For the question where the expected values are equal (Q15), Table 2 shows that 64% of the participants choose to take option B; this value corresponds to the mean of the participants' answers. To calculate the mean for the overall population of the construction project leaders' potential answers, an approach would be to compute a confidence interval using the binomial analysis. This confidence interval is shown in equation 2:

\[ \bar{x} - t \cdot \frac{\sqrt{\bar{x}(1 - \bar{x})}}{\sqrt{n}} ; \bar{x} + t \cdot \frac{\sqrt{\bar{x}(1 - \bar{x})}}{\sqrt{n}} \]

Where:

- \( n \) = Sample Size
- \( \bar{x} \) = Sample Mean
- \( t \) = Value linked with the confidence level

For this experiment, the t-value corresponding to a 95% confidence interval is equal to 1.96. So, the 95% confidence interval for this question (Q15) computed with equation 2 is 36 ±13% for option A and 64 ±13% for option B. This interval is too large to quantify the impact of this behavioural tendency but it is enough to show the pattern of certainty effect on construction leaders' choices as the confidence interval of the two options are not intersecting. It means that more than half of the population of construction project leaders makes the choice to avoid the risk when the expected values are equals, which proves the impact of the certainty effect on them when they are making a decision under risk.

Concerning the second question (Q2), the 95% confidence interval computed with equation 2 is 72 ±12% for option A and 28 ±12% for option B. This interval is also too large to quantify exactly the part of the population of construction leaders who are avoiding the risk and prefer option B. However, it is enough to prove that this non-negligible part of the population of construction leaders can engender losses, because they choose to avoid the risk taking option, even if it is more attractive in terms of expected value. Those potential losses are most likely generated by the certainty effect (Tversky and Kahneman 1986). This behavioural tendency has an impact on daily decisions made by construction leaders, and it may lead to some losses for the construction project.

4.2.2 Computation of the expected utilities

Usually, when people are making a decision under risk, they are not computing expected values, but they are computing expected utilities. Following Prospect Theory (Kahneman and Tversky 1979), the expected utility represents the evaluation phase of the choice process. Following are the expression of the expected utility and the definitions of the scales used to compute it:

\[ U(x_1, p_1; \ldots ; x_n, p_n) = \pi(p_1)v(x_1) + \ldots + \pi(p_n)v(x_n) \]

- The first scale, \( \pi \) associates with each probability \( p \) a decision weight \( \pi(p) \), which reflects the impact of the probability.
- The second scale, \( v \) assigns to each outcome \( x \) a number \( v(x) \), which reflects the subjective value of that outcome.

For this question, only the first scale was considered to compute the expected utilities. The outcomes of the two options are close to each other, so the subjective values of the outcomes might still be close and so, might not create any difference in the computation of the expected utilities compared to the expected values.
Two expected utilities are computed for these questions: one adding 10% to the original probability of risk and a second one adding 20%. Inversely, the same amount is subtracted from the complementary probability. As everyone considers the risk from their own point of view, and there is no general expected utility true for everybody and for each problem, people see the risk from their own perspective. Some are adding 10% to the probability of risk, some add less, and some add more. This value of 10% corresponds to the mean found from previous studies made in behavioural economics to understand the choices under risk (Tversky and Kahneman 1992).

This study is looking for trends in decision making, so using approximates values like 10% or 20% is useful to understand the decision of the participants when they are making this decision under risk. The computation of the expected utilities for the question where the expected values are equal (Q15) is shown in Table 3. It explains the choice of the participants: for either of the expected utilities n°1 or n°2, option B is more attractive, explaining why a majority of participants chose option B. Participants who chose option A, may have considered the risk of option A as zero.

Table 3: Results of the “Quality of the materials” question – EV equal (Q15)

<table>
<thead>
<tr>
<th>Options</th>
<th>Shingle A (Risk Taking)</th>
<th>Shingle B (No Risk)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Expected Values</td>
<td>-$200</td>
<td>-$200</td>
</tr>
<tr>
<td>Expected Utilities n°1 (+10%)</td>

<td>Expected Utilities n°2 (+20%)</td>
<td>-$252</td>
<td>-$200</td>
</tr>
<tr>
<td>Percentage</td>
<td>36%</td>
<td>64%</td>
</tr>
</tbody>
</table>

For the question where the expected value of option A (risk taking) was more attractive compared to the expected value of option B (no risk), the expected utilities are presented in Table 4. These computations are helpful to understand the participants’ choices. The expected utilities n°2 are close to each other, which means that if someone overvalues the probability of the risk in option A by more than 20%, option B was selected instead. This happened for 28% of the participants. Conversely, if someone undervalues or overvalues the probability of risk in option A by less than 20%, option A was selected.

Table 4: Results of the “Quality of the materials” question – EV different (Q2)

<table>

<td>Expected Utilities n°2 (+20%)</td>
<td>-$210</td>
<td>-$207</td>
</tr>
<tr>
<td>Percentage</td>
<td>72%</td>
<td>28%</td>
</tr>
</tbody>
</table>

These computations show how the certainty effect impacts the participants’ choices. The influence of the certainty effect differs between participants. Some are not affected by this behavioural pattern, however some are influenced by it, and they increased the probability of risk of the question linked with that pattern. By reacting like this when externalities are not considered, they are avoiding the best option in terms of expected values. An aggregation of all these types of decisions could represent non-negligible losses for construction projects.

5 CONCLUSION AND RECOMMENDATIONS

This experiment shows the impact of one behavioural pattern, the certainty effect, on construction project leaders when they have to make a decision under risk. When this pattern is present in the question, they are in the majority risk-avoiding. This can lead to some losses on the construction project. This happens when the risk-taking option is more attractive in terms of expected values. Some respondents avoided the
risk and took the safer option, which leads to small losses. Aggregated together, these small losses may represent significant losses for the construction project.

The “certainty effect” is not the only behavioural tendency which has been studied for its influence on decisions under risk. Other behavioural tendencies such as “loss aversion” may have an impact on construction project leaders’ decisions as well. What’s more, this impact may be more or less important depending of some critical factors for a construction project, such as the cost performance or the experience of the decision maker.

This application of behavioural economics, and more precisely of prospect theory, on common decisions made frequently and quickly by construction leaders helps to understand how these decisions are made for a construction project. Understanding them can lead to the prevention of the losses generated by illogical behavioural patterns. The final goal would be to quantify and prevent these losses by detecting those decisions and help the construction leaders when they have to deal with them.

APPLYING THE CHRONOGRAPHICAL APPROACH FOR MODELLING TO DIFFERENT TYPES OF PROJECTS

Adel Francis

1 Department of Construction Engineering, École de technologie supérieure, University of Quebec, Canada, adel.francis@etsmtl.ca

Abstract: Graphical modeling is considered to be a suitable approach for displaying project data because of its ability to effectively communicate information. To meet this objective, the Chronographic Approach analyses the layout of the user interface in the spatial dimension and discusses the suitable visual parameters and their associated values. The main goal is to communicate information clearly and effectively through a visual graphical representation of the schedule. This paper discusses the application of the Chronographical Approach to modeling different types of projects, such as buildings and infrastructure. The graphical approach describes how the schedule information can be communicated using tabular and graphical interfaces, in order to manage specialties, locations, means, processes and constraints on different strata and show them either separately or combined using layering, sheeting, juxtaposition, alterations and permutations while allowing for groupings, hierarchies and the classification of project information. The result is the presentation of the same project schedule through different compatible approaches. The planner has the ability to switch from one approach to another by changing the graphical parameters. In this way, graphic representation becomes a living, transformable image, thus assisting planners in solving problems of a variable nature, and simplifying site management while simultaneously utilizing the visual space as efficiently as possible.

1 BACKGROUND

1.1 Graphical modeling of projects’ schedules

Over time, graphic modeling has become an essential tool for project managers. Project schedules represent the graphical modeling of project performance that serves as decision support tool. In order to construct a model, we isolate a class of phenomena and try to report on them using a number of assumptions and rules. As a simplification of the world, every model has its limitations and its range of validity (Legay, 1997). Facing increasingly complex processes and procedures, and multidisciplinary infrastructures, a model with a clear visualization can facilitate the demonstration of the necessary information, and becomes a useful tool for decision making. Shen-Hsieh et al (2002) support the fact that each decision is a step based on the experience and intuition of the manager, and remains subjective. Graphical tools can easily summarize the information in order to improve response time and facilitate decision making for managers, designers, and other stakeholders to a project. What cannot be modelled cannot be properly managed. Any model must allow proper identification of a problem’s source, or even anticipate them upstream. The aim is to improve the level of coordination and the ability to identify problems. Karavakis et al (2010) mention that the extraction of the desired data is facilitated from simple graphical interfaces.
Visual representation usually allows for faster data exploration and often provides better results, especially in cases where automatic algorithms fail (Keim, 2002). According to Friedman (2008) the main goal of data visualization is to communicate information clearly and effectively through graphical means. Bertin (2005) notes that visual perception has three sensitive variables: the two planar dimensions and the variation of the mark on the plane. For comparison, sound perception and its representations (such as scriptural or mathematical), possess only two variables. Graphs are understood differently than text, i.e. the former is understood globally, whereas the latter is understood sequentially. In addition, graphs can act as both a type of artificial memory and as a research tool in that they allow for the simultaneous display of the general structure, as well as the details and exceptions: they can show the leaves, the branches and the whole tree at the same time (Bertin, 2005).

1.2 Actual Limitation for Graphical modeling of Project schedules

Kuo et al (2010) states that the development of methods of presenting information in building a multi-mode system will improve access to and understanding of the project information required for each. They also state that although technological developments today enable the development of high performance tools, the fact remains that the current planning software only partially meets the demand of managers. Francis and Miresco (2006b) remark that many weaknesses are associated with the existing scheduling software. None of this software is intended for the planning of all types of projects. In addition, they are only directed by activities and cannot graphically use the other constraints, such as resources or work area, to present a production schedule. We can also remark that the proposed graphical schedule is global. These systems do not use multiple sheets, like spreadsheets, in order to manage lots separately. They also do not use multiple layers, as CAD does, in order to lay out data and constraints on different layers, thus allowing managers to improve the graphical visualizations of the schedule. Consequently, we can note the complexity encountered in the following the project schedule on screen (Fisk 2010; Francis 2004).

Francis and Miresco (2006b) states that the actual situation of project scheduling demonstrates that traditional methods seem to be unable, individually, to answer all planners’ needs, to solve multiple kinds of problems or to represents all types of projects. The managers have to deal with various project types and they are confronted with problems of different natures. Modeling information using several strategies and displaying them on numerous angles of points of view seems to be appropriate as a decision-making tool. It is thus relevant to model simultaneously more than one scenario and to perform analyses in order to improve the works coordination, optimize the performance execution, reduce risks and minimize uncertainties. In addition, the quality of needed information to be displayed on the project schedule model, and the required level of detail depends on the role and position of an entity in the project and the hierarchical reporting of the manager. As an example for a building project, the primary role of the general contractor's project manager is to manage the project site. This manager is responsible for coordinating the deliverables of the subcontractors, monitoring the progress of work, quality control and insurance and health security, managing workspaces, storage areas, the vertical and horizontal circulation of materials on site and the reverse cycle for recycling and scrap. Schedules and progress monitoring are preferably arranged according to the price schedule. The sub-contractor's manager is responsible for the planning, coordinating and monitoring of the daily or weekly progress of work teams. He also manages the supply according to the site progress.

Francis and Miresco (2014) state that subcontractors and general contractors do not share the same goals. Figure 1 shows the intersection between two schedules, the vertical for the general contractor and the horizontal for the subcontractor. The general contractor organizes project planning and monitoring vertically in which he coordinates the work and deliverables of the various subcontractors. He is interested in completing the project within time and budget. The sub-contractor promotes the optimal use, the leveling and the improvement of the productivity of his teams between the different projects in which he is involved to the detriment of the overall health of these projects. Francis and Miresco (2013) state that a schedule capable of providing a user-friendly tabular and graphical interface, able to easily structure project information, able to adapt to work in an interactive, changing environment, and accept productivity variation, is necessary for everyone on the site, especially the foremen and superintendents.
This paper discusses the application of the Chronographical Approach to modeling different types of projects, such as buildings and infrastructure. The graphical approach describes how the schedule information can be communicated using tabular and graphical interfaces, in order to manage specialties, locations, means, processes and constraints on different strata and show them either separately or combined using layering, sheeting, juxtaposition, alterations and permutations while allowing for groupings, hierarchies and the classification of project information. In this way, graphic representation becomes a living, transformable image (Francis 2013).

1.3 The Chronographical Modelling Approach

As designed by Francis (2013), the Chronographic Approach analyses the graphical representation of the schedule and discusses the suitable visual parameters and approaches. The main goal is to communicate information clearly and effectively using tabular and graphical means. The Chronographic Approach defines five categories, called Entities (Table I) as modelling parameters:

- The Physical Entities represent all the elements required to perform the construction operations (e.g. activities, labor, permanent materials, operators or haulers, construction site locations).
- The Associative Entities indicate the dependencies among the Physical Entities. They can represent: Relationships and Constraints; Hierarchy; Grouping; c) Layering and Sheet; and Attributes.
- The Functional Entities characterize the Physical or Associative Entities. These entities may denote deterministic relations, decisional or probabilistic functions or Temporary Functions.
- The Scale Entities designate the external measuring units (e.g. Time, Cost, Quantity, % Progress, Risk, Performance, or Resources) or internal measurement.
- The Direction Entities present the coordinates on up to three Cartesian axis systems. Each axis allows for no scale, single scale with cumulative data, or grouping.

Table 1: Entity Types (Francis, 2013)
2 APPLYING THE CHRONOGRAPHICAL APPROACH FOR MODELLING DIFFERENT TYPES OF PROJECTS

Managers have to deal with various project types and they are confronted with problems of different natures. To answer these various needs, managers must currently handle information within several incomplete methods, which are incompatible between each other. Although the existence of several scheduling methods is criticized because of the lack of compatibility, the existence of a complete model, which can present information within different and compatible facets, is considered as an optimal solution (Francis and Miresco 2006b). To meet this objective, the Chronographic Approach analyses the layout of the user interface in the spatial dimension and discusses the suitable visual parameters and their associated values. The main goal is to communicate information clearly and effectively through a visual graphical representation of the schedule.

Francis (2013) describes the preparation steps for the project schedule using the Chronographical Model. First, we should define the necessary Physical and Associative Entities that simulate the construction operation: a) the work breakdown structure (WBS) for deliverables, activities and tasks; the work location breakdown structure (WLBS), by dividing the site locations; b) the Organization Breakdown Structure (OBS) for the composition of project teams and specialities. Then we define the attributes’ entities and we define the Cartesian axis and their measurements. We can use zero to three Cartesian axes; external and internal measurement scales; hierarchy, grouping, layering, sheeting and attributes; relationships and constraints to model construction operations through the Physical Entities (e.g. activities, labour, permanent materials, operators or haulers, construction site locations).

The result is the presentation of the same project schedule through different compatible approaches. The planner has the ability to switch from one approach to another by changing the graphical parameters. In this way, graphic representation thus assists planners in solving problems of a variable nature, and simplifying site management while simultaneously utilizing the visual space as efficiently as possible.

2.1 Linear Projects

Developed by the US Navy Department in the early fifties, linear methods are designed to ensure continuity of resource use and support a stable and optimized production. Trimble (1984) mentions that schedules oriented by resources are more realistic than those dominated by activities. These methods show graphically any imbalance due to uneven progress of activities and quickly allow the manager to quantify the deviation (Khisty 1970).

These methods have been the subject of countless improvements either through their graphical models and their methods of calculation. These methods are therefore well-suited to road, highway, railway and...
pipeline projects. We note that within these projects the machinery and the work teams operate continuously in a linear way. The difference with the simulation methods based on CYCLONE is that simulation are used to optimize the production, versus a target of linearity and operating in parallel way between the successor activities for the linear methods.

Figure 2 shows a linear project for installing a drainage system. In these types of projects, mainly the activities are linear. However, the schedule could combine simultaneously linear activities (such as excavation and backfill) and repetitive activities (such as manholes). The approach uses two axes. Time is shown as the scale of the horizontal axis and the units (meter) scale the vertical axis.

2.2 Repetitive Projects

Repetitive projects are projects where assigning tasks are usually repeated from unit to unit or from floor to floor. This differentiates them from the linear projects where machinery is operating continuously. We can distinguish two types of repetitive projects: a) Vertical projects such as multi-storey building; and b) Horizontal projects such as the construction of several similar units.

2.2.1 Repetitive Vertical Projects

In repetitive vertical projects, such as a multi-storey building, some activities are non-repetitive activities, such as the foundation and the roof, while others are repeated from one floor to another, such as structure, architectural finishing and services.

![Figure 3: Example of scheduling Repetitive Vertical Projects](image)

Figure 3 proposes an approach that uses two axes. Time is shown as the scale of the principal direction. The second direction shows the different levels: Foundation (non-repetitive) and repetitive floors (1 to 4). Thus, these projects combine mainly repetitive activities (structure and finishing), and occasionally non-repetitive activities (Foundation and Roof) or linear operations (Envelope). Team work describes the detailed operation of these buildings symbolizing the Physical Entity. In this figure we can track the sequence of work of each team on the different floors.

2.2.2 Repetitive Horizontal Projects

In repetitive horizontal projects, such as the construction of several similar units, most activities are repetitive. In these horizontal projects the work of several units can be planned simultaneously to accelerate the project schedule. The number of specialty teams can be calculated by the quotient of the duration required to complete a single unit by the total time available to complete the work of this specialty for all units.

Figure 4 proposes an approach that uses two axes. Time is shown as the scale of the principal direction. The second direction shows the repetitive horizontal buildings. Team work describes the detailed operation of these buildings symbolizing the Physical Entity. In this figure we can track the sequence of
work of each team on the different buildings. For example, the buildings’ foundations are executed by two teams: “Found 01” and “Found 02”. The team “Found 01” consecutively executes the buildings 1, 3, 5 and 7 (see also Figure 5). The time required for building is 4 days and the total duration of the work of this team is 16 days.

![Diagram of scheduling Repetitive Horizontal Projects](image)

Figure 4: Example of scheduling Repetitive Horizontal Projects

The utilization of resources as a second direction represents an effective solution for showing resource allocation and levelling. Manpower occupations are easily optimized and work over-load or under-load are avoided. Francis (2013) classifies this approach as “Chrono-Allocation Modelling: Using Resources as a second direction”. Figure 5, shows an approach with two directions. Time shows the scale of the principal direction. The second direction shows teams. This example uses: two (2) teams for foundation works, three (3) teams for structure; four (4) teams for finishing. It should be noted that teams use a scale of dark colours and building uses a scale of light colours.
2.3 Non-Repetitive Projects

Non-repetitive projects are projects where the intervening work teams are specific. Generally, there are only a few repetitive activities. This type of project is well-planned through a time-scaled Precedence network (unfortunately not modeled by commercial scheduling software) or a Gantt/Precedence Diagram, modeled by commercial scheduling software such as MS-Project or Primavera. The difference is that time-scaled Precedence networks plot activities in parallel and in series while in a Gantt/Precedence Diagram each activity is drawn on a separate line resulting in the non-optimal use of the modeling area.
Figure 6 shows a non-repetitive project modeled with the Chronographic Method. The difference between this method and the time-scaled Precedence network is the use of internal divisions and internal relationships as function of quantities or productions (Francis and Miresco 2006a). In this figure, the activities that represent the implementation of walls are divided into four internal divisions as a function of quantities or work steps. The two first divisions are critical while the two other divisions possess margins. The three activities Electricity, Doors & Windows and Plumbing are related to the end of the first internal division with Finish-to-Start relations. Their end dates should be completed before the start of the last division of the implementation of walls.

