that have been observed to improve coverage of pneumococcal vaccination among community dwelling adults [15].

Uncertainty about the effectiveness of pneumococcal vaccines among physicians may help to explain the apparent lack of advocacy for immunization. Some clinical trials and recent large observational studies have found that the polysaccharide vaccine is associated with reduced risk of pneumococcal bacteremia, presumptive pneumococcal pneumonia and both pneumococcal and all-cause community acquired pneumonia [16-19] however, a meta-analysis of clinical trials investigating the efficacy of PPS in adults found higher quality trials failed to find a protective effect [16]. A recent nested case-control

study found the effectiveness of the vaccine higher for females compared to males (68% vs. 34% respectively) [20]. These conflicting results make it difficult to determine the true efficacy of the vaccine. It is possible, that if strong evidence of improved performance of the conjugate vaccine relative to PPS in adult populations is found, clinicians may be more motivated to provide recommendations to their adult patients. Other barriers to physicians immunizing with PPS that have been previously identified include other urgent concerns dominating office visits, rarity of pneumonia in their daily practice, not being able to

determine vaccine status and lack of knowledge regarding the possibility of revaccination [21-23].

Consistent with previous findings from the United States [14], Spain [24] and Sweden [25], individuals 70 years of age or older had a significantly higher probability of having been vaccinated relative to participants less than 70 years of age. Also consistent with previous findings, participants who were "well, with treated comorbidities" had a higher probability of vaccine receipt relative to those who were deemed "very fit" on the frailty scale [25,26]. This observation may be partially

explained by self-perceived risk of pneumococcal infection. Individuals who were deemed "very fit" or "well" were significantly more likely to strongly or somewhat disagree to the statement "I am at high risk for pneumonia" relative to those who were deemed "well, with treated-co-morbid disease" or "apparently vulnerable" (20.2% vs 12.2%). A 2007 meta-analysis of the relationship between risk perception and vaccination behaviour among adults found that an individual's perceptions of risk, and perceived severity of the disease are both associated with vaccination behaviour [27]. This suggests that one area of intervention to increase vaccine uptake could include education programs for individuals in their late

60's and who are apparently healthy, which focus on their heightened risk of IPD and their risk of more severe outcomes due to their age.

Increasing awareness about pneumococcal vaccines and the risk of infection among older adults is needed as it has been found that not being vaccinated with PPS is directly associated with a lack of knowledge about the vaccine among adults 65 years of age or older [14]. We found that having heard of the vaccine and knowing that the pneumococcal vaccine was different than the influenza vaccine were associated with a higher probability of recalling vaccination. Although not surprising, these findings are an important reminder that the older adult

population should be educated in an ongoing fashion regarding the availability of vaccinations that can be accessed to maintain good health. Among the vaccine-accepting population recruited for this study, 20% indicated they had not heard of the pneumococcal vaccine despite all participants being eligible to receive the vaccine free of charge. The proportion of individuals lacking knowledge of the vaccine is likely higher among the general older adult population of Canada.

Because a recommendation from a healthcare provider is the strongest predictor of vaccination, information on the pneumococcal vaccine would likely be well-received from such a source and healthcare providers will be the key source for most people. However, other sources of communication may also be important. Approximately 26% of participants in our study who had heard of the pneumococcal vaccine said their healthcare provider did not tell them about it or offer it to them, indicating that these participants accessed their information differently. Of interest is the developing role of pharmacists in providing vaccinations in Canada. Pharmacists are, or will soon be licensed to vaccinate in six provinces and are another potential route of informing the population about the vaccines recommended and available to them [28].

Individuals participating in this study had a history of vaccination, since they had all received an influenza vaccine in the prior two years. They were ambulatory adults 65 years of age or older, in good health or with stable health conditions. With this in mind, these results may not be generalizable to all older adults in Canada. Even in this highly motivated population, the uptake was lower than the national target indicating room for improvement. The outcomes of vaccination status, and having been offered the pneumococcal vaccine by a health care provider were both based on self-report and thus subject to recall bias. Finally, this is an analysis of cross-sectional data so it is not possible to determine temporality. It is not clear if participants heard of the vaccine because they were vaccinated or were vaccinated because they had heard of the vaccine. Although temporality cannot be established, it remains valuable to consider the strongest relationships identified and the role these variables may play in increasing vaccination against IPD.

Conclusions

Coverage with PPS among older adults in Canada remains low. The results of this study indicate that investing resources to educate healthy seniors about their risk of IPD could increase coverage with PPS. The largest gains in coverage would likely be achieved through improved education of patients and physicians as well as recommendations to vaccinate, and provision of vaccine by health care providers.

Competing interests

AS: None. JAB: None. MD: None. CLC: None. BLC: None. ML: None. ER: Has received payments for lectures and participation in advisory's for Pfizer and Merck. SH: Acts as a co-investigator in clinical trials and surveillance studies funded by Pfizer. No financial interests. JM: Participated on advisory boards and in the preparation of educational materials for Merck. DWS: Participated on an advisory board on pneumococcal vaccines (2010) sponsored by Pfizer and holds an unrelated investigator-initiated grant from Pfizer. SAM: Holds an investigator initiated research grant from Pfizer and acts as an investigator for studies funded by Pfizer and Merck. BW: In the last 5 years has helped Wyeth (Pfizer) develop CME teaching tools related to pneumococcal vaccination. Has also received honoraria from Pfizer for talks related to vaccine use in adults (including pneumococcal vaccine) and vaccine science in general. Pfizer had no input regarding the content of these talks other than the suggested topic.

Authors' contributions

AS participated in the study design, carried out statistical analysis, and wrote the manuscript. JAB designed and supervised the study and data collection, provided direct supervision of AS and revised the manuscript. MD participated in the study design, implementation and data collection at the Quebec City site. CLC participated in the study design, implementation and data collection at the Ottawa site. BLC participated in the study design, implementation and data collection at the Toronto site. ML participated in the study design, implementation and data collection at the Hamilton site. ER participated in the study design, implementation and data collection at the Winnipeg site. SH participated in the study design, implementation and data collection at the Halifax site. JM participated in the study design, implementation and data collection at the Vancouver site. DWS participated in the study design, implementation and data collection at the Vancouver site. SAM participated in the study design, implementation and data collection at the Ottawa site Halifax. BW participated in the study design, implementation and data collection at the Montreal site. All authors read and approved the final manuscript.

Acknowledgements

The authors acknowledge the support provided by the site coordinators, nurses and other staff of participating centers, the study coordinator (Carol LaJeunesse), and the data manager (Kim Marty). This study was conducted by the Public Health Agency of Canada/Canadian Institutes of Health Research Influenza Research Network (PCIRN), with funding from an investigator initiated grant from Pfizer, Inc. Pfizer had no role in the study design, conduct or analysis. The authors would like to acknowledge the networking assistance provided by the Canadian Association for Immunization Research and Evaluation (CAIRE). AS was supported by a PCIRN scholarship. JAB is supported by a Career Investigator Award from the Michael Smith Foundation for Health Research.