2.4 Scheduling Projects by Working Areas

Most building project activities are carried out by subcontractors. As a result, the majority of project resources are assigned to subcontractors who are responsible for the planning and management of their work programs. Thus, project planning complexity is generally related to the coordination of the subcontractors’ work. The planners of multi-storey building projects also face many other difficulties such as avoiding conflicts of use within limited workspace, the organization of on-site traffic to avoid congestion, the supplying, handling, and storage of project materials, and waste management and recycling (Francis and Miresco 2013). Kuo et al (2010) quote that assembly sequences require an interface of spatial and temporal information. Therefore, a schedule oriented by work areas is considered to be an appropriate approach for planning building projects.

Figure 7: Example scheduling Projects by Working Areas
Figure 7 shows the construction work during week 12. In this plan, we can see: a) Areas 1, 2, 3 and 9 are vacant demonstrating underutilization of the work area; b) the conflict between teams 1 and 2 in Zone 4; and c) team 3 is used at the same time in both zones 6 and 8. Using this type of planning we can easily manage conflicts and adjust the plan manually during weekly site meetings without complex calculations.

3 CONCLUSION

The present paper discusses the application of the Chronographical Approach to modeling different types of projects, such as buildings and infrastructure. The main concern is studying the modalities of information representation. The graphical approach describes how the schedule information can be communicated using tabular and graphical interfaces, in order to manage specialties, locations, means, processes and constraints on different strata and show them either separately or combined using layering, sheeting, juxtaposition, alterations and permutations while allowing for groupings, hierarchies and the classification of project information. The Chronographical Approach defines the graphical parameters that model the construction operation, establishes constraints, and determines directions and scales. Using these parameters, the planner can schedule the construction operation by laying out project information under diverse approaches. The result is the presentation of the same project schedule through different compatible approaches. The planner has the ability to switch from one approach to another by changing the graphical parameters. In this way, graphic representation becomes a living, transformable image, thus assisting planners in solving problems of a variable nature, and simplifying site management while simultaneously utilizing the visual space as efficiently as possible. The use of understandable visual communication methods facilitates the sharing of information while aiding in planning and controlling project activity, including the improvement of productivity, performance and effectiveness.

Résumé: L'industrie de la construction est un secteur dans lequel la circulation de l'information, entre les diverses disciplines de projet impliquées, est intense. Paradoxalement, on constate que le secteur de la construction repose sur un processus de communication s'appuyant sur un format papier ainsi que sur des moyens obsolètes, tels que le téléphone, le télecopieur ou le courriel, afin de partager et d'accéder aux données de projet. Pourtant, malgré le fait que les problématiques de circulation de l'information se répercutent sur l'ensemble des phases de construction, on observe que la phase de réalisation est de loin celle qui dépend le plus de l'information et qui, malheureusement, est la moins informatisée. En considérant le rythme avec lequel évoluent les tablettes et les téléphones intelligents, les technologies mobiles (TM) offrent désormais des moyens efficaces afin de remplacer la communication papier sur le chantier par des solutions numériques et infonuagiques. Cet article traite des résultats d'une recherche visant à comprendre comment le déploiement des TM et des technologies infonuagiques peut améliorer l'accès à l'information et faciliter la communication entre les intervenants, lors de la phase de réalisation. L'objectif principal de ce papier est de démontrer les bénéfices à employer ces technologies sur les chantiers lorsqu'il s'agit d'un contexte d'administration de projet. Les résultats de cette recherche s'appuient sur la réalisation de trois études de cas dans lesquelles un total de 58 intervenants ont participé aux diverses étapes de cette étude, échelonnée sur une période de quinze mois. L'ensemble des données est issu de la réalisation d'observations \textit{in situ}, d'entrevues et de l'envoi de questionnaires.

Mots-clés : Technologies mobiles (TM), technologie infonuagique, NTIC, environnement virtuel, BIM, Traitement de l'information.

1 INTRODUCTION

L'industrie de la construction est un secteur dans lequel il y a une intense circulation de l'information entre les diverses disciplines de projet (Hewage et Ruwanpura, 2006). La réussite des projets repose donc sur la capacité des intervenants à échanger de l'information fiable, cohérente et en quantité suffisante afin de réaliser le produit (Deibert, Hemmerk et Heinzl, 2009). Paradoxalement, on observe que les projets de construction reposent sur un processus de communication s'appuyant sur un format papier et sur des moyens obsolètes, tels que le téléphone, le télecopieur ou le courriel, afin de partager et d'accéder aux données de projet (Dave, Boddy et Koskela, 2010). Malgré le fait que les problématiques de circulation de
l'information se répercutent sur l'ensemble des phases de construction, on constate que la phase de réalisation est de loin celle qui dépend le plus de l'information et qui, malheureusement, est la moins informatisée (Tam, 1999). Le papier demeure le moyen le plus répandu, afin de collecter l'information et de la partager, et ce, en dépit des améliorations informatiques de ces dernières années, par exemple, les technologies mobiles (TM) telles que des tablettes et des téléphones intelligents. Considérant le rythme avec lequel ces outils évoluent, les TM offrent désormais des moyens, afin de remplacer la communication papier sur les chantiers, par des solutions numériques performantes. En parallèle, les recherches concernant les nouvelles technologies de l'information et de la communication (NTIC) évoluent et celles-ci énoncent que ce type de technologies offre de nouveaux moyens de communication plus performants, en améliorant notamment le traitement, la mise en mémoire, la diffusion et l'échange de l'information parmi les intervenants. Parmi ces technologies, les plateformes infonuagiques se sont relevées des outils pouvant contribuer à l'amélioration des processus de communication. Ceci s'explique en raison de la centralisation de l'information sur « des serveurs distants interconnectés par Internet, permettant un accès en réseau, à la demande, à un bassin partagé de ressources informatiques configurables, externalisées et non localisables »1. Les technologies nuagiques offrent conséquemment, des alternatives à l'hébergement et aux traitements de données conventionnelles, par des services virtuels disponibles pour les intervenants de projet, et ce, non seulement partout où ils le souhaitent, mais aussi, en temps réel. Malgré tout, peu de recherches exposent véritablement les améliorations de ces outils, notamment en raison d'un manque de recherche et de développement (R&D) dans le secteur de la construction.

Cet article traite donc des résultats d'une recherche visant à comprendre et définir comment le déploiement des TM et des technologies infonuagiques peut améliorer l'accès à l'information et faciliter la communication entre les intervenants, durant la phase de réalisation. Celle-ci se décomposse en deux phases soit, une évaluation du taux de pénétration des TM dans l'industrie de la construction du Québec (Phase 1) (Frenette et al., 2014) et, une réalisation d'études de cas, afin de développer un cadre d'opération issu d'une collecte de données in situ (Phase 2). Cet article présente la phase 2 de cette recherche qui expose les bénéfices observés, lors de l’emploi d’applications logicielles sur les chantiers.

2 LA GESTION DE L'INFORMATION SUR LES CHANTIERS ET LES TECHNOLOGIES MOBILES

Lebeau et Plourde (2003) ont défini que l'industrie de la construction représente un secteur singulier, en raison de la nature temporaire de ses équipes de travail, ayant pour principale conséquence d'affecter la coordination des équipes de réalisation et de gestion de projets. Pourtant, le cheminement de l'information est une composante essentielle affectant toutes les autres séquences d'interventions dans la chaîne d'approvisionnement (Koskela, 2000). Les recherches Koskela (2000) démontrent l'importance de la gestion de la production en phase de réalisation et elles identifient que les processus de production actuels négligent l’aspect de la circulation de l'information (Koskela, 2000). Pourtant, il est reconnu que la mauvaise gestion de l'information a un impact sur le processus de décision, résultant ainsi à d'importantes pertes de temps et d'argent lors de la phase de réalisation (Lucas, Bulbul et Thabet, 2013). Cette situation est liée à une coordination inefficace et inadéquate de l'information, résultante d'une communication insuffisante, inopportune, imprécise et contradictoire lors des échanges de données (Lucas, Bulbul et Thabet, 2013).

2.1 Les problématiques de gestion de l’information sur les chantiers

L'industrie de la construction repose sur des processus traditionnels d'acquisition et d'échange de données (Dave, Boddy et Koskela, 2010). Des études ont pourtant démontré que l'intégration des technologies, et particulièrement des TM sur les chantiers, a un potentiel considérable d’accroissement de l’efficacité des processus de communication, au sein des équipes de projet (Chen et Kamara, 2005). À l'occasion, on observe que 65 % des reprises de travaux effectuées par les entrepreneurs sont attribuables à de l'information insuffisante sur le chantier, perturbant le taux de production des équipes de travail (Bowden, 2005). Il est déterminé que le manque de correspondance dans les méthodes de gestion

1 Source : Office de la langue française. [En ligne]. [http://www.oqlf.gouv.qc.ca/] (Consulté 16/06/14).
d'information des divers intervenants est directement responsable du manque d'information sur le terrain (Bowden, 2005). Afin de pallier à ces problématiques, les intervenants ont besoin de moyens efficaces, pour échanger d'information dynamique, afin de coordonner les exigences et les objectifs ainsi que résoudre les conflits, dans un environnement où l'évolution des données, des documents et d'information est en perpétuel changement (Dossick et Neff, 2011). En contrepartie, on constate que la coordination de l'information est complexe, en raison de la pression du calendrier, des exigences de productivité et des diverses méthodes de travail des entreprises impliquées dans le processus.

2.1.1 L'accès à l'information

L'accessibilité à l'information est un enjeu critique pour le succès des projets. En revanche, pour être efficace, l'information disponible doit être de qualité et en quantité suffisante afin d'être utile pour les intervenants (Saram et Ahmed, 2001). L'acquisition et le transfert de l'information représentent donc des éléments majeurs dans le succès de l'administration des projets (Tsai, 2009) et il a été établi que les TM peuvent avoir un rôle à jouer en matière d'accessibilité aux données de projet. Saidi, Haas et Balli (2002) ont appliqué six critères d'évaluation afin d'établir le potentiel des TM à augmenter le temps effectif de travail sur le chantier soit : 1) le suivi de qualité, 2) suivi des matériaux, 3) suivi des quantités, 4) suivi des fiches signalétiques, 5) l'accès aux plans de construction et 6) les demandes d'information. Ils ont alors constaté que d'importants délais de production pourraient être évités grâce à l'utilisation des TM en chantier. Ce constat s'appuie sur le fait qu'un temps de contrôle qualité pourrait être potentiellement réduit d'environ 50 à 70 % en raison d'un meilleur échange de données entre les intervenants de projet.

2.2 Les problématiques d'adoptions technologiques

Le secteur demeure une industrie réfractaire aux changements et elle est réticente à adopter de nouveaux processus axés vers l'usage des technologies et les TM ne font pas exception (Bowden, 2005). Les raisons invoquées font état de la perception d'un manque de retour sur les investissements et de la rareté d'exemples concrets de réussite d'implantation de ce type de technologie. On observe alors que le fait que leur apparition soit relativement récente, le manque d'études de cas et la perception d'un faible rendement de l'investissement ajoutent un frein à leur mise en place définitive (Bowden, 2005). En se penchant sur cette problématique, on observe que l'industrie est celle qui investit le moins dans les NTIC et l'enseignement supérieur (Dale, Mun et Kevin, 2005). Ce manque de financement entraîne en conséquence, des lacunes sur le plan des connaissances et n’incite pas le secteur à revoir ses pratiques. Il contribue également à une résistance aux changements généralisée, qui représente la première source d'échec d'implantation des technologies au sein des entreprises (Maurer, 1996), appuyant ainsi cette prise de position et les nombreux cas d'échecs subis par le secteur par rapport à l'intégration des TM. Ce constat vient soutenir l'importance de la R&D en soutien au secteur.

2.3 Les technologies mobiles et les technologies nuagiques en chantier

À la lumière de certaines recherches, l'évolution des TM apporte des fonctionnalités et des retombées respectant les contraintes de mobilité des intervenants. D'abord, parce que les appareils sont de plus en plus petits, légers et portables s'adaptant davantage aux activités d'une industrie mobile (Lee, Cheng et Cheng, 2007). Ensuite, il a été défini trois types de bénéfices issus de l'usage des TM soit : 1) l'amélioration de la saisie d'information en chantier, 2) l'amélioration de l'accessibilité aux informations de projets et 3) la réduction des erreurs en chantier par l'amélioration de l'intégrité des données (Bowden, 2005). On observe également que l'exploitation des TM offre des moyens de transformation de données brutes, en informations utiles pour la gestion rapide de celle-ci (Gamage, 2011). Couplés aux technologies nuagiques, les TM peuvent s'avérer une composante à forte valeur ajoutée, afin de centraliser, partager et gérer l'information à travers l'ensemble des équipes de projets, par exemple, en offrant la possibilité au personnel de terrain d'être informé rapidement des activités et des événements de chantiers (Trupp et al., 2004). Selon une étude conduite par Forgues et Staub-French (2013), les technologies infonuagiques apporteront d'importants changements dans le secteur notamment en raison qu'il y a de plus en plus de solutions orientées vers ces types de services. Les études concernant l'implémentation des technologies en construction font état de quelques déductions qui expliqueraient cette tendance migratoire vers des solutions infonuagiques, soit :
- les frais d'accès se font mensuellement, éliminant des investissements coûteux en infrastructure;
- tous les intervenants ont un accès en tout temps aux plateformes, aux outils et aux données;
- les problèmes d'interopérabilité et de gestion des versions logicielles sont éliminés.

2.4 Les TM et l'infonuagique au service des projets de construction

À la lumière de ce qui précède, l'adoption des nouvelles technologies, en phase de réalisation, représente une avenue prometteuse, afin de pallier aux enjeux actuels du secteur. Les raisons justifiant cette position sont que l'exploitation de ces outils permettra aux intervenants d'accéder rapidement et simplement à un large ensemble de données. D'une part, par l'intermédiaire d'outils adaptés aux conditions de chantier, c'est-à-dire des appareils légers, petits et portables. Ensuite, en raison d'une information centralisée à l'aide des technologies infonuagiques, permettant d'améliorer le traitement, la gestion et la diffusion de l'information sous diverses plateformes informatiques, telles que des ordinateurs et des plateformes mobiles. En revanche, on constate que les principaux obstacles à l'atteinte de leur potentiel et de la mise en place de ceux-ci sont liés, d'une part, à l'obsolescence rapide des technologies et, d'autre part, à l'absence de standards d'utilisation (Venkatraman, 1994). Il est alors primordial que les entreprises et utilisateurs demeurent à l'écoute des avancées technologiques de ces outils et que la R&D soit en mesure d'accompagner le secteur de la construction dans la modernisation de ses pratiques.

3 MÉTHODOLOGIE

Cette recherche-action s'appuie sur la réalisation de trois études de cas réalisées in situ dans le but d'identifier les retombées réelles d'exploitation des TM, lors de la phase de réalisation. La sélection de ces études de cas fait suite au développement du canevas construit lors de l'enquête réalisée en Phase 1 (Frenette et al., 2014). Ces choix s'appuient sur le fait que ces entreprises représentent les niveaux les plus avancés en matière de déploiement et du contexte d'utilisation de TM au Québec. L'étude de cas A représente un entrepreneur général. L'étude de cas B est constituée d'un consortium d'entrepreneurs généraux, tandis que l'étude de cas C est un donneur d'ouvrage. L'échantillon est orienté vers les intervenants de chantier responsables du suivi des différentes activités, lors de la phase de réalisation, soit les intervenants de terrain, de gestion et de surveillance. L'étude de cas A est constituée d'intervenants de terrain, tels que les surintendants, les contremaîtres ainsi que les intervenants de gestion, tels que les gestionnaires de construction. L'étude de cas B est constituée d'intervenants de surveillance, tels que ceux de contrôle de la qualité et d'intervenants de terrain, tels que le contremaître de l'entrepreneur spécialisé. Finalement, l'étude de cas C est constituée d'intervenants de surveillance, tels que les inspecteurs de chantier du donneur d'ouvrage, ainsi que d'intervenants de gestion, tels que les gestionnaires de construction.

3.1 Méthode de collecte de données

Cette recherche-action se décompose en cinq étapes : 1) envoi d'un questionnaire de démarrage, 2) entrevues semi-dirigées de démarrage, 3) observation en chantier, 4) envoi d'un questionnaire de fin et 5) entrevue semi-dirigée de fin de test. L'objectif des étapes 1 et 2 est d'identifier les besoins et les défis actuels des intervenants de chantier. L'objectif de l'étape 3 est d'observer in situ l'utilisation de la TM. Les étapes 4 et 5 visent à déterminer les bénéfices réels obtenus suite à l'usage des TM en soutien au mécanisme de traitement de l'information lors de la phase de réalisation. L'Analyse quantitative s'appuie sur des métriques établies lors du projet pilote et ils correspondent à 1) Économie de temps, 2) Suivi des coûts, 3) Suivi de la qualité et 4) Gestion de projet. L'analyse qualitative s'appuie sur l'observation en chantier permettant d'étudier les différents contextes d'utilisation en situation réelle, en fonction des choix technologiques réalisés. Un total de 58 participants ont participé à l'étude. 44 ont répondu au questionnaire de l'étape 1, tandis que 30 participants ont été rencontrés en entrevue en étape 2. En étape 3, 21 participants ont été observés dans leur environnement, sur une période de 1 mois. Un total de 46 participants ont répondu au questionnaire en étape 4, tandis que 8 participants ont été rencontrés en étape 5. L'ensemble des cadres responsables de l'intégration des TM a été rencontré en entrevue, afin de connaître la justification de l'implantation de ces outils dans leur contexte. Les études de cas A et
B utilisent des applications logicielles de nature commerciale, tandis que dans l'étude de cas C, on a fait usage d'une application de conception maison. L'ensemble des questionnaires qui ont été produits est inspiré des travaux réalisés par Rivard (2000), Bowden (2005) et Ruwanpura, Hewage et Jergeas (2008).

3.2 Analyse des données

Les résultats présentés s'appuient sur des axes de bénéfices identifiés, à la suite d'essais effectués lors de la réalisation d'un projet pilote conduit par Forgues et Staub-French (2013). Ces axes de bénéfices sont des champs de transformation regroupés sous cinq thématiques, dont quatre seront présentées dans cet article. Les données obtenues à l'aide des différents questionnaires ont été traitées et compilées à l'aide d'un chiffrier électronique, tandis que les données obtenues à la suite des entrevues ont été transcris à mot à mot afin d'être codées, traitées et comparées. Les données issues de la période d'observations ont permis d'appuyer les résultats obtenus par des citations et des artefacts.

4 CADRE CONCEPTUEL

4.1 En route vers une maturité dans l'utilisation des TM

À la suite de la présentation des résultats de l'enquête provinciale (Phase 1), un cadre conceptuel a été proposé et les résultats ont été présentés dans l'article de Frenette et al. (2014). Ce cadre s'appuie sur les différents types d'exploitation des TM en fonction de la nature et du type d'utilisation des applications mobiles exploitées par les différentes entreprises participantes. Il a été défini, à l'aide des données issues des entrevues avec des intervenants clés des entreprises innovantes et la Figure 1 en présente le canevas.

![Diagramme de maturité exploitation TM](image)

Figure 1 - Diagramme de maturité d'exploitation des TM en phase de réalisation

Ces catégories permettent de connaître la maturité des entreprises, en fonction du type d'applications utilisées, s'appuyant sur le degré de complexité de mise en place. En l'occurrence, la consultation de documents (N1) correspond au plus bas niveau de maturité tandis que l'administration et la gestion de projets (N4), au niveau le plus élevé. Spécifiquement, les catégories 1 à 3 demandent des changements mineurs au sein des entreprises et représentent des usages passifs de la TM. En revanche, la catégorie 4 représente des changements majeurs dans les pratiques d'une organisation et requiert un usage actif des utilisateurs. La principale raison de cette coupure est que les catégories 1 à 3 n'imposent pas de changements majeurs dans les méthodes de travail et ne demandent pas de révision des processus de travail, telle que suggère la catégorie 4. Ces catégories permettent alors d'évaluer la maturité des entreprises en fonction de l'utilisation des TM dans les projets. Suite à l'analyse des résultats de cette phase, il a été établi que le Niveau 4 est celui qui demande le plus d'efforts, lors de l'implémentation, et ce, tant d'un point de vue financier que celui de la transformation des pratiques. En revanche, ce niveau est celui ayant le plus haut potentiel de transformation et d'amélioration des mécanismes de traitement et de gestion de l'information lors de la phase de réalisation.
5 CONTEXTE D'EXPLOITATION DES TM ET DES TECHNOLOGIES INFONUAGIQUES

5.1 Étude de cas

Chacune des entreprises a effectué son choix technologique en fonction de son rôle et de son mandat dans les projets. Le Tableau 1 présente le sommaire du contexte des études de cas ayant participé à cette étude et les applications logicielles qui leur sont associées.

5.2 Technologies mobiles

5.2.1 Smart-use

*Smart-Use* est la solution logicielle sélectionnée par l'étude de cas A et correspond à une application de consultation et d'annotation de documents de niveau 3. Celle-ci est conçue pour centraliser des documents PDF 2D et pour permettre leur annotation. Cette application peut être utilisée sur trois plateformes différentes, soit sur un ordinateur, sur une tablette PC ou sur une table *Smart-Use*. Le Tableau 2 présente différentes caractéristiques de l'application logicielle.

5.2.2 Latista

*Latista* correspond à une application logicielle d'administration et de gestion de projets de catégorie 4. Elle est conçue pour capturer l'information en temps réel, sur le site de construction et le Tableau 3 présente différentes caractéristiques de cette application logicielle. *Latista* a été mis en place afin de permettre aux intervenants de contrôle de la qualité de créer des listes de tâches et de travaux à compléter sur une base de données partagée, afin de diminuer le temps de partage de l'information aux autres disciplines.

5.2.3 Rétroaction de chantier

*Rétroaction de chantier* est une application logicielle de niveau 4, développée par l'entreprise afin de standardiser les journaux de chantier, en fonction d'un découpage des travaux qui correspond au devis technique produit lors des phases de conception et de planification du projet. Le Tableau 4 présente différentes caractéristiques de l'application logicielle. Cette standardisation de la collecte de données permet une rétrospective juste et rapide des travaux exécutés en fonction des travaux estimés.

6 RÉSULTATS

Cette section traite des données obtenues après l'exploitation des TM, lors de la phase de réalisation des différentes études de cas et s'appuie sur les métriques établies, lors de la conduite du projet pilote. Dans le cadre de cet article, seules les 3 principales retombées sont présentées, suite à l'usage des applications mobiles sélectionnées par les différentes études de cas. Il est à noter que les résultats présentés ci-dessous varient en fonction des résultats obtenus, suite au questionnaire de fin d'essai acheminé aux participants de chacune des études de cas.

6.1 Économie de temps

Cet axe de bénéfices présente les résultats obtenus suite à l'exploitation des applications logicielles. Le Tableau 5 expose le classement des trois éléments principaux identifiés par les usagers des différentes études de cas.

**Tableau 5 - Bénéfices - Économie de temps**

*Question : À la suite de votre usage de TM, évaluez l'impact de son utilisation sur le suivi des coûts du projet.*

En dépit de la vocation différente des applications logicielles en vigueur, on constate que les utilisateurs ont senti un impact important dans leur pratique, lors de l'exploitation de ces outils, dans une perspective d'économie de temps. On observe que le niveau d'impact est élevé, et ce, indépendamment du type d'usage des trois études de cas.

0 - Aucun impact 1 - Impact mineur 2 - Impact modéré 3 - Impact important 4 - Impact très important

Question : À la suite de votre usage de TM, évaluez l'impact de son utilisation sur le suivi des coûts du projet.

D'abord, l'application logicielle ayant eu le plus gros impact est celle de l'étude de cas B, soit Latista. En se penchant sur ses fonctionnalités, on constate que cette application vise, non seulement à rendre disponibles les plans de projet, mais aussi offre la possibilité de mettre en place des séquences d'opération personnalisées. Les rencontres auprès des participants ont permis de mettre en lumière que l'exploitation de cette application permet de sauver des coûts en raison de la mobilité et de la rapidité avec laquelle, l'information peut circuler au sein des différents acteurs du projet.

6.3 Suivi de la qualité

Cet axe de bénéfices présente les résultats obtenus suite à l'exploitation des applications logicielles. Le Tableau 7 expose le classement des trois éléments principaux identifiés par les usagers des différentes études de cas.

Tableau 7 - Bénéfices - Suivi de la qualité

Échelle

0 - Aucun impact 1 - Impact mineur 2 - Impact modéré 3 - Impact important 4 - Impact très important

Question : À la suite de votre usage de TM, évaluez l'impact de son utilisation sur le suivi des coûts du projet.

Cet axe de bénéfices est celui exposant le plus grand écart entre les différents cas d'usage des TM. On observe que les applications de niveau 4, soit d'administration et de gestion de projets, ont une forte valeur ajoutée dans le contexte de ce pôle d'amélioration. D'abord, on constate que l'étude de cas C est celui ayant obtenu l'impact le plus important lors de son exploitation. Toutefois, son temps d'exploitation est de loin supérieur aux deux autres études de cas impliquées dans l'étude. De plus, son contexte d'exploitation est axé vers une exploitation locale, ce qui limite son champ d'action sur les autres disciplines. En revanche, l'étude de cas B, dans laquelle les TM ne sont utilisées que depuis quelques mois, exploite ces outils dans un contexte global, c'est-à-dire, avec l'ensemble des disciplines de projets. En se penchant de plus près sur les résultats, on constate que les participants ont mentionné avoir un meilleur suivi des événements de chantier et du contrôle de la qualité. Les résultats de cette étude de cas
justifient alors que l'exploitation d'une application logicielle, permettant la mise en place d'une séquence d'opérations et jumelée à une utilisation collective de la TM, permet d'atteindre de plus grandes retombées sur le projet.

6.4 Gestion de projet

Cet axe de bénéfices présente les résultats obtenus suite à l'exploitation des applications logicielles. Le Tableau 8 expose le classement des trois éléments principaux identifiés par les usagers des différentes études de cas.

Tableau 8 - Bénéfices - Gestion de projet

</tbody>
</table>

Échelle

0 - Aucun impact 1 - Impact mineur 2 - Impact modéré 3 - Impact important 4 - Impact très important

Question : À la suite de votre usage de TM, évaluez l'impact de son utilisation sur le suivi des coûts du projet.

De manière globale, on constate que l'exploitation des TM a un impact de modéré à important pour l'ensemble des études de cas. Pourtant, on observe qu'en fonction des applications logicielles utilisées, les critères d'amélioration varient en fonction du type de technologies sélectionnées. Par exemple, dans le contexte de l'étude de cas A, le partage de documents est le critère ayant le plus haut taux d'impact, tandis que celui de l'étude de cas B, la recherche et le contrôle de l'information est le principal point d'amélioration. Ces résultats mettent en lumière que l'exploitation des applications logicielles, permettant d'effectuer une administration et une gestion de l'information, permet d'atteindre un haut niveau d'impact sur les mécanismes de gestion de projet dans le secteur. Ceci s'explique par le fait que l'environnement de chantier représente un secteur en évolution et que l'information doit non seulement y circuler rapidement, mais doit être accessible à un maximum d'intervenants.

7 DISCUSSION ET CONCLUSION

À la lumière des résultats présentés, les TM ont le potentiel d'améliorer les processus de communication dans le secteur, et ce, indépendamment de la technologie sélectionnée. Cependant, cette recherche demeure exploratoire en raison de la grande diversité des applications et de leurs usages dus à leur faible coût. Malgré tout, l’ensemble des participants a perçu des bénéfices à leur usage :

« L'usage de l'application est véritablement devenu incroyable, c'est devenu un outil indispensable pour le suivi des travaux en chantier. Je fais non seulement ma surveillance de chantier, mais je prépare également mes rencontres de coordination avec mon patron. Sans l'application, je me dis que cela aurait été impossible d'avoir un suivi aussi présent et d'avoir toute cette information à disposition. »

Surveillant qualité

Mais naturellement les retombées sur le projet varient en fonction du type de technologies sélectionnées et des stratégies de déploiement. Par exemple, dans l'étude de cas A, et les bénéfices de l'application de communication sont plutôt orientés vers la rapidité d'accès à l'information et le partage de documents. En revanche, dans l'étude de cas B, application d'administration et de gestion a été mise en place et elle a été accompagnée d'une séquence d'opération personnalisée a été établie grâce à l'application d'administration et de gestion de projet. On constate alors que le niveau d'impact des TM, lorsqu'utilisé dans un contexte administratif, permet d'atteindre des niveaux de rendement plus élevés, considérant le fait qu'elles soient exploitées dans un cadre collaboratif. Parallèlement, l'exploitation de l'application logicielle de l'étude de cas C, dans un contexte interne, a permis à l'entreprise de standardiser
l'information collectée sur le terrain. Cet aspect est d'ailleurs un point fort de l'exploitation des applications d'administration et de gestion, car elles appellent à redéfinir les critères de saisie d'information, afin de faciliter le traitement de données. Plusieurs intervenants ont d'ailleurs mentionné ne plus vouloir revenir en arrière, suite à leur expérience avec les applications logicielles d'administration et de gestion de projet.

En résumé, il en ressort que les TM offrent des solutions particulièrement bien adaptées à la gestion de l'information sur le chantier. Cependant, le grand nombre et la diversité des applications disponibles rendent l'identification des applications et leur déploiement complexe, ouvrant de multiples perspectives pour des recherches futures.

Abstract: The use of alternative project delivery methods (PDMs) is perceived to create collaborative environments that result in less adversarial relationships between construction parties, which consequently leads to less disputes. While many research studies investigated the alternative PDMs’ impact on cost, schedule, quality, and sustainability, there is limited research to empirically investigate the impact of the PDM on the dispute resolution process choice. This aim of this paper is to conduct a preliminary investigation on how PDMs’ choice has affected Department of Transportation (DOTs) selection of the dispute resolution method (DRM). To achieve this objective, the researchers conducted content analysis of three State DOTs’ specification documents, both for Design-Bid-Build (DBB) and Design-Build (DB) PDMs. Results show that a stepped process is used in all three states with some form alternative DRM being used before resorting to litigation to provide opportunity for prevention and early resolution of disputes. In terms of PDM effect on the DRM, one state used an amicable dispute resolution process that fosters partnerships in DB and not in DBB projects, while another used partnering efforts regardless of the PDM employed. Also, the use of non-binding DRBs in another DOTs’ DB specifications before resorting to binding DRM provide opportunity for amicable ADR methods to be used before being escalated to litigation. This study serves as a preliminary investigation of how PDM choice could affect the way disputes are handled and results show that there is no consistent manner on which the dispute resolution process is selected based on PDM.

1 INTRODUCTION

Being a very complex and competitive industry in which participants with different expertise, talents, and levels of knowledge work together to achieve set objectives, conflicts become inevitable. If conflicts are not well managed and resolved in a timely manner, they quickly turn into disputes, which prevent the successful completion of the construction project (Cakmak & Cakmak, 2014). With 10 to 30 percent of construction projects having serious disputes and one in four construction projects having a claim, disputes can become very expensive. Transactional costs for dispute and claims resolution may total $4 - $12 billion per year. Such costs include lawyers and witnesses fees, employees’ salaries and overhead (who divert from productive profit-making work to litigation activities), in addition to construction process inefficiencies and delays, and ultimately the costs of hostile relationships that remove any opportunity for profits from repeat business (FFC 2007).
Acknowledging the fact the construction disputes will occur inevitably, the construction industry has made tremendous progress in developing more efficient and amicable methods for dispute prevention and resolution. Paradoxically, experts frequently refer to the construction industry as being on the innovative edge regarding dispute resolution (ENR 2000). One of the early decisions that prevents disputes on a project is selecting the most appropriate project delivery and management method (FFC 2006). It has been conceived that the use of traditional PDMs and low bid process often create adversarial relationships between the parties involved compared to alternative PDMs that are characterized by being highly collaborative intending to replace the individual parties’ success with overall project success. In line with the various contract conditions that reflect the collaborative-based approach of alternative PDMs, the dispute resolution process selected should portray the level of collaboration expected on the project, i.e., offer opportunity for using amicable dispute resolution process before resorting to hostile DRMs. However, to date, there has been little research conducted, especially on highway infrastructure projects, to investigate this notion and its implication on the project management. Therefore, this research aims to conduct a preliminary investigation on the impact of different PDMs on selection of the dispute resolution process by the State Departments of Transportation (DOTs). In essence, has the use of more collaborative forms of PDMs resulted in selecting less adversarial Dispute Resolution Methods (DRMs)? In order to achieve this objective, the paper first introduces the various forms of PDMs and DRMs used in the construction industry. Then, the result of a content analysis that was conducted to compare the current dispute resolution practices in various PDMs is presented.

1.1 Project Delivery Methods

PDMs define the relationship, roles, and responsibilities of project team members and the sequence of activities required to provide a facility. The particular method through which a given construction project is designed and constructed is an important consideration prior to beginning a project, as it has a significant impact on cost, risk, and the overall schedule. Examples of PDMs used in the construction industry are the traditional design-bid-build (DBB), design-build (DB), construction manager at risk (CMR), integrated project delivery, and public-private-partnerships. This paper will mainly focus on DB and DBB PDMs.

In DBB, the traditional and most popular form of PDM, the owner hires an engineer to design the project in its entirety, creating both the plans and specifications that identify all the project parameters. The project is then put up for a competitive bid after which a separate firm is hired to serve as the general contractor. Project award is usually based on the lowest responsive bid. Some of the challenges with this system are the adversarial relationships among project participants and lack of contractor’s input during design leading to potential change orders. In case of DB PDM, the owner hires one entity to serve as both the contractor and the design professional. This set-up also allows contractor’s input during design, single point of responsibility for construction and design, and fast-track delivery. However, there is potential loss of owner’s control specifically loss of checks and balances. Over the past 15 years, use of DB has greatly increased in the U.S., making this delivery method one of the most significant methods in design and construction today (DBIA n.d.). Research has found that the DB PDM is more effective in large and complex projects (Koncher and Sanvido 1998). Other than contractual PDM method implementation, the U.S. Army Corps of Engineers developed the partnering process in the 1980s to fundamentally change the manner in which contractual parties relate to each other – creating a cooperative team approach rather than the more historically common adversarial approach. Partnering do not modify any existing contractual requirements; it is a voluntary process, and joint costs are typically shared by the parties. Partnering involves working together as a team, developing a common set of project goals, open communication and access to information, empowering participants to resolve issues at the lowest appropriate organizational level, reaching decisions and solving problems quickly and by consensus, and maintaining the relationship throughout the project (AAA 1996).

PDMs is a well-researched topic in construction research. Most studies conducted, in public highway projects, focused on comparing various PDM in terms of their performance (cost, schedule, sustainability, and quality). Warne (2005) conducted a performance assessment of DB contracting for highway projects in terms of schedule, cost, quality, and owner satisfaction, by gathering information on 21 DB highway projects ranging in size from $83 million to $1.3 billion. Shrestha et al. (2012) also focused on highway project investigating project performance metrics of 130 DB large highway projects in Texas. Results, in
both studies, showed that the selected projects were built faster using DB than they would have been with DBB (Warne 2005, Shrestha et al. 2012). As DB is more widely being implemented, studies whether on the national or state level are continuously being conducted to evaluate DB projects’ performance (FDOT 2004; FHWA 2006). In January 2006, FHWA published the results of a comprehensive national study conducted to evaluate DB contracting effectiveness, from different states that were taking the lead on DB implementation. Research studies were also conducted to evaluate quality such as the Arizona DB projects quality study (Ernzen and Feeney 2002), quality qualifications assessment in DB solicitation documents (Gransberg and Molenaar 2004) and a synthesis of how quality is handled in DB projects (Gransberg et al. 2008). In another study, Minchin et al. (2013) compared time and cost performance of 60 projects from Florida DOT (FDOT) and found that DBB projects outperform DB projects in terms of cost. As can be seen, most research discussed earlier have considered cost, time, and quality but there hasn’t been any major work that directly addresses the relationship between PDM use and disputes/dispute resolution process, especially as related to highway projects.

1.2 Disputes and Claims

With all the PDMs discussed and different degrees of collaboration among parties involved, the complexities involved in construction projects and the magnitude of risks, it is still a fact that construction industry is characterized by being one of the most adversarial industries generating disputes and claims. Disputes occur on construction projects for many reasons such as schedule targets, acceleration, coordination, culture, differing goals, and delays conditions. Claims would generally occur if the contractor requests additional compensation for deviations from original contract or the owner seeks compensation for contractor’s failure to meet contractual requirements (FFC 2007). In Korea, Acharya and Lee (2006) identified six critical construction conflicts: site conditions, local people obstruction, errors and omission in design, double meaning in specification, excessive quantity of works, and difference in change order evaluation. Sigitas and Tomas (2013) hypothesize that the true cause of construction-related conflicts is unsuccessful communication among the construction project participants.

There are different methods to resolve disputes on construction projects. Litigation is the traditional method employed in courts, where all parties are subject to all of the forms of discovery, such as interrogatories, requests for admission, document production demands, and depositions. The parties then have a trial, which if they are dissatisfied by its results, they can appeal. Historically, litigation has had a reputation for being a long expensive process. In the public sector, there are often requirements that contractors must first file a government claim and go through an administrative hearing procedure before they can proceed to arbitrate or litigate their claims. This is known as Government Claims Procedure (Klinger 2009). According to the American bar, Alternative Dispute Resolution (ADR) methods are increasingly used in the construction industry in lieu of or as a step preceding litigation, as they can handle disputes quicker and are relatively inexpensive. Some of these ADR could be binding to assure parties that they will not have to resort to outside litigation to settle disputes (Dettman and Harty 2008).

Commonly used ADR methods include: step negotiation, mediation, Dispute Review Boards (DRBs), and arbitration. Step Negotiation requires the individuals getting directly involved in dispute to seek resolution by direct negotiation. In the event of resolution not being reached within a certain period, the dispute is taken to the next level which could continue to senior level of each organization. According to Texas Civil Practice and remedies code 154.023, “mediation is a forum in which an impartial person, the mediator, facilitates communication between parties to promote reconciliation, settlement, or understanding among them.” Whether it is during the course of construction or after the project is complete, mediation is arguably the most satisfying DRM. It can occur as early in the process as the parties are able to organize a mediation and identify a mutually agreeable mediator (Klinger 2009). DRB, on the other side, involves three neutral experts who visit the site periodically and monitor progress and potential problems that might lead to disputes. Once a dispute occurs, it is brought to the board who conducts an informal hearing and issues an advisory opinion that could be either binding or non-binding. DRB cost is typically 0.15% of the total construction cost which is far less than using arbitration or litigation. Finally, arbitration is a non-judicial forum to settle disputes; its benefit emerges from the fact that construction disputes often require the decision-maker to be well versed in technical and industrial matters, in addition to legal issues (Yates and Smith 2007). However, in a survey conducted in the U.S., 31 out of 42 arbitrators reported
that “arbitration is becoming too much like court litigation and thereby losing its promise of providing an expedited and efficient means of resolving commercial disputes…” (AAA 2010, p.42).

Few papers address the topic of disputes occurrence and contracting strategy/PDM. The Federal Facilities Council (2007) compiled a report of presentations given by speakers who are experts in resolving construction disputes. Using the Pentagon renovation project, the report highlighted how projects transferring more risk to contractor and using a low-bid process are more prone to having claims. Contracts should portray realistic risk assignment to parties rather than convey the bargaining powers of the parties. In addition to inequitable risk allocation, the report addressed disputes’ causes that are attributable to the contracting/bidding strategy such as low bid process, poorly developed contracts, and lack of project management procedures (FFC 2007). Another interesting observation by Independent Project Analysis’s study conducted on projects of diverse types was that, in contrary to the perception that fewer claims are anticipated in shared risk contracts, no difference was seen between claims’ frequency on shared risk versus contractor-allocated risk contracts. This was attributed to inappropriate risk allocation strategies. The study also looked at DRM choice showing that arbitration encouraged inflated claim values while other forms such as DRBs and mediation did not affect claim frequency (FFC 2007).

Two other studies, one in Malaysia and the other in UK reported that alternative PDMs reduced disputes frequency (Ndekugri and Turner 1994, Yusof et al. 2011). Mante et al. (2012) conducted a preliminary study on dispute resolution by analyzing DRM provisions in standard contract forms showing that regardless of the PDM, the same dispute resolution provisions were used. The paper also reinforced our literature review that the amount of research done related to PDM and dispute reduction/resolution is limited.

The previous sections show that, on one side, there are many DRMs, with varying degrees of hostility, that evolved to manage the numerous claims/disputes that occur on construction projects while on the other side, there are many forms of PDMs, some of which are assumed to create more collaborative environments less prone to disputes. Although there seems to be a strong link between PDM use and dispute process selected, there has not been any consolidated research conducted to investigate the effect of PDMs choice on selection of DRMs or process, especially as related to public highway projects.

2 METHODOLOGY

This aim of this paper is to conduct a preliminary investigation on how the choice of different PDMs has affected how DOTs are currently selecting the DRM used. To achieve this objective, the researchers conducted content analysis of three State DOTs’ specification documents, both for the traditional PDM and DB PDM. The aim of the content analysis was to develop valid inferences using a set of procedures from the documents studied (Neuendorf 2002). The three state DOTs studied were Florida DOT (FDOT), Ohio DOT (ODOT), and Colorado DOT (CDOT). These three State DOTs were selected because they have a well-established DB process. CDOT started using DB on a few projects in the 1990’s after obtaining FHWA Special Experimental Project Number 14 (SEP-14) – Innovative Contracting program approval, however, in 1999, the Colorado State Legislation was officially obtained allowing DB use. As for FDOT, DB has been permitted by all agencies for all types of design and construction since 1997. ODOT represents also one of the early participants in SEP-14 in 1990, to test and evaluate DB, among other PDMs, as a potential effective method to deliver highway projects (DBIA, n.d.). Over the past few decades, DB has been increasingly used by ODOT in projects of different characteristics.

Specification documents were retrieved from the DOTs’ websites (Table 1). In cases where it was not possible to locate the DB standard specification, DOT DB projects solicitation documents were studied to identify the dispute resolution process used. It was assumed that the specification document was for traditional PDM if no specific PDM was specified. Six state DOT specification/bid documents from the three DOTs, together with three FDOT solicitation documents, were analyzed to determine the process followed from the occurrence of the event giving rise to the claim until resolution of the claim using any form of DRM. The content analysis of the documents focused on three main aspects; 1) how DOTs define the word ‘claim’ and ‘dispute’, 2) the process that precedes resorting to the formal DRM, if stated, and 3) the formal DRM employed. After each State DOT specifications were analyzed, the traditional versus the
alternative PDM specification document was compared to infer the differences (if any) between the DRM and the process utilized to resolve in each of these State DOTs given different PDM.

3 Results & Analysis

3.1 Colorado DOT

Both CDOT 2011 Standard Specifications for Road and Bridge Construction (with no PDM specified), here in after called ‘2011 CDOT SS’, and the RFP documents (Book 1 DB Contract Provisions) define dispute as a “disagreement”. As per 2011 CDOT, dispute is a “…disagreement concerning contract price, time, interpretation of the Contract, or all three between the parties at the project level regarding or relating to the Contract”, or as the DB RFP documents, disputes could be disagreements “resulting from a change, delay, change order, another written order, or an oral order from the Project Director or his designee…” Claim on the other side, as per the DB project RFP documents (Book 1 Contract Provisions), is defined as “…a separate demand by the Contractor for: (i) a time extension which is disputed by CDOT, or (ii) payment of money or damages arising from work done by or on behalf of the Contractor in connection with the Contract which is disputed by CDOT. A claim will cease to be a Claim upon resolution thereof, including resolution by delivery of a Change Order or Contract amendment signed by all parties.” Thus, as per CDOT, the process starts with a dispute that is then elevated to a claim, if not resolved at the project level.

The 2011 CDOT SS (traditional PDM) document subsections 105.22, 105.23, and 105.24 detail the dispute resolution process. It states that either party can initiate the resolution process when an issue arises that cannot be resolved between the parties. CDOT follows a stepped-process that starts at the project level and can be escalated all the way to litigation or arbitration (Figure 1). The process starts with the contractor providing a written notice of dispute to the project engineer about the failure of the parties to resolve the dispute. This notice is then followed by a request for equitable adjustment (REA) -within 15 days- which should include supporting documents such as nature of the circumstance which caused the dispute, statement explaining provision of the contract, and all evidences. Within 15 days of receiving the REA, the engineer meets with the contractor and in seven days issues a written decision on the merits of the dispute. If the contractor does not accept the decision, the contractor provides notice to the resident engineer who meets with the contractor as well as the project engineer within 7 days of receiving the contractor’s written notice, on a weekly basis for a period up to 30 days, to discuss and resolve the dispute. If dispute remains unresolved, the project engineer directs it to DRB.

CDOT specifies two types of DRB in their provisions: “On Demand DRB” and “Standing DRB”. “On Demand DRB” is the default DRB to be used unless the project contract documents specify otherwise. On Demand DRBs constitute only one member, if the dispute value is less than $250,000, and three members in larger dispute values. However, Standing DRBs always have three members that are selected during the preconstruction stage and will meet regularly during the course of the project. Standing DRBs (as per the standard special provision dated November 6, 2014 that revises CDOT’s Standard Specifications for Road and Bridge Construction) are typically used in projects that are larger than $15 million, involving complex construction or structures or multiphase construction, with major traffic...
impacts, or other complicating factors that could lead to disputes. Standing DRB remain in effect all through the duration of the project and are in full force until all disputes are resolved.

![Figure 1: Typical CDOT dispute resolution process](image)

Whatever the DRB type selected, once the project engineer initiates the DRB process, parties will need to submit prehearing submittals that include all supporting documents/evidence. At the hearing, both parties present their positions. After the meeting has been closed, the DRB shall issue its recommendation and the DRB and parties shall agree on the time (maximum time being 30 days) for analysis and review of the issuance of the recommendation. DRB’s chairperson signs and sends the signed recommendation and all documents to the parties who will have 10 days to request clarifications. If the parties are not satisfied with the recommendations, other forms of nonbinding dispute resolution could be optionally used such as mediation or as CDOT specifications section “claim for unresolved disputes” states, the contractor can “file a claim” that starts by a written notice of intent to file a claim to the Region Transportation Director (RTD). Based on documents submitted, RTD issues a decision, which if not accepted by the contractor could be escalated to the Chief Engineer. If contractor is not in agreement with the Chief Engineer’s decision, the contractor can initiate litigation or binding arbitration (following American Arbitration Association’s Construction Industry Arbitration Rules) to finally resolve the claim. The standard special provision, dated November 6, 2014, that revises 2011 CDOT SS notes that the same process should be used in DB projects unless the Standards & Specifications Unit approves a SSP modified version.

On the other side, CDOT DB Manual (dated April 15, 2006 and revised on June 11, 2014) states that the DB Request for Proposals (RFP) follows a structure that includes Book 1 (Contract terms and conditions component) and Books 2 through 5 (Technical components). Depending on the DB type (a Streamlined DB or a standard DB), 2011 CDOT SS could remain as an integral part of the contract requirements or could be completely replaced by Book 1. The authors could not locate Book 1 template so three DB projects RFPs were reviewed to identify the DRM process followed; I-25/Cimarron Street (US 24) Project issued 2014, I-25 North Project issued 2012, and SH 285 Reconstruction – Wadsworth to Federal Project issued 2008. The significant difference in the DB projects compared to the process described in the 2011 CDOT SS is the steps preceding the dispute resolution process initiation. Under Article 19 entitled “partnering”, the RFP documents state that the dispute resolution process described shall not apply until “…the normal CDOT-Contractor issue resolution efforts through partnering are not successful…” The RFPs of the projects studied either then refer to dispute resolution section of the 2011 CDOT SS as being an integral part of the contract document or completely replace it by a similar stepped process that concludes with the Chief Engineer’s decision followed by litigation. As for the DRB type, one of the DB projects used standing DRB while the other used on-Demand DRB, which makes DRB type project-specific (following the requirements explained earlier) rather than related to the PDM used.

### 3.2 Florida DOT

FDOT Standard Specification for Road and Bridge Construction dated January 2015 (with no PDM specified), here in after referred to as 2015 FDOT SS, defines Contract Claim as a “… written demand submitted to the Department by the Contractor … seeking additional monetary compensation, time, or other adjustments to the Contract, the entitlement or impact of which is disputed by the Department.” p. 3. No definition was found in 2015 FDOT SS documents for the word “dispute”. 2015 FDOT SS Article 5.12
entitled "preservation, presentation and resolution of the claim" details the claim resolution process including time frames and submittals required. The process must start with "submission of timely notice of intent to file a claim, preliminary time extension request, time extension request, and the certified written claim..." to the Engineer before contractor can seek any formal claim resolution process including litigation. Claims by contractors cannot also be filed to litigation or arbitration before FDOT grants the contractor final acceptance of all the work. The Engineer, after submittal of all required documents, will have 90 or 180 calendar days depending on the contract amount to respond to the contractor. It is interesting though to note that 2015 FDOT SS contains a paragraph in multiple sections stating that ultimately "Statewide Disputes Review Board in effect for this Contract will resolve any and all disputes that may arise involving administration and enforcement of this Specification...the determinations of the Statewide Disputes Review Board for disputes... will be binding on both the Responsible Party and the Department, with no right of appeal by either party." p.297. Accordingly, some of the disputes could be escalated to the binding DRB, while the 2015 FDOT SS was not specific about the other forms to be used in other types of works where Statewide DRB was not specifically listed.

On the other side, FDOT’s DB specifications document dated September 8, 2014 added two entire sections to the procedures followed in conducting DRBs that discusses both DRB and Statewide DRBs and details the choice of the members, schedule, responsibility of each party, and basis of payment in each. DRBs are used essentially when normal dispute or claim resolution is unsuccessful and by either the choice of the DOT or the Contractor. The steps involved in dispute resolution start with the contractor filing a written protest with the Engineer within 15 days after the event and states its reasons for objection. The Engineer then responds to the written protest within 15 days of receiving it and in its response furnish the contractor with its decision. This decision is final unless the contractor files a written appeal to the Engineer within 15 days. In this case, the issue is referred to the DRB by the parties involved. The DRB then fixes a date to conduct the hearing. All evidence to the claim or disputes must be submitted to the board within 15 days before the date set by the board. The owner/contractor would provide a position paper that outlines the dispute/claim nature and scope together with the basis for entitlement. During the hearing, all parties shall be given the opportunity to be heard and provide their evidences. Within 15 days of completing the hearing, the board shall give recommendations of the dispute or claim to the parties involved. Also, within 15 days of receiving the board’s recommendations, the parties involved shall respond whether or not they accept the recommendations. It is noted that in the Section regarding DRBs “both the Department and the Contractor should place great weight on the Board’s recommendation, it is not binding” (Article 8.3.7.4) while in the section regarding the Statewide DRBs “recommendations of the Board will be binding on both the Department and the Contractor.” (Article 8.3.8.1). Thus, DRB hearings of any unresolved disputes/claims needs to supersede any initiation of arbitration or to filing a lawsuit, while in Statewide DRBs, DRB decisions are final and binding. Figure 2 shows the stepped process used in FDOT.

![Figure 2: Typical FDOT dispute resolution process](image)

### 3.3 Ohio DOT

ODOT Construction and Material Specifications dated January 1, 2013 (with no PDM specified), here in after referred to as 2013 ODOT SS, defines claims as “Disputes that are not settled through Steps 1 and 2 [discussed below] of the Dispute Resolution and Administrative Claim Process. The Dispute becomes a Claim when the Contractor submits a Notice of Intent to File a Claim." p. 6. Disputes, on the other side, are defined as “Disagreements, matters in question and differences of opinion between the Department's personnel and the Contractor." p.7. So in essence, disputes are escalated to claims.
ODOT’s introduces the dispute resolution process under Section 108.02 ‘Partnering’ where ODOT sets partnering as the “proactive effort and spirit of trust, respect, and cooperation among all stakeholders in a project…” p.46. Figure 3 shows ODOT’s dispute resolution process, which is a stepped approach to be followed in sequence. The contractor should first provide immediate oral notification to the Engineer once a circumstance that might result in changes evolves. Both the contractor and engineer should discuss various mitigation efforts such as re-sequencing activities and acceleration, and the engineer should try to resolve the issue expeditiously. If the engineer does not resolve the issue in 2 working days from oral receipt of notice, contractor should provide a written notice. If these mitigation steps do not resolve the issue under consideration, the contractor should escalate the issue to the ‘Dispute Resolution and Administrative Claims Process’ that should be totally exhausted before filing a claim in the Ohio Court of Claims. Figure 3 shows the stepped process followed by ODOT:

- **Step 1: On-Site Determination:** Engineer meets the contractor’s representative within two days of Contractor Written Early Notice receipt in an attempt to reach a resolution. The Engineer then issues a Step 1 written decision within 14 days. If no resolution is reached, dispute is escalated to next level.

- **Step 2: District Dispute Resolution Committee (DDRC):** Each District establishes a DDRC for deciding disputes that escalate to Step 2. Within 7 days of receipt of Step 1 decision, a written notice is submitted to the District Construction Administrator (DCA), followed by all the dispute documentation required (such as additional compensation requested and narrative of disputed work) in 14 days. After which, in 14 days, the DDRC meets with the contractor and issues a decision.

- **Step 3: Director’s Claims Board Hearing (Board) or ADR:** Within 14 days, if contractor is not in agreement with the decision reached in Step 2, a written notice of intent to claim filing is to be submitted to the Dispute Resolution Coordinator that requests either a Board hearing or an acceptable ADR method. This is the point in time where the ‘dispute’ becomes a ‘claim’. In case of a Board hearing, the Board hears the claim on behalf of the Director and submits a written recommendation to the Director who takes the final decision which is considered the final step of the Dispute Resolution Process within ODOT. In case of ADR choice, binding arbitration or mediation could be selected and agreed upon by the parties. The neutral third party will now have complete control of the claim.

![Figure 3: Typical ODOT dispute resolution process](image)

Looking through ODOT document “Revisions to 2013 C&Ms for DB Projects” dated December 31, 2012, the same dispute resolution process is followed on DB projects, as this section was not amended.

4 DISCUSSION

Figure 4 shows a comparison between the three DOTs’ dispute resolution processes moving from a dispute to be resolved on the project level to a formal claim involving third party control. Both CDOT and ODOT define claim as the level succeeding the failure to resolve a dispute. Based on the documents analyzed, all states have some sort of stepped resolution process whether on DB or DBB method. The use of the stepped process provides an opportunity for the parties to resolve disputes at the job site level in a more efficient manner before resorting to lengthy and costly DRMs such as arbitration or litigation. CDOT had the maximum number of steps, followed by ODOT, then FDOT. Different forms of ADR were used in the three states with DRB (in its various forms) being used in all three. CDOT used either standing (specific for the project) or on-demand DRBs based on the characteristics of the project in both PDMs. FDOT used standing non-binding DRBs generally and State wide binding DRBs in specific designated work types of the project. The binding nature of the Statewide DRB in FDOT’s process raises
the concern that once the parties are unable to resolve the dispute at the project engineer level, the process is rapidly escalated to a costly adversarial process involving lawyers. ODOT, on the other side, formed a DDRC that is similar to FDOT’s Statewide DRBs yet issues non-binding decisions that could be further elevated to other forms of ADR.

Figure 4: State DOTs dispute resolution process comparison reflecting both DB and DBB processes

Both ODOT and CDOT mandate the use some form of partnering/mitigation process before initiating a dispute resolution process and move through a stepped process passing through DRB, as well as in some cases a mediation process and in all cases ends up with arbitration or litigation. In CDOT specification documents, it was interesting to see how partnering was listed as an integral process in DB projects but not in DBB projects. As for FDOT, the main difference observed between DBB and DB specification standards was how in DBB projects - other than Statewide to be used under specific work disputes- there were no mention of the DRM method to be employed if the contractor is not in agreement with the engineer’s decision. In DB specifications, however, non-binding DRB was added as an option to be used generally. Finally, ODOT did not amend the dispute resolution section in its DB specification.

5 CONCLUSIONS

Results of this preliminary investigation show the some states (e.g. CDOT) must be realizing that alternative PDMs necessitate the use of a dispute resolution process that is more amicable and fosters partnerships while others are using mitigation/partnering efforts (ODOT) regardless of the PDM. A stepped process in general is preferred in all states with some form ADR (DRB mostly and mediation sometimes) being used before resorting to litigation. It is anticipated that early resolution of disputes through transparent procedures in an environment that fosters understanding, communication, and cooperation will ultimately result in less disputes escalating to claims. While, the contribution of the study is significant, there are several limitations that need to be addressed in future studies. First, the external validity of study is limited to three states DOTs (Colorado, Florida, and Ohio); therefore, other studies should be conducted to explore DRM being followed in the remaining DOTs not only in the standard specification but also as pertinent to the project specifics. Second, this study was limited to conducting content analysis on current documents and lacks empirical support; future studies should be conducted to collect empirical data from completed projects and analyze the impact of various project delivery methods and dispute resolution process on disputes occurrence and resolution. Third, this study just looked at the DRMs provided by owners and does not provide any insight towards the behavior of stakeholders in a project. There is a common belief that more integrated PDMs provide a more collaborative environment and as a result reduce potential of disputes in a project. Future studies should be conducted to test this hypothesis statistically. Finally, a study should be conducted to understand how the choice of a stepped
process versus the other affect the numbers of claim that evolve and the number of claims that move to litigation and how, if any, the stepped process help reduce the number of claims in these DOTs compared to others. Despite of these limitations, this study addresses an important knowledge gap and paves the way for future in-depth studies regarding dispute prevention and minimization and alternative PDMs.

Abstract: Viewing water and wastewater infrastructure systems from a network or functional viewpoint down to an individual component goes hand in hand with life-cycle management. Therefore, three concepts are incorporated: (1) Strategic Planning; (2) Tactical Planning; and (3) Operational Planning. The data relevant to each of these areas are generated and managed by software applications that operate in isolation. A multi-level integration can link and share data among strategic, tactical, and operational asset management plans. The Industry Foundation Classes schema concept is used to develop a framework to support efficient sharing and management of data and planning information among strategic, tactical and operational asset management plans of the water and wastewater infrastructure systems. The proposed multi-level integration framework is comprised of a comprehensive database of water and wastewater infrastructure physical asset inventory, financial and consumer sectors that stores and manages flow of information through strategic, tactical, and operational asset management plans. Data are identified by reference of time and date (temporal) and by physical relation of data to the location of a facility in the water and wastewater infrastructure networks (spatial). The proposed framework enables the integration and interoperation of various domain-specific software applications through developing and maintaining a multi-level integration of strategic, tactical and operational asset management plans based upon the Industry Foundation Classes data model concept. Municipalities and water utilities can use the findings to make optimized asset management decisions.

1 INTRODUCTION

Grigg (2012) defines infrastructure asset management as “an information-based process used for life-cycle facility management across organizations”. This paper proposes a multi-level integrated asset management framework to store and manage flow of information through strategic, tactical, and operational asset management plans for water distribution and wastewater collection networks. The data relevant to each of these asset management planning models are generated and managed by software applications that operate in isolation. A multi-level integration should enable water infrastructure stakeholders and software developers to extract and exchange the required data and information from any of the strategic, tactical, and operational asset management planning model using a centralized neutral data file.

Environment Canada (2004) defines the water infrastructure system as comprised of “water treatment plants that purify our water, the water mains in the ground that transport water, and the towers and reservoirs that store water. The term includes the sewer pipes that carry away wastewater and the
sewage treatment plants that treat wastewater before returning it to the environment ...". The other components of a water infrastructure system that include water and wastewater treatment plants, towers, and reservoirs are outside the scope of this study.

2 BACKGROUND

Froese (2003) indicated that information technologies (IT) play an effective role in architecture, engineering, construction, and facilities management (AEC/FM). Various domain-specific software applications are used to facilitate most of the AEC/FM design and management tasks, and the information entered into all of these computer tools describes the same physical project (Froese, 2003).

To facilitate efficient sharing and management of data between AEC/FM, the topic of interoperability has become one of the main areas for research and development in IT for the AEC/FM sectors (Froese, 2003). Froese, (2003) defines Interoperability as “the ability for information to flow from one computer application to the next throughout the lifecycle of a project which relies on the development and use of common information structures”.

To develop an integrated AEC model structure, model-based systems have been known as the main empowering technology (Halfawy and Froese 2002). Caldas and Soibelman (2003) noted that model-based systems are being utilized more and more to support exchanging information among AEC/FM projects. Industry Foundation Classes (IFCs) are one of the most remarkable of these model-based systems. IFCs have had significant positive impact on integration and interoperability.

2.1 Industry Foundation Classes

The IFCs specification is developed by the International Alliance for Interoperability (IAI). The IFC specification is a neutral data format to describe, exchange, and share information among AEC/FM industry projects (Caldas and Soibelman, 2003). The latest version is IFC4 and is available at buildingSMART International Ltd.

The IFCs data model is substantially built in a hierarchical structure, and its object-oriented design enables complex relationships to exist between entities (Dimyadi et al., 2008). Entities can be physical objects such as watermain pipes, service connections, valves, etc. or conceptual entities such as processes, budgets, scheduling details, etc..

Froese (2003) noted that the scope of the IFCs is limited to the building industry and should be extended to a broader range of civil infrastructure to include the entire built environment. To some extend this has happened in the industrial sector with ISO 15926. This research presents a framework to support efficient sharing and management of data and planning information among strategic, tactical and operational asset management plans for the water and wastewater infrastructure systems, and to enable the integration and interoperation of various domain-specific software applications through developing and maintaining multi-level integrated asset management plans based upon the IFC data model concept. A critical functionality of a multi-level integration of strategic, tactical and operational asset management plans is the requirement to link and manage the inter-dependencies of these data, and to enable different applications to share these data through the use of the integrated asset management model.

Strategic planning is a long-term (10+ years) group of activities including capital planning, operational and maintenance planning, policy planning, risk management, and life-cycle costing at the management level of an organization. The organization policy levers and the level of service are established at this stage of planning. Embedded in and dependent on strategic planning, a tactical planning (2-10 years) cycle is required to prioritize capital works activities as well as operating and maintenance (O&M) activities, and to flag candidates for capital works and O&M activities. Operational planning is defined as plans that specify details on how overall objectives are to be achieved (Robbins and Coulter, 1996) and to implement tactical plans.
2.2 EXPRESS Modeling Language

EXPRESS (ISO 10303-11, 1994) is an internationally standardized general-purpose data modeling language in contrast to a domain-specific data modeling language. The data model structure is often represented using the EXPRESS-G notation—a graphical modelling language subset of EXPRESS language (ISO 10303-11, 1994) used for identifying model classes, data attributes and their relationships. Every object which is drawn in EXPRESS-G can be defined in EXPRESS. However, not every object which can be defined in EXPRESS can be drawn in EXPRESS-G (ISO 10303-11, 1994). This section presents the basic symbols used in the EXPRESS-G data modeling language.

2.2.1 Classes

Classes are identified in a rectangular box with solid lines and the name of class is enclosed in the box (ISO 10303-11, 1994). Figure 1 shows three examples of classes where Iwis means integrated water infrastructure system.

![Figure 1: Classes (Entities)](image)

2.2.2 Data Types

EXPRESS-G consists of four main data types as follows:

a) Simple data types

There are seven simple data types: BINARY, BOOLEAN, INTEGER, LOGICAL, NUMBER, REAL, and STRING which are shown in Figure 2. A simple data type is presented as a solid rectangular box with its name enclosed and a double vertical line at the right hand side of the box (Figure 2).

![Figure 2: Simple data types in EXPRESS-G data modeling language](image)

b) Enumeration data type

Data attributes can be described in an enumeration data type when there is a range of possible values and the attribute may only choose one value from the possible range. This data type is shown in a dashed lines rectangular box with a double vertical bar to the right. The name of enumeration data is enclosed into the box. Figure 3 shows an enumeration example for IwisPipeMaterial that enables the IwisPipeMaterial to choose only one type of pipe material.
c) Defined data type

A simple STRING data type can be used to define a data type but there are some types of data that require a detailed description. In this case a defined data type is used to make a clear description for a defined type of data. Figure 4 shows an example of a defined data type in EXPRESS-G. This type of data is shown in a dashed lines rectangular box with its name enclosed into the box.

```
WaterUtility
```

Figure 4: An example of defined data type in EXPRESS-G

d) Select data type

A select data type enables data attributes to choose the class based upon different purposes. For example, the IwisWaterDistributionElement enables selection of, watermain pipe, valve, hydrant or service connection (Figure 5). Select data type is shown in a rectangular box with dashed lines and a double vertical bar on the left hand side. The name of the data type is written in the box.

```
IwisWaterDistributionElement
```

```
IwisServiceConnection IwisHydrant IwisValve IwisWatermainPipe
```

Figure 5: An example of select data type in EXPRESS-G

2.2.3 Relationships

Mandatory and optional relations are two types of attributes that are related to a class. The value of attributes must be given when a Mandatory relation is assigned to a class. However, it is not necessary for the optional attributes. Figure 6 shows an example of a mandatory and optional relation to IwisWaterDistributionElement where TotalLength has a mandatory relation and TotalVolume is considered an optional relation.

```
REAL
TotalLength
```

```
REAL
TotalVolume
```

```
IwisWaterDistributionElement
```

Figure 6: An example of a mandatory and optional relation in EXPRESS-G
The above discussion briefly introduced the EXPRESS-G data modeling language for the purpose of this study. A detailed discussion on this graphical data modeling language can be found in ISO 10303-11 (1994).

3 MULTI-LEVEL INTEGRATION FRAMEWORK

There are inter-dependencies and relationships that exist between strategic, tactical and operational (STO) asset management plans for water and wastewater infrastructure systems. The data relevant to each of these areas typically generated and managed by separate software applications that operate in isolation. Multi-level integration of STO planning is intended to link and manage the inter-dependencies of these plans. The IFCs schema concept is used to develop a centralized database management system that enables the interoperability of various function-specific tools and the exchange of data among different asset management planning disciplines.

The proposed multi-level integration framework is comprised of a comprehensive database of water and wastewater infrastructure physical infrastructure assets with financial and consumer sectors that exchanges and stores data through strategic, tactical, and operational planning (Figure 7). An Integrated Water Infrastructure System (IWIS) database stores and manages flow of information between strategic, tactical, and operational planning models. Data will be identified by reference to time and date (temporal) and by physically relation of data to the location of a facility in the water infrastructure network (spatial).

![Diagram](image)

Figure 7: The Research vision for Multi-Level Integration

3.1 Asset Management Plans

This section presents the typical steps required to develop strategic, tactical and operational asset management plans for water infrastructure systems.
3.1.1 Strategic Planning

The implementation steps for strategic planning of a water infrastructure system are categorized as follows (adopted from Uddin et al., 2013):

1. establish policy levers
2. establish level of service performance (consumer satisfaction) policies
3. categorize urban water infrastructure networks needs and funding sources
4. estimate long-term (10+ years) financial performance
5. prepare long-term (10+ years) capital works program
6. prepare long-term operating and maintenance program

Types of modeling techniques used for this level of planning currently include financial spreadsheets, simple data base management systems (DBMS), system dynamics models, large business oriented models, scenario based models, etc.

3.1.2 Tactical Planning

The implementation steps for tactical planning of a water infrastructure system are summarized as follows (adopted from Uddin et al., 2013):

1. prioritize all capital works activities,
2. prioritize all operating and maintenance (O&M) activities,
3. flag specific activities for capital works, and
4. flag specific activities for O&M activities

Types of modeling techniques used for this level of planning currently include deterministic mathematical modeling, simulation, optimization, etc..

3.1.3 Operational Planning

The implementation steps for operational planning of a water infrastructure system are categorized in the three disciplines of (1) engineering and design, (2) construction, and (3) operation and maintenance within a water utility (adopted from Uddin et al., 2013):

1. Engineering & Design
   1.1. perform structural and hydraulic analysis
   1.2. analyze cost effectiveness of project level alternatives
   1.3. prepare plans and specifications and perform actions
   1.4. analyze cost effectiveness of O&M activities
   1.5. analyze cost effectiveness of capital works

2. Construction
   2.1. perform capital works

3. Operation & Maintenance
   3.1. perform structural and hydraulic analysis
   3.2. perform O&M activities
   3.3. collect condition assessment and financial data

Types of modeling techniques used for this level of planning currently include simulation models, “what-if” scenario models, sensitivity analysis, modeling infeasibilities, opportunity costs and marginal economic value, etc.
The implementation steps of the above asset management plans need to be considered when developing the neutral strategic-tactical (ST) and tactical-operational (TO) data files to recognize data and planning information to be exchanged between the strategic, tactical and operational planning models.

### 3.2 Neutral Data Files

The neutral strategic-tactical and tactical-operational data files are divided into the three subtypes of neutral physical infrastructure asset, finance and consumer data files (Figure 8). A brief description of each subtype is presented in this section. The division into these three sectors is established in the literature and is used in systems dynamics models developed for strategic planning (Rehan et al., 2011, Rehan et al., 2013 and Rehan et al., 2014).

![Figure 8: A hierarchy of the neutral data files](image)

#### 3.2.1 Physical Infrastructure Asset Sector

This sector represents the asset inventory of water distribution and wastewater collection networks. The physical condition of the water network is classified based upon the age distribution of water pipes (e.g. in 25-year increment). The physical condition of the wastewater network is divided into five variables based upon the internal condition of the pipes using the UK’s Water Research Centre rating system proposed in the fourth edition of the Sewerage Rehabilitation Manual.

#### 3.2.2 Finance Sector

This sector describes the network’s financial condition including revenues, expenses, fund balance, debt, utility user fee, etc. Revenue is the utility’s income that is calculated based upon user fee, total water consumption, and total generated sewage. Fund balance is the difference between the revenue and expenditures of the network in dollars value, and user fee is the unit cost of water and sewage ($/m^3$) that a utility charges its consumers to cover the expenses associated with the water and sewage services.

#### 3.2.3 Consumer Sector

This sector presents the behavior of consumers in response to user fee oscillations (i.e. water demand) and level of service delivered to them. This sector establishes the policy levers and level of service performance (consumer satisfactions) policies.

The neutral strategic-tactical (ST) and tactical-operational (TO) data files will be developed to support efficient sharing and management of data and planning information among strategic-tactical and tactical-
operational models using EXPRESS-G data modeling language. Figure 9 shows a high-level example of the integrated water infrastructure system model structure displaying in EXPRESS-G.

![Diagram of integrated water infrastructure system model structure in EXPRESS-G](image-url)

Figure 9: A High-level example of the integrated water infrastructure system (Iwis) model structure in EXPRESS-G.
4 CONCLUSIONS

This paper reviews the basic concepts of Industry Foundation Classes and the EXPRESS-G data modeling language. A framework is proposed to integrate strategic, tactical and operational asset management planning models for the water and wastewater infrastructure systems. Further work is needed to completely develop the proposed multi-level integration framework. It is important that the developed neutral IWIS data files are reviewed by the water infrastructure industry experts and software developers to ensure that the specification is validated universally by the agreement of a wide cross section of water infrastructure industry experts and does not rely on a particular region. It should also be demonstrated with various currently utilized software packages. The proposed framework is the first known approach for data integration, sharing, and exchange between strategic, tactical, and operational asset management planning models of the water and wastewater infrastructure systems. In practice, this framework should enable water infrastructure stakeholders and software developers to extract and exchange the required data and information from any of the strategic, tactical, and operational planning model using a centralized IWIS neutral data file.

³ Professor, Department of Civil and Environmental Engineering, University of Alberta, Canada

Abstract: Simulation modeling is a powerful tool widely used for designing construction processes and improving the efficiency of operations. However, there is often difficulty in estimating the duration of manual tasks for simulation purposes due to its dependence on the physical attributes of the worker performing the task. When designing a new process, there is usually a lack of sufficient data regarding the required duration for manual tasks, and in the case of evaluating and improving existing processes, there is no benchmark data for workers’ performance to enable comparison of the efficiency of the existing process. This study attempts to address this issue by exploring micro-motion-level simulation modeling in order to provide standard motion time required to perform a manual task for effective workplace design. The research method involves integrating a Predetermined Motion Time System (PMTS) into discrete event simulation, which provides the production planner with a standard task duration within which a worker must complete the task without delays or idling. As a case study, a manual task taking place in the production line of a construction steel fabrication company has been modeled using the developed automation tool in order to verify the feasibility of the proposed approach. The results show high correlation between the simulation model output and the actual time data from the jobsite and confirm the validity of the approach and its effectiveness in evaluating the productivity of the existing operations and providing detailed information for process improvement.

1 INTRODUCTION

Construction simulation is a powerful tool that enables analysis of different scenarios of the work process in order to optimize the use of available resources. Decision makers and production planners can highly benefit from simulation modeling in order to increase the productivity of construction operations. One of the most essential pieces of information required to create effective simulation models is time data. It is crucial to use accurate and realistic time information to represent the duration of the various tasks of a simulation model. Production planners usually use company historical data to calculate the duration of different activities. However, due to the uniqueness and complexity of manual tasks, it is difficult to record sufficient historical time data pertaining to manual tasks. Also, in the case of assessing and improving existing work processes, there is a lack of benchmark data for workers’ performance to enable comparison of the efficiency of the existing process. Estimating the duration of manual tasks is difficult due to the variety of factors affecting it and also its dependence on the physical attributes of the worker performing the task. Time studies can be conducted to obtain estimates of manual task durations but require a substantial amount of time. As a result, Predetermined Motion Time Systems (PMTS) have been developed that provide a standard task duration within which a worker must complete a task without...
delays or idling. By taking advantage of PMTS, construction practitioners can use more reliable estimates of the duration of manual tasks, and thus develop more realistic and efficient simulation models. This study explores micro-motion level simulation modeling and integrates PMTS into discrete event simulation to automatically calculate the standard duration required to perform a task based on simple design data used as input.

1.1 Simphony Platform for Special Purpose Simulation

Simphony (Hajjar and AbouRizk 1999) is a simulation modeling platform that enables creating general and special purpose simulation tools. In this context, Special Purpose Simulation (SPS) is defined as (AbouRizk and Hajjar 1998):

[A] computer-based environment built to enable a practitioner who is knowledgeable in a given domain, but not necessarily in simulation, to model a project within that domain in a manner where symbolic representations, navigation schemes within the environment, creation of model specifications, and reporting are completed in a format native to the domain itself.

Simulation theory, application domain, and object-oriented programming are the main components of creating a special purpose simulation tool (Ruwanpura et al. 2001). Simphony provides a structured approach to developing user-friendly SPS templates and offers a comprehensive set of services under its framework including a discrete event simulation engine, a trace manager, statistics collection, graphing, random number generation, and report generation (AbouRizk and Hajjar 1998). This study uses Simphony as a discrete event modeling platform in order to develop a special purpose simulation focusing on manual tasks at a motion level. The developed SPS is compatible with Simphony’s general purpose simulation which enables integrating elements representing manual activities into larger simulation models of the construction operations.

1.2 Predetermined Motion Time System (PMTS)

Various PMTSs have been developed based on studying large samples of diverse manual operations in order to provide a standard time required to perform a task. PMTSs are created based on the assumption that a universal and precise duration can be determined for each basic motion (e.g., moving a finger, grasping an object), and the time for a complete task can be calculated by adding the time values of each basic motion described in the task (Genaidy et al. 1989). The most widely used PMTSs include Methods-Time Measurement (MTM) (Maynard et al. 1948), Maynard Operation Sequence Technique (MOST) (Zandin 1980), and Modular Arrangement of Predetermined Time Standards (MODAPTS) (Heyde 1966). The MODAPTS method is used in this study since it is has more potential applications than earlier PMTSs and is reported to be 25% faster to apply than the latest MTM (MODAPTS 2006). Another advantage of the MODAPTS method is that it describes tasks in human terms rather than mechanical, making it easier to understand (Aft 2000).

MODAPTS was developed by Chris Heyde in 1966 (Stewart 2002) and is widely used in many industries, such as transportation, manufacturing, and health care, due to its simplicity and effectiveness. Designers, production planners, process engineers, and ergonomic analysts can evaluate and improve manual tasks using MODAPTS without the difficulties of recording and analyzing time data (Harputlu et al. 2012). The main concept behind MODAPTS is that all body motions can be expressed as multiples of a single finger movement and the time required to move a finger is called 1 MOD, which is equal to 0.129 second. MODAPTS enables users to describe a manual task as a sequence of motions, known as modules, and calculate an estimate of the standard time to perform the task as the sum of these modules. In order to use MODAPTS, a task has to be decomposed into basic motions defined by MODAPTS and for each basic motion a class and a numeric value (MOD value) has to be assigned. The final duration of the task will be the sum of the MOD values for the basic motions converted into seconds. MODAPTS classes are represented in MODAPTS codes with a capital letter and describe the motion type. Some frequently used MODAPTS classes include Movement, Get, Put, Walk, and Load Factor. As an example, M4G3 can represent the motion of moving the hand 12 inches with the whole arm to grasp a sheet of paper from a desk. For the purpose of this study, the MODAPTS method has been integrated into the simulation
modeling environment, enabling its use based on design data only, without requiring prior knowledge about MODAPTS and PMTS.

2 MICRO-MOTION LEVEL SIMULATION

Using the previously mentioned features of Simphony, the authors developed a micro-motion level special purpose simulation template, named MODAPTS.vb. In order to create a new SPS template, the modeling elements that will be used to create simulation models pertaining to the specific domain have to be first designed and then implemented. Designing these tasks requires thorough understanding of the targeted construction modeling domain (Hajjar et al. 2000). In the case of micro-motion level simulation, the modeling elements will need to represent motions associated with manual activities performed by a worker. In essence, one primary modeling element and six secondary elements were designed and implemented based on the MODAPTS method. The primary modeling element, named ManualTask, represents a manual task performed by a worker and requires some design data as input. Figure 1 shows these design inputs required. Based on the inputs, the simulation will calculate the required amount of time to perform the task based on the MODAPTS standard. As shown in Figure 1, the required set of inputs only includes simple design data (e.g., distance an object is carried, weight of the object, difficulty of grasping the object) that an operation designer or production planner will have at hand during design or redesign of a construction operation. As a result, this model will enable using a reliable standard duration for manual tasks without requiring prior knowledge about PMTS methods. Table 1 describes each attribute of the ManualTask element. This element can be used in any construction operation simulation model in conjunction with other elements of Simphony’s general template to represent a manual task (e.g., lifting, carrying, and placing an object).

Figure 1: Required inputs for the ManualTask modeling element
Six secondary elements have also been developed which encapsulate the lower level activities performed by a worker in order to complete a manual task. These elements include: Get, Move, Put, Walk, BendAndArise and SitAndStand. Figure 2 shows the ManualTask element and also the secondary elements inside the Simphony modeling environment. The secondary elements are designed based on the classes used by the MODAPTS standard. However, a designer not familiar with MODAPTS can also use these elements to model a detailed level motion of a worker. Some of these elements require an input (e.g., distance for the Walk element) and some can be used without any input from the designer (e.g., BendAndArise). The inputs required are the same as the ones used in the ManualTask element, but they are used as the attributes of the corresponding element. As an example, the PutCondition attribute of the Put element, which can be selected as GeneralLocation, WithTidiness, or ExactLocation, is the same as the EndPosition attribute of the ManualTask element.

The Move element represents the task of a worker moving his hand in order to grasp an object or put it down. The input for this task is the distance between the worker's fingers and the object. The Get element represents how a worker will grasp an object, which will either be touching an object (e.g., pressing a button), simple grasp (e.g., grasping a small tool without the need of visual feedback), or impeded grasp (e.g., grasping a particular bolt in a particular orientation from a container of bolts). The weight of the object should also be specified when using the Get element. The Put element deals with the condition of placing an object at a designated location and can be selected as placing an object in a general location (e.g., dropping a bolt into a bin), placing an object in a predetermined location and in a predetermined orientation, or placing an object at an exact location. The Walk element represents the task of a worker walking and requires the walking distance as input. The BendAndArise element represents the task of a worker bending to pick up an object and then arising and the SitAndStand element simply represents the task of a worker sitting and standing, while other tasks might occur in between. The secondary elements have been developed to give the designer or production planner more flexibility during redesign of the operations. The designer can focus on one of the lower level motions and change its attributes to investigate the impact on the simulation results. Furthermore, in cases when only one of these manual

3 CASE STUDY

As a case study, the developed SPS template has been used to model manual activities taking place in a fabrication shop of a steel fabrication and construction service provider in Edmonton, Canada. The main base of operations of the company is a 70,000 m² facility comprising six fabrication shops and various manual tasks are performed by workers at these shops in two ten-hour shifts every day. Using micro-motion level simulation is essential for effective modeling of the construction operations at such a facility. The general sequence of operations at the shop is shown in Figure 3. In particular, the manual task of moving drilled steel plates from the drilling equipment and placing them in the designated bins is modeled as an example to illustrate the functionality of the elements in the MODAPTS.vb template. The sequence of motions consists of the worker picking up a drilled plate from the drilling station and walking a few meters to place it in a bin. The average weight of the plates is approximately 20 kilograms and the average size is 40 cm x 40 cm x 5 cm. In order to collect the required data, the task has been observed at the steel fabrication facility and the duration for the worker to perform the task has been recorded using a stopwatch. Also, for each iteration of the task, the weight of the plate that the worker handled, the distance that he walked carrying the plate, and the conditions of grasping (e.g., difficulty of grasping the plate) and placing (e.g., precision of the final location of the plate) the plate was also recorded. This data was collected for 18 instances of the task, with each cycle starting when the worker moved his hands to grasp the plate, until when he placed the plate at the designated bin.
The sequence of the manual tasks in the plate drilling workstation includes the worker collecting the plate from the drilling machine when the drilling is finished, carrying the plate to the designated bin, and placing the plate inside the bin. This whole task can be modeled using the ManualTask element. Figure 4 describes what each of the input attributes of the element represent in this manual activity.
The same task can also be created using the secondary elements. Figure 6 shows the model using the secondary elements and a description of what activity each element represents. It should be noted that the plate handling task is modeled in Figure 5 as the only task for demonstration purposes and it will be used as part of larger construction operation simulation models in construction process design.

Table 2 shows the inputs for 10 instances of the plate handling task and the result of running the simulation model. For each task, the actual time that it took the worker to perform the task at the jobsite is also shown. The MODAPTS code and duration for each task is also calculated in order to compare it to the duration reported by the simulation time. The manual MODAPTS time is calculated for each task by summing the digits (MODs) of the MODAPTS code and multiplying it by 0.129 (1 MOD = 0.129 sec). As shown in the table, the simulation duration is consistent with the MODAPTS duration calculated manually.

Figure 6 depicts the actual time versus the MODAPTS time resulting from the simulation model, visualizing the correlation between the actual time from data collection and the result of the simulation. Each point represents an iteration of the task. A correlation analysis has been performed between the actual time and the simulation time for 18 instances of the plate drilling task and a Pearson product-moment correlation coefficient of 0.96 has been calculated which indicates a very strong relationship.

![Pearson correlation coefficient = 0.96](image)

Figure 6: Correlation between actual time and MODAPTS simulation time

The results of the case study indicate that the proposed approach provides construction managers and production planners with a reliable estimate for the duration of manual tasks based on the MODAPTS system. The developed SPS template can be used to estimate the actual time of non-existing manual tasks based on MODAPTS using the correlation between the simulation time and the actual time from the jobsite. This correlation can be used as a benchmark for worker’s performance to evaluate the efficiency of the ongoing operations and implement improvements.

The developed simulation template, in its current form, can be used to improve the efficiency of manual tasks of construction operations. In future work, the authors will also study incorporating ergonomic analysis into simulation modeling using the developed template, in order to provide the designer with an initial insight into the ergonomic risks associate with the operation design. The model will be linked to motion data by using the secondary elements and automated ergonomic evaluation will be performed to evaluate each manual activity based on standard ergonomic analysis tools.

## 4 CONCLUSION

Despite the wide use of simulation modeling for analyzing the efficiency of construction operations, there is a lack of automated methods to model manual tasks involved in construction processes. As these manual tasks have a considerable impact on the productivity of the operations, having reliable estimates
of the duration of different types of manual construction activities can provide designers and production planners with more accurate production analysis results. The special purpose simulation tool developed in this study provides standard motion time data required for performing manual tasks based on the MODAPTS method inside a simulation modeling environment. One primary element and six secondary elements have been developed to model different types of manual construction activities. These elements can be used in conjunction with the elements of Simphony’s general template to model the manual motions of any construction process simulation model. This study can assist practitioners in modeling construction manual activities based on MODAPTS, without requiring prior knowledge about PMTS methods, and can assist researchers to further explore the impact of manual activities on construction operation efficiency. The correlation between simulation time and actual time can be used to evaluate the efficiency of the ongoing operations by providing a benchmark for production performance.

IMPLEMENTATION OF CONSTRUCTION INDUSTRY BEST PRACTICES INTO WORKFLOW MANAGEMENT SYSTEMS

Behrooz Golzarpoor1,2, Carl T. Haas1
1 Civil and Environmental Engineering Department, University of Waterloo, Waterloo, ON, Canada
2 bgolzarpoor@uwaterloo.ca

Abstract: Several research studies have confirmed that identification and adoption of industry best practices drive performance improvements in terms of cost, schedule, and productivity. Best practices specifications facilitate the reuse of experience within a domain. However, they typically offer abstract suggestions and recommendations that include not only explicit, but also tacit knowledge. Key approaches of adopting and promoting best practices include socialization and face to face interactions, such as meetings, workshops, and training. These approaches, however, are not easily scalable to large capital projects, to provide systematic and consistent adoption of best practices throughout different phases of a project or among different projects. An alternative solution is to transform best practices into processes implementable into workflow management systems. In this paper, well-known best practices in the domain of the construction industry and their common characteristics are investigated. A framework is then established for transforming best practices into structured processes implementable into workflow management systems. Only parts of a best practice can be transformed into a structured process. The proposed framework describes which components of a best practice are more suitable for this transformation. The result is a process with the essence of a best practice that can be embedded into and automated through workflow management systems. This approach of integrating construction industry best practices into workflow management systems, not only facilitates consistent implementation of best practices throughout the project lifecycle and within projects, but also improves conformance to those practices, with the end result of improved capital project performance.

1 INTRODUCTION

It is well established from statistical analysis of several projects that effective implementation of best practices and integration of information technologies are correlated with substantial improvements in project performance (Figure 1 & Figure 2). Research studies state that systematic implementation of best practices is one of the most important contributing factors to mega projects’ success (Chanmeka et al. 2012). A best practice might be a single procedure or method, but most usually it is a combination of several policies, rules, procedures, and methods, in a particular domain.
Well-known organizations, such as the Construction Industry Institute (CII), the Construction Owners Association of Alberta (COAA), and the Project Management Institute (PMI), develop and promote best practices pertaining to various aspects of capital project management and delivery. Table 1 presents a list of organizations that develop and promote such practices and the term they use for best practices. However, the systematic and consistent implementation of such practices throughout the lifecycle of a construction project and from project to project remains a significant challenge.

According to CII, best practices are processes or methods that provide improved results when implemented effectively, and thus, can lead to enhanced project performance. Companies implementing best practices consistently, report higher profits, increased customer satisfaction, and improved safety and productivity. Traditional approaches of adopting best practices include socialization and face-to-face interactions, such as meetings, workshops, and training, which are not easily scalable to large-scale
capital projects. An alternative solution is to transform best practices into workflow processes implementable into Electronic Product and Process Management (EPPM) systems – a type of workflow management system particularly being used for managing mega capital projects. This approach utilizes business process models and workflow engines to facilitate more consistent implementation of best practices throughout different phases of a project or among different projects.

Fundamental improvements in communication and collaboration technologies and the increased use of EPPM systems – that are process-based and workflow-driven – in managing mega capital projects provided the required infrastructure, and facilitate putting this approach into practice. Utilization of EPPM systems and workflow engines offer the advantages of consistency, accuracy, and scalability, and thus can be considered a key tool for adopting best practices in mega capital projects.

2 BACKGROUND

Mega construction projects typically involve many stakeholders from different parts of the world, with diverse organizational structures and cultures, and with distinct specialized expertise. A typical oil and gas project is comprised of a few owners, tens of general contractors, and hundreds of sub-contractors from different firms and disciplines, such as engineering, consulting, construction, and facility management; nevertheless, all striving towards the common goal of completing the project.

This level of cooperation is made possible in part by advancements in communication and collaboration systems in the domain of information technology. This includes essential communication infrastructure provided by the World Wide Web, database management systems, and real-time data exchange services. Furthermore, such multilateral accomplishments have been aided by substantial improvements in systems tailored to projects and corporations. Examples include advanced project management tools, enterprise resource planning (ERP) (Chung, Skibniewski, and Kwak 2009; Ghosh et al. 2011; O’Connor and Dodd 2000), workflow engines (Tang and Akinci 2012; Cardoso, Bostrom, and Sheth 2004), electronic document management systems (Al Qady and Kandil 2013), knowledge-based information systems (El-Gohary and El-Diraby 2010; Kang, O’Brien, and O’Connor 2012), and more specifically electronic product and process management (EPPM) systems (Shahi et al. 2014).

Electronic Product and Process Management (EPPM) Systems are the new technology trend for management of mega capital projects. Their core components are typically a combination of a workflow management system (WfMS), a document management system (DMS), and a collaboration management system. A workflow engine at the heart of the workflow management system facilitates enactment of workflow processes; a document management system supports several types of files and enables sharing and modifying various types of documents. The collaboration management system enables project delivery by collaboration among several stakeholders.

The services that EPPM systems offer encompasses planning, coordination, and management activities within the product and project lifecycle. EPPM systems store and retrieve various types of information regarding the lifecycle of a project, and can be used to mine repositories to capture hidden knowledge, and analyze the acquired knowledge for more informed decision making. This knowledge is typically represented in the form of status and progress reports, lessons learned, cost and performance analysis, etc. through dashboards. Implementation of best practices into EPPM systems involves transforming practices into workflow processes. Thus, distinguishing the differences between practice, process, and workflow is vital. Before establishing a framework for practice to process transformation, this paper discusses these differences.

2.1 Process vs. Practice

A process is a series of well-defined inter-related steps which delivers repeatable, predictable results. Key features of a process include 1) predictable and definable inputs, 2) linear, logical sequence, 3) clearly definable set of activities, and 4) predictable, desired outcome (Lee 2005). An activity is typically considered as a major unit of work comprising more detailed steps called sub-activities. Whenever an activity is considered as the smallest unit of work, it is called a task. A process is typically used in routine
circumstances in which repeatable, predictable results are required. Each necessary step is codified in
detail and there is no spontaneous decision making involved.

A process can be performed manually or can be automated through an information system. For an
automated process, the inputs, outputs, and steps involved should be clearly defined; and to implement a
process in a workflow management system it should be defined in a standard process modeling
language. Typically, automated processes include both automated and manual activities. Request for
Information (RFI) and Change Request (CR) processes are examples of such processes. Processes in
which all of their activities are automated are called fully automated processes, such as the buying
processes in Amazon or eBay.

A practice, on the other hand, is a frequently repeated act, habit, or custom that needs a recognized level
of skill to be performed. It is an un-codified knowledge that results from human experience and
improvisation (Lee 2005). While a practice is still a series of steps, the steps are loosely defined, and the
details of how to perform each step is left to the experts who perform them based on their knowledge,
experience, skill, and judgment. Practices, thus, are more suitable for dealing with uncertain situations
with uncommon or unique results (“IT Catalysts” 2013). Table 2 summarizes key differentiators of
processes and practices.

### 2.2 Process Modeling Tools and Standards

To implement a process in a workflow management system, it should be defined as a process model
using a standard process modeling notation. Several process modeling languages and standards have
been developed for modeling business processes. Process modeling can be performed either by
representing a process using graphical notations or by representing the semantics of the process using
modeling languages. Using graphical notations is more convenient for communication, reengineering,
and improvement of processes. Recent modeling tools such as XPDL and BPMN support both a graphical
notation and a modeling language. A classification of the most popular modeling tools and standards is
presented in Table 3.

<table>

</tr>
</tbody>
</table>

Business Process Modeling and Notation (BPMN) is the most promising process modeling standard. It
has been designed by the Object Management Group (OMG) with the aim of identifying best practices of
existing modeling tools and combining them into a widely accepted, easy to use language. The same
process model in BPMN may encompass different levels of details, each useful for a particular group of
stakeholders, from business administration people to business analysts and software developers. BPMN defines three levels of process modeling conformance. ‘Descriptive level’, useful in high-level modeling, only includes visible elements and attributes; ‘analytic level’ includes descriptive and a minimal subset of supporting process attributes; and ‘common executable’ offers the elements required for execution of process models. In this paper we use BPMN 2.0 notation for representing sample process models.

2.3 Workflow vs. Process

Workflow and process are similar terms and, in certain situations, might be used interchangeably. However, workflow implies a more specific concept than process. While any group of well-defined interconnected steps with an expected result can be called a process, in a workflow the focus is on the piece of work or information that is being passed through initiation to completion. Therefore, a workflow associated with a particular process might not be involved with all the details that are important for completion of the process, such as recording to a database or calling a web-service, but is more dedicated to the flow of work through all the steps. A workflow thus can be defined as an outline or blueprint of a process. A summary of process and workflow differences are presented in Table 4.

</tr>
</tbody>
</table>

2.4 Workflow Management Systems (WFMS)

Workflow management and workflow specification are concepts tightly related to business process management and process modelling; however, their approach is rather different. Workflow management involves the automation of processes which are comprised of human and machine-based activities (Hollingsworth 1995) and focuses on the flow of information or work among participants. A workflow specification is an abstraction of a process that might not be concerned with all the details of a task, but in any case it is concerned with the inter-relationship, the inputs and outputs, and the externally visible behavior of tasks (Krishnakumar and Sheth 1995).

Automation of business processes partly relies on the coding of software developers for embedding business processes into information systems. Originally, any modification to the process logic, the sequence of activities, and the execution constraints of a process was affecting the programming code and required software developer's attention. The introduction of object-oriented programming concepts facilitated the separation of process logic modifications from the programming code, and led to the emergence of workflow driven systems. In a workflow management system, features of an application, or tasks of a process, are defined as steps in a workflow, and therefore, the behavior of the system can be modified through changing the steps without any modification to the programming code. Workflow technology, thus, provides separation of business process logic from IT operational support (Hollingsworth 1995).
A workflow engine is responsible for managing and enacting tasks within workflow specifications according to their execution constraints and organizational predefined rules. The execution constraints of a process are typically defined as properties or attributes of tasks in the workflow specification. The Workflow Reference Model (Hollingsworth 1995), developed by the Workflow Management Coalition (WfMC) is a key reference for workflow management systems and their interfaces. Workflow management systems facilitate more convenient design and implementation of processes with less involvement in programming details.

3 PROPOSED FRAMEWORKS

A best practice is a guideline to an improved way of organizing and performing a work. The steps offered in a best practice does not necessarily include well-defined sequence and details, and thus it typically relies on the skills and experience of the actor to fill the gaps, whereas in a structured process the sequence of activities and their execution constraints are completely defined. This paper proposes two frameworks for transformation of best practices into structured processes suitable for implementation via workflow management systems. The frameworks explain how the inherent knowledge of a best practice can be combined with the key characteristics of a structured process, such as well-defined steps, sequence, and execution constraints. In addition, the frameworks clarify how the components of a best practice can be associated with elements of a structured process.

3.1 A Conceptual Framework

A practice as a form of knowledge includes explicit, tacit, and implicit types of knowledge (Anand and Singh 2011; Faust 2007). The explicit is the category of knowledge that can easily be identified, codified, stored, and retrieved, and thus, its implementation and automation is relatively straightforward. Interrelated components of a best practice comprising explicit knowledge can be defined as a high level organizational process. Tacit knowledge is inherent with the skills and experience of people, and is hard to capture and codify, and thus, cannot easily be automated. Tacit knowledge or judgmental steps in a practice can be embedded into manual human-tasks of a process. A fraction of tacit knowledge, that is hard but possible to capture and make explicit, is called implicit knowledge. Implicit knowledge is associated with how a process is defined and how it is implemented. It affects the way a process behaves.

<table>
<thead>
<tr>
<th>Table 5: Types of Knowledge in a Practice and their Association with a Process</th>
</tr>
</thead>
<tbody>
<tr>
<td>Practice Components</td>
</tr>
<tr>
<td>Explicit Knowledge</td>
</tr>
<tr>
<td>Tacit Knowledge</td>
</tr>
<tr>
<td>Implicit Knowledge</td>
</tr>
</tbody>
</table>

Accordingly, we can associate elements of a process with components of a practice. The structure of the process – which defines what is performed – can be defined based on the explicit knowledge present in the practice. The human-tasks of the process – which is related to who has the capability of performing the task – are associated with the tacit knowledge of the practice. The behavior of the process – which is consistent with how the process is defined – signifies the implicit knowledge of the practice (Table 5).

3.2 A Practical Framework

The practical framework for transformation of a best practice into a process involves two main steps: (1) identify the related components of a best practice and define them as one or more high-level organizational processes, and (2) transform the organizational processes into well-defined structured processes suitable for implementation via workflow management systems. These steps are presented in Figure 3 and are discussed with examples in the following sections.
3.2.1 Practice to Organizational Process

Studying the contents of several known construction industry best practices, such as materials management, lessons learned, zero accidents techniques, and change management, confirms that construction industry best practices either include organizational processes or the related components can be defined as organizational processes. For instance, CII best practice for change management offers five principles, each of which has been defined as an organizational process. Figure 4 illustrates the five principles for change management offered by CII change management best practice (Project Change Management - Special Publication 43-1 1994).

An organizational process is a high level process that includes the conceptual steps of performing work, but does not include all the details of the steps, and the execution constraints that are necessary for implementation of the process. For instance, Table 6 presents an organizational process offered by CII change management best practice for the Evaluate Change principle.
Table 6: Evaluate Change Process (Project Change Management - Special Publication 43-1 1994)

3.1 Determine the time frame for change decision.
   3.1.1 Immediate or high priority decision required? If not, process through routine measures.
   3.1.2 Determine funding source for handling interim approval of a high priority change decision.

3.2 Collect data needed.
   3.2.1 Conduct a thorough analysis on cost, schedule, quality, safety, resources, and other items.
   Evaluate on both direct and associated indirect costs.
   3.2.2 Propose and evaluate alternate solutions and options.

3.3 Identify impacts.
   3.3.1 Finalize impact on cost and schedule.
   3.3.1.1 Primary impacts.
   3.3.1.2 Secondary (indirect/ripple/cumulative) impacts.
   3.3.2 Route to all involved disciplines/functions/organizations for impact.

3.4 Determine final funding source or “who pays” (cost reimbursable, design development, lump sum, and others). If applicable, confirm the interim funding source decision.

3.5 Re-evaluate project feasibility with proposed change included.
   3.5.1 If change makes project unfeasible, determine whether it is a required or an elective change.

3.6 Authorize change and send out notice to all affected organizations/disciplines.

Organizational processes, however, cannot directly be implemented into workflow management systems. They lack the required structure and details. As such, they should be transformed into structured workflow processes.

3.2.2 Organizational to Structured Process

In workflow management systems the flow of work or information among participants is a key characteristic. Thus, to transform a best practice to a structured process, implementable into workflow management systems, the steps of the associated process need to be defined as the flow of work or information among participants. Thus, the roles and responsibilities of participants should first be determined. The Responsibility Assignment Matrix (RACI chart) is a useful tool for this purpose. Then, the flow of work among participants should be identified. Finally steps of the high level process should be defined as activities that are performed by participants along with the flow of work.

In addition, the workflow should be defined as a structured process. A process in which the sequence of activities and their execution constraints are completely defined is called as structured process. To clarify, Figure 5 represents the main activities of a change request (CR) workflow and their sequence. A CR workflow is a formal process for authorizing any change in the scope, cost, or schedule of the project. Figure 6 is a more structured representation of the same workflow.

![Figure 5: Main Steps of a Change Request (CR) Process](image-url)
Formal process modeling tools and techniques, such as Unified Modeling Language (UML), Business Process Execution Language (BPEL), or Business Process Modeling and Notation (BPMN), are typically being used to model a structured process. Such standard notations are required for the automation of structured processes via information systems. Figure 7 presents a change request workflow in BPMN notation.

3.3 Summary

In this paper well-known best practices in the domain of the construction industry are explored, and their common characteristics and components are examined. Further, the differences between practices, processes, and workflows are investigated. Then two frameworks – a conceptual and a practical – are proposed for transformation of best practices into structured processes implementable into workflow management systems. The proposed frameworks suggest that specific components of best practices can more easily be transformed into structured processes. The result is a structured process with the essence of a best practice that can be automated through workflow management systems. Implementation of best practices via EPPM systems offers the advantages of consistency, accuracy, and scalability, and thus can be considered a key approach of adopting best practices in large scale construction projects.

IDENTIFYING THE SOURCES OF COMPLEXITY IN THE URBAN TRAIN PROJECT IN PUERTO RICO

Antonio Gonzalez Quevedo¹, and Carla Lopez del Puerto²,³
¹ Professor, Department of Civil Engineering and Surveying, University of Puerto Rico at Mayaguez, Puerto Rico
² Associate Professor, Department of Civil Engineering and Surveying, University of Puerto Rico at Mayaguez, Puerto Rico
³ carla.lopezdelpuerto@upr.edu

Abstract: The metropolitan area of San Juan in the Commonwealth of Puerto Rico has the highest concentration of vehicles per mile of paved road in the world. In order to improve the public transit system and decrease automobile dependency, the Commonwealth of Puerto Rico decided to embark on a major infrastructure project, which consisted on the design and construction of a heavy rail train to serve the Metropolitan Area of San Juan. The first phase of the project consisted of a 10.69 mile segment with 16 stations. This paper uses a five dimensional project management (5DPM) model and develops a complexity map to identify the sources of complexity in the project. The 5DPM model includes the following dimensions: cost, schedule, technical, context and finance. The results indicate that the major source of complexity in this project was the technical dimension which was complex due to variable site conditions and the owner’s the lack of experience managing a project of this magnitude. Due to its scope and significance, the Urban Train project (Tren Urbano) provided an opportunity to train a group of young professionals who would later assume leadership positions in public projects in the Commonwealth of Puerto Rico. A structured professional development program was created in a partnership between the University of Puerto Rico (UPR) and the Massachusetts Institute of Technology (MIT). The professional development program consisted of 6 key elements: (1) MIT short course in public transportation in Boston, (2) UPR Winter short course on the Urban Train and Transportation in Puerto Rico, (3) Student research project, (4) Professional Practicum (summer work internship) (5) Site visit to an operating transit system, and (6) Possible employment opportunities with contractor or consultant. The paper concludes that including a professional development component in the project benefited the students and faculty who were involved. It also concludes that the professional development program contributed to managing complexity in the technical dimension for future projects and in the context dimension for this project by increasing public support to the project through marketing and dissemination efforts. This paper contributes to the body of knowledge by increasing our understanding on how to manage complexity in large transit projects and how to develop and implement a professional development program that contributes to project success.

1 INTRODUCTION

Public transportation systems are necessary in metropolitan areas to keep the traveling public moving while addressing traffic congestion (Bhattacharjee, S. and Goetz A. 2012). The metropolitan area of San Juan in the Commonwealth of Puerto Rico has the highest concentration of vehicles per mile of paved road.
road in the world. In order to improve the public transit system and decrease automobile dependency, the Commonwealth of Puerto Rico decided to embark on a major infrastructure project, which consisted on the design and construction of a heavy rail train to serve the Metropolitan Area of San Juan (Fosbrook and Gonzalez 1997). The government of Puerto Rico did not have any experience in developing an urban rail system, therefore, they decided to establish a professional development program aimed at creating a group of professionals that could embark in future transportation projects. What better teaching tool that learning by participating in the single largest infrastructure project Puerto Rico had experienced in its recent history? Using this extraordinary opportunity to developed future professionals in infrastructure development showed forward thinking from the part of the government. Many of the students that participated in this project became involved professionally with the planning, design, construction and operation of the Urban Train. The professionals that were involved in the program also developed a special understanding of the project, since they had to interact with the students as mentors. This interaction proved effective during the project. As an example, the design of one of the stations was changed due to the interaction with the students.

Undergraduate and graduate students and professors from engineering, architecture and planning from two campuses of the University of Puerto Rico, namely, Mayaguez and Rio Piedras, as well as from the Massachusetts Institute of Technology (MIT) participated in the program. (González-Quevedo, et al. 1999, González-Quevedo, et al. 2000). The participation of MIT was justified because the metropolitan area of Boston and this particular university is known for its strong involvement in the planning, design and operation of urban rail systems. The interaction among the students, professors, and other professionals from both universities and the public and private sectors proved to be very beneficial for all involved and especially for the project.

1.1 Five-Dimensional Project Management

Traditional project management involves managing three dimensions to successfully complete a construction project. These three dimensions are cost, schedule and technical (also termed quality). Cost is quantifying the scope of work in monetary terms. Schedule are the calendar-driven aspects of the project. Technical are the typical engineering requirements. The traditional approach serves well for routine projects, however, as projects become more complex, optimizing the three dimensions is not enough to successfully complete complex construction projects. The difference between routine projects and complex projects revolves around the level of interaction and uncertainty between aspects of the project that are outside the project manager’s direct control (Gransberg et al. 2013). In order to manage complex projects effectively, the project team must manage five dimensions: the three previously mentioned plus financing and context. Financing is the availability of funding and knowing how the project is going to be financed. Context are the political issues, procurement constraints, environmental requirements, public opinion, acquiring right-of-way, agency preferences/biases, and other similar issues (Shane et al. 2013).

The objective of this paper is to present a case study of a complex transportation project in the Commonwealth of Puerto Rico. The five-dimensional project management model was used to identify sources of complexity and rank each source on a relative basis to create a complexity footprint of the project.

2 METHODOLOGY

This study replicated the case study project protocol methodology that was developed for (the second Strategic Highway Research Program (SHRP 2) research project (Shane et al. 2013). Case studies can be used to gain insight on in-depth personal perspectives, behaviors, meanings, and experiences by obtaining details from a number of relevant or involved sources related to a project (Taylor et al. 2009; Yin 2002). The methodology involved using multiple sources of information including public records, project websites and media coverage, journal articles and interviewing the Secretary of the Puerto Rico Department of Transportation (DTOP). Multiple sources of information were used to cross-check that the information found in the data collection was accurate.
The structured interview questionnaire that was developed for the SHRP2 project was administered during the face-to-face interview with the Secretary of the DTOP. Per the U.S. GAO method, ample time was given to ensure that the interviewee understood each question and that the interviewer understood the responses (U.S. GAO 1991). The interview consisted of structured questions but the interviewee was able to deviate from the questions which allowed the interviewers to obtain valuable information that they had not originally contemplated. The interview also included the completion of complexity maps for the project. Complexity maps are a visual tool to manage complexity by creating a footprint. The first step to create a complexity map is to identify the sources of complexity in each of the five dimension (cost, schedule, technical, context and finance). A list of potential sources of complexity was provided to the interviewee. The interviewee was given the opportunity to select from the list provided as well as add any other sources based on his experience.

The second step is to rank the five dimensions in order of complexity where 5 is the most complex dimension and 1 is the least complex dimension. The third step is to assign a value to each dimension. A routine project with normal complexity has a value of 50. If the interviewee believes that the project is more complex than a routine project, a value higher than 50 is assigned. If the interviewee believes that the project is less complex than a routine project, a value lower than 50 is assigned. No two dimensions can be assigned the same value. The final step is to plot the data on a radar diagram and calculate the area of the pentagon (Gransberg et al. 2013). After the interview was completed, the authors discussed in-depth the data collected on the project (literature and interview) to gain an understanding and document the reasons for project success and the lessons learned.

3 RESULTS

3.1 Project Description

The Tren Urbano project is a heavy rail transit system in the San Juan Metropolitan Area in the Commonwealth of Puerto Rico. The heavy rail transit system connects three municipalities in the metropolitan area of San Juan: Bayamón, Guaynabo and San Juan. The scope includes 10.69 miles of heavy rail, 16 transit stations, and a tunnel. The project construction phase was divided into seven Design-Build contracts, one of them being a large Design-Build-Operate contract which included design, construction, power, communications, train control, signaling and the supply of cars, in addition to operation of the transit system for 5 years with a possible extensions. (Fulcher et al. 2004).

3.2 Complexity Map

The results of the complexity map exercise, as shown in Table 1, were used to determine the complexity footprint of the Urban Train. The results indicate that all five dimensions were significantly more complex when compared with the agency’s routine projects. The complexity footprint (Figure 1) shows that the technical dimension was the most complex. Next each dimension will be discussed separately to allow for identification of the sources of complexity by dimension.

</tbody>
</table>
3.3 Cost Dimension

The original cost estimate was $1.2 billion. Changes in the scope of work and different site conditions increased the cost to $2.25 billion (Railway Gazette 2005).

3.4 Schedule Dimension

The original schedule indicated that the project would be completed in 44 months following the Notice-to-Proceed (NTP). The contract scope had to be increased several times due to additional works that were required to upgrade the aging utilities and to provide local community improvements. The changes in the scope resulted in time extensions. It took almost six years from NTP to project completion (Fulcher et al. 2004).

3.5 Technical Dimension

The technical dimension was ranked as the most complex dimension due to the site conditions where the project was built. The owner recognized during the planning state that the following issues will make the project more complex than routine projects:

- Densely populated historic area
- Variable site conditions
- Uncharted utilities and building foundations
- High water table (Fulcher et al. 2004)

The project was divided into 7 contracts to minimize the risk of a company defaulting and to allow multiple companies to participate in project construction phase. The main contract was a Design-Build-Operate contract, the remaining six contracts were design-build. Having multiple contracts allowed the agency to acquire the right-of-way (ROW) for each segment separately which was necessary to guarantee that the ROW of the first segment was completed prior to the 2000 elections. This reduced the likelihood that the project would be cancelled if the opposing party won the elections.

The owner had no experience designing and building a major transit project which greatly contributed to the complexity of the project. In order to address this weakness for future projects a professional development program was created. Since the lack of skilled project managers spans across the technical
and context dimensions, details about the professional development program will be discussed in the context dimension.

3.6 Context Dimension

The project spanned several state government election periods. During the 1993 and 1996 election periods, the project had bipartisan support. This was not the case during the 2000 elections where the opposition party was against the project due to the cost increase, project delays and concerns about the contractor’s ability to successfully complete the project. In order to keep the project moving forward, a significant effort had to be made to counteract the negative press.

The construction industry in Puerto Rico during the late 1990’s and early 2000’s was booming which resulted in a shortage of skilled labor for the project. In addition to the shortage of skilled labor, there was a shortage of trained young professionals who could assume leadership positions. In order to address this challenge, a structured professional development program was created in a partnership between the University of Puerto Rico (UPR) and the Massachusetts Institute of Technology (MIT). The UPR/MIT/Urban Train Professional Development Program (González-Quevedo et al. 1999, González-Quevedo et al. 2000) was an integral part of the Urban Train Project due to the fact that the government of Puerto Rico realized it needed to develop a group of professionals that could plan, design, construct and operate the Urban Train in its present and future conceptions. The program was managed from the government’s side by the General Management, Architectural, and Engineering Consultants (GMAEC). The University of Puerto Rico through its Civil Infrastructure Research Center (CIRC) managed the project from the university’s perspective.

The professional development program consisted of five major components: 1) an educational experience that lasted a week at MIT during the summer; 2) an educational experience that lasted a week in Puerto Rico early in January; 3) a visit to a city with a fully function heavy-rail public transportation system (e.g., Medellin, Caracas, Bilbao, New York City and Miami); 4) a research experience for the students in a project related to the Urban Train, with the participation of professionals involved in the project as advisors and professors as advisors; and 5) a summer internship with the GMAEC, the government, one of the contractors or designers. The University of Puerto Rico, through its CIRC, kept a record of the accomplishments of the program by measuring the number of students who were involved the professional development program and their career growth. Many of them obtained jobs related to transportation infrastructure development and some of them proceeded to further their studies by obtaining advanced degrees.

3.7 Finance Dimension

The Federal Transit Administration in 1993 included the Tren Urbano in its list of Turnkey Demonstration Projects. Through this arrangement the government of Puerto Rico provided 57% of the financing for the project, while the Federal Government provided 18% through its New Start Funds and 25% from other federal transportation funds. (Scheinberg 2000)

4 CONCLUSION

The five-dimensional project management model was used to develop complexity maps to identify the sources of complexity in the Tren Urbano project. The 5DPM model included the following dimensions: cost, schedule, technical, context and finance. The results indicate that the major source of complexity in the project was the technical dimension due to the site conditions where the project was built and due to the fact that the owner had no experience designing and building a project of this magnitude in the Commonwealth of Puerto Rico. Realizing that a professional development program was needed to address the lack of experience in designing and building complex projects by the owner and transportation professionals in Puerto Rico was a wise decision.

Future extensions of the Urban Train as well as other major rail transportation project will benefit from the creation of a cadre of professionals much better prepared to handle such projects. This program was very
successful and the Commonwealth of Puerto Rico still benefits from having skilled project managers, who were part of the program, managing current projects. The professional development program contributed to managing complexity in the context dimension by increasing public support for the project through marketing and dissemination efforts. This paper contributes to the body of knowledge by increasing the understanding of project managers, transportation professional and academia on how to manage complexity in large transit projects and develop and implement a professional development program that contributes to project success.

The cost and schedule dimensions were ranked the least complex among the five dimensions of complex project management. However, it is important to note that the project experienced significant cost overruns and schedule delays. The main limitation of this study is that the results may not be applicable to other similar projects or other locations.

Abstract: Site layout planning and logistics is an important part of effective management of construction projects. A site layout defines where the optimum location for objects such as materials, temporary facilities and equipment on a given construction site are. When properly planned, site layout can improve efficiency, cut down on lost time, and ensure occupational health and safety. Site layout planning includes the three steps of 1) identifying the different objects required on site; 2) determining the relationship between the objects; and 3) optimizing the location of objects based on the defined relationships among them. Previous site layout studies have mainly focused on the development of optimization methods, often without giving sufficient attention to the first two steps. The objective of this study is to determine whether the construction site objects and the relationship between them can be classified using generic typologies, in an effort to standardize object and relationship definitions. The study was conducted using nine (9) case studies of construction sites in Alberta, Canada. Observations on the existing objects and their specific location on the site were recorded. Interviews with the site managers were conducted to identify the “reason” behind the selected location for the objects, and specifically, to define their spatial relationships with other objects on the site. This study found eight (8) generic types that the objects from these case studies can be classified into. It further found four (4) generic spatial relationships between objects. These typologies can be used in the development of future models for site layout planning and other related areas of construction management.

1 INTRODUCTION

Site layout planning and logistics is an important part of effective management of construction projects. A site layout defines where the optimum location for objects such as materials, temporary facilities and equipment on a given construction site are. When properly planned, site layout can improve efficiency, cut down on lost time, and ensure occupational health and safety. Site layout planning includes the three steps of 1) identifying the different objects required on site; 2) determining the relationship between the objects; and 3) optimizing the location of objects based on the defined relationships among them. Previous site layout studies have mainly focused on the development of optimization methods, often without giving sufficient attention to the first two steps. The objective of this study is to determine whether the construction site objects and the relationship between them can be classified using generic typologies, in an effort to standardize object and relationship definitions. The study was conducted using nine (9) case studies of construction sites in Alberta, Canada. Observations on the existing objects and their specific location on the site were recorded. Interviews with the site managers were conducted to identify the “reason” behind the selected location for the objects, and specifically, to define their spatial relationships with other objects on the site. This study found eight (8) generic types that the objects from these case studies can be classified into. It further found four (4) generic spatial relationships between objects. These typologies can be used in the development of future models for site layout planning and other related areas of construction management.
objects. These typologies can be used in the development of future models for site layout planning and other related areas of construction management.

2 METHODOLOGY

The case studies were conducted through the following steps that were applied to all nine (9) site visits invariably.

(1) Site Visit:
Construction sites were visited and walked about with a site expert working on the project (Project Manager, Site Superintendent, or Civil Engineers of Record). During the visit, a list of objects and site space usage on the site was created based on the observations. The specific locations of the observed site objects were marked on the Site-Plot provided by the site expert. Site managers and other site personnel were inquired on the reasoning/logic for specific location of objects on the site. Multiple pictures were taken to accompany notes for the creation of actual site plan.

(2) Developing Actual Site Plan:
After each site visit, the photos taken from the site were cross-referenced with the notes and the marked site plot to develop an actual and precise plan of the site. The actual site plans provide visual representations of the layout of the site for that particular period of time.

(3) Object and Relationships Cataloguing:
As the list of objects and space usage on the site was reviewed, categories of objects were naturally emerged (e.g. equipment, work area). Objects and site space usage were categorized into groups at this point. Similarly, categories of spatial relationships emerged by reviewing the relationship catalogue. Another interesting information extracted from the relationships between pairs of objects were overlap between the reasoning/logic provided by the site expert on why an object was located in a specific area e.g. practicality, convenience, specifications or regulations. Additionally, a qualitative weight (as will be discussed in section 6) was identified for each relationship that expressed how important each relationship was.

(4) Matrix Production & Pair-Wise Comparison:
Using the object catalogue for a site, an object matrix was created and populated with relationships identified between pairs of objects. In a matrix prepared for a site, it is possible to see all relationships between all objects on one particular site. Relationship information indicated in the matrix included the types of relationships, the logic for the relationship, and the qualitative weights identified for the relationships.

(5) Re-visiting Site Plan:
After the object relation matrices were created, the generated site layout was revisited to evaluate its accuracy. Any inconsistencies found between the object relations matrix and the site layout helped to expose a potential error. This error could either be the result of poor site planning, or the result of an inaccuracy in recording site information. Identifying inconsistencies between the site layout and the matrix actually helped in identifying a number of poor choices in assigning locations to the objects on the site.

3 SITE LAYOUT CASE STUDIES

A total of nine (9) construction sites from four (4) different construction companies were visited for this project. The construction companies are referred to as company A through D. The sites varied in size, project type, congestion level, and phase of construction. Table 1 summarized the characteristics of the studied sites. Categories of size scale and congestion scale of the construction sites were defined based on the definitions provided by the site experts as shown in Tables 2 and 3, respectively. Figure 2 depicts some examples of various site size and congestion scales.

4 OBJECT TYPOLOGIES

As mentioned before, as object catalogue for each site was generated, categories of objects emerged based on their general purpose. Eventually, from the objects identified in these case studies eight distinct types of objects were emerged. It should be noted that in the context of this study, an object need not be a physical entity, but might instead be a classification of an area that serves a specific function (e.g. work area). The following are the object types identified in this study:

(1) Site Objects
These objects, as the name suggests, exist on the site, and eliminate available area otherwise usable for site lay-down. These could include trees, traffic thoroughfares, or even portions of the completed project. Site objects create are considered as obstructions in site layout, and should be identified before the mobilization phase, as the may lead to congestion issues further along in the project schedule if ignored.

(2) On-site Facilities
These objects (e.g. office trailers, wash-cars) provide service to construction activities on the site. Facilities are usually fixed, if not very difficult to move. Therefore their location should be given a good amount of forethought. Where to put a facility should depend on its purpose, and the proximity of those who use it to their respective activities. For example, an office trailer may be better suited towards the site parking lot, while the lunch-car might be better suited closer to current work-areas.

(3) Work Areas
These objects are non-physical areas in which a designated work task is being performed. These could include formwork construction areas, concrete pours, or cladding application areas. Actual project progress is happening within these areas, and as such an effort should be made to eliminate possible obstructions within these areas. Simple rules like “only keeping relevant material within a work area” and “keeping work areas close to tradesman related facilities” can go a long way in helping project efficiency.

(4) Paths and Moving Corridors
These objects are non-physical areas designated for use by either mobile equipment, or the transportation of objects. These go all the way from on-site roads on larger sites to hallways within smaller interior sites. The main goal within any operational corridor is to preserve open space. Doing so will result in more efficiency for mobile equipment, and will improve general site safety.

(5) Construction Equipment
Regardless of their size (e.g. pick-up trucks, or full sized crawler-crane)s these objects are grouped as construction equipment. They require the use of operational corridors in order to safely move, and often have their own “safe work” radii. These radii are typically due to either a minimum turn distance, or a rotationary swing radius.
(6) Materials – Laydown/staging areas
On-site materials can be considered the “meat and potatoes” of any given construction site. These are the materials that will be eventually added to the final product and become a part of the structure under construction. Materials are most aptly placed close to their respective work areas (staging areas), but may be placed elsewhere if they are not needed at the time being (laydown area).

(7) Support Objects
These objects are the tools and equipment that are needed to get the construction project done. They may cover a variety of objects such as power tools, heating gas tanks, utility lines, formwork, or anything else that is required in order for construction tasks to be completed. Support objects should never be stored too far away from their respective activities. Doing otherwise could result in unnecessary unproductive time causing workers have to walk back and forth multiple times throughout the day.

(8) Entrances / Exits
These refer to physical or non-physical points along the site boundary limits whereby materials, vehicles, and/or personnel may enter or leave the site. The amount and location of these egress points depends on a multitude of factors. These range from the size of site to the current phase of construction.

5 OBJECT RELATIONSHIP TYPOLOGIES

Different objects on a construction site will inherently have different spatial relationships with one another. The following types of spatial relationship between objects were identified between in this study:

(1) Linear Distance Relationships
These relationships specify that objects be either as close to, or as far away from each other as possible. There is no specified minimum or maximum separation between objects, but either object proximity, or the lack thereof is preferred. For example, it is preferred that portable washrooms be as close to work-areas as possible, but there is no requirement that bounds the washrooms to be within certain distance of a work area.

Figure 2: Linear Distance Relationship

(2) Binary Distance Relationships
These relationships pertain to object relations that are invalid either inside a minimum allowable distance, or outside a maximum allowable distance. These relationships are most relevant in cases of OH&S regulations, or in cases of fixed utility lengths. For example, if only 20m of power cords are available on site, a power tool could be no more than 20m away from the nearest substation and/or generator. Any further and the power tool would cease to work.

Figure 3: Binary Distance Relationship
(3) Containment Relationships
These relationships cover objects that must be either inside of, or outside of other objects found on site. Once again, these relationships pertain most to OH&S regulations, and most typically involve one of the objects in relationship is the work area or storage area for the other object in the relationship. A simple example of this relationship type is the necessity for a fire extinguisher to be found within all relevant work areas. To not satisfy this relationship would be against Alberta OH&S standards, and could result in fines.

![Containment Relationship Diagram](image)

Figure 4: Containment Relationship

(4) Adjacency Relationships
These relationships involve objects that are required to be directly next to the object they are interacting with. These relationships often satisfy some form of functionality between the two objects, and not satisfying them could result in a loss of functionality. An example would be a concrete pump to be adjacent to the pour area. Simply put, if the concrete pump is not next to the pour area, the pour wouldn’t be happening.

![Adjacency Relationship Diagram](image)

Figure 5: Adjacency Relationship

6 QUALITATIVE WEIGHTS FOR RELATIONSHIP

When reviewing the site expert explanations they provided for the spatial relationships they provided for pairs of objects, it was noticed that besides the spatial relationships, they also indicated two other pieces of information; the first one related to the reasoning for the indicated spatial relationship, and the second one their relative importance. For example they indicated the washroom should be close to work areas to improved functionality on the site. In this example, the functionality was the reasoning, and should be was their perceived level of importance. After compiling the reasoning for all relationships provided between pairs of objects in this study, it was noticed that they can be distilled in the nine (9) categories: Functionality, Safety, Specification/Regulations, Barrier, Rear-end swing, Efficiency, Obstruction, Convenience and Interruption. On the other hand, it was noticed that four (4) levels of a relative importance are commonly expressed between different relationships as follow: “Has to be”, “Must be”, “Should be” and “Can be”. These expressed levels of importance can be thought of as qualitative weights for the relationships. An interesting observation was that each level of importance was closely associated with a number of six identified reasoning/logic categories mentioned above. Below is the detailed
explanation on the meaning behind the qualitative weights, and the reasoning commonly associated with them.

(1) Has to Be
This is the strongest level used in expressing the importance of spatial relationship between a pair of objects. If not satisfied, it would either result in a halt in construction, or would compromise safety. The following are reasons that were closely tied to the "has to be" relationships.

• **Functionality**: The use of one object is required for the operation of another. For example, a gas powered heater will not function without a gas source; therefore it has to be close to a propane tank within the length of a standard gas line.

• **Safety**: Governments and contractors alike are responsible to adhere to the Occupational Health and Safety Standards that dictate certain objects relationships. These relationships have to be satisfied under the Professional Engineering code of conduct (e.g. APEGA in Alberta). Not doing so would be both unlawful and irresponsible.

• **Specifications**: Certain objects and work areas carry a list of specifications that need to be adhered to at all times. Typically these specifications have to deal with regulations of the professional associations or recommended usage of the equipment. Not adhering to these specifications are also against Professional Engineering Code of Conduct and cannot be tolerated on the site.

(2) Must Be
This qualitative weight expresses the second highest level of importance for spatial relationships between objects. These are relations that if not satisfied, many not cause a halt to the construction altogether, but would result in large and unnecessary delays. The reasons could include:

• **Barrier**: Certain objects, when misplaced, can be a barrier to other operations on the site. A barrier, as defined here, is what would require large mobile equipment and/or a large time investment in order to remediate. A typical example is misplacing a large facility inside an excavation zone. The excavation activity cannot proceed as planned until the facility is removed by large mobile equipment.

• **Rear-end swing**: Certain large pieces of mobile equipment, such as excavators carry with them a rear end swing radius. This is the radius that projects from the tail of the equipment and should be free when the equipment is rotating about itself. Keeping objects outside this radius is a must, otherwise it can create delays in the operations of the equipment.

(3) Should Be
*Should be* weights are used for relationships that are intuitive with everyday operations, yet would result in considerable delays if they are not satisfied. The following are typical reasons:

• **Efficiency**: These are relations that if not satisfied will slow down the daily operations on the site and possibly cause delays. Efficiency-related relationships are those crucial to either the worker’s daily operations, or the function of the object. An example of this would be to ensure that a worker has all of his or her required raw materials in his or her designated work area.

• **Obstruction**: Certain objects, when misplaced, can be obstructive to the objects working around them. Obstructive typically cause a delay in construction, but would not require as large of an effort as barriers to remediate. For example, a garbage dumpster misplaced inside of an operational corridor can be moved out of the way with small mobile equipment, and without much hassle.

(4) Can Be
The lowest weight expressed for an object relationship is the *Can Be* category. These are relations that exist to make the overall operations on the site smooth. The following are typical reasons:

• **Convenience**: This reasoning is used when it is preferred to locate an object in a certain location as opposed to another to add to worker’s convenience. Similar to efficiency reason, not satisfying a worker’s convenience can slow down their daily operations. Unlike efficiency-related
relationships, convenience relationships are secondary to either the worker’s daily operations, or the function of the object. For example placing the tool crib near a particular work area. It would be nice for the worker to not have to walk long to the tool crib, but not very crucial as they would only have to cover the distance 2 or 3 times in a work day.

- **Interruption:** Misplaced objects can be obstructive to the operations of the site. Interruptions cause a delay in construction, but can be easily, and relatively quickly, remediated. An example is removing a misplaced truck from the operational corridor.

7 QUANTIFYING QUANTITATIVE WEIGHTS

In order to enable the use of weights in optimization models, they need to be quantified. This section proposes an approach for the quantification of the weights. Quantification of weights can start by assigning a default score to the four weights for example: has to be (100); must be (75); should be (50); and can be (25).

In the next step, Pairwise comparisons are performed on the matrix of the identified objects for a specific project. Pairwise comparisons are a series of analytical techniques borrowed from the field of Psychometrics. Traditionally, Pairwise comparisons are used to solve otherwise insolvable qualitative problems with iterative quantitative results. The comparison method used in this study is a simplified version of the Thurstone Method (Thurstone, 1297). The comparison begins by going row by row in the Object Relations Matrix to identify and compare relationships that have similar quantitative weights. For example in Figure 6, there are two relations related to Object 1 (one with Object 2 and one with Object 4) with the “should be” weight. It needs to then be decided by the site planner, which of the two is more important. This decision must be based from the perspective of the object in the subject row (Object 1 in this example). This is to say “If I were to place Object 1 on site, would I prefer it to be closer to Object 2, or Object 4?

![Figure 6: Pairwise comparison – identifying conflicts](image)

The objects determined to be less important are downgraded by a defined points, for example 5 points. If there are more similar weights in one row, then another point downgrade is applied to each until there are no two similar weights in one row. In the above example, it was determined that Object 4 is less important to Object 1 than Object 2. As a result, the quantitative weight assigned to the relationship between Objects 1-4 was lowered to 45 (Figure 7).
Once all the similarities in the rows are addressed, the qualitative weights are averaged out with their duplicate cells on the other side diagonal side of the matrix (e.g. Object 1-4 relation vs. Object 4-1 relation). This allows for weights to be analyzed from the perspective of both objects in each individual relation. In the above example, the weight of the relationship between Objects 1 and 4 is averages to 47.5 (Figure 8). This approach allows for defining a clear preference for the importance of satisfying the defined spatial relationships between objects in a systematic manner. As a result, the quantitative weights taken from site experts can be converted to quantitative scores and used in site management applications such as site layout optimization models.

8 SUMMARY AND CONCLUDING REMARKS

The main objective of this study was to identify the typology of space usage on construction sites that can be used in applications developed for site management. This study used nine (9) different construction sites with various size and congestion levels and collectively observed over seventy seven hundred (7700) object relationships. This study could identify eight (8) types of objects, four (4) types of spatial relationships, nine (9) typical reasons for the implementing a spatial relationship between two objects, and four (4) importance weights defined for relationships based on the observations and explanations of the site experts. These typologies can be used in future applications for site management to ensure all aspects of different projects can be accommodated in an application.
Using the relations and weights described for the objects on each site by the site expert, the existing layout of each site was then reviewed to see the adherence to the described relationships. It was interesting that there were a number of “common mistake” trends among the studied sites. The most commonly observed of these trends was the tendency for contractors and/or sub-contractors to infringe within the bounds of operational corridors. On small sites with limited mobile equipment, blocking op-corridors is less of an issue. On the other hand, on large sites with dozens of subs present, a blocked corridor could lead to massive delays in project schedule. Another persistent trend was for contractors to organize materials on the site on a first-come-first-served convenience, rather than tradesman convenience. This trend was more present on smaller sites, as there was typically both a lack of operational corridors, and minimal distance for trades people to travel. While this trend could have little overall effect in project schedule of small projects, it would result in daily inconveniences for workers, and at times, trades people who were less than pleased about how lay down had occurred.

Another interesting observation was that contractors seemed to be commonly prepared with a plan B in cases where a relationships with high importance (Has to be) cannot be satisfied. Contractors were often prepared for such circumstances and an alternative plan prepared in order to save schedule. For example, due to the important role of a tower crane, a heavy-duty crawler was often available on the site in case the tower crane became inoperable. Having such contingencies in place is critical to schedule, therefore these substitutive relations of such nature were expressed as “Must” category.

Whether a relation is considered a “should be” or a “can be” was sometimes difficult. The two weights seem very similar in nature, and one might think of it as almost judgmental to differentiate between the two. A good rule of thumb to follow when trying to evaluate whether a relationship is “Should Be” or “Can Be” is to ask, “Would my worker have ample cause to complain to me if I did not satisfy this relation? If the answer is “Yes,” then it is likely a “Should Be” relationship. If the answer is “No,” or if the worker has no real reason to complain, then it is likely a “Can Be” relationship.

Clearly this study is only scratching the surface for identifying typology of objects and relations for construction sites that can be used in related applications. Construction sites are complex by nature and developing site management applications and solutions have proven to improve efficient planning and management of construction sites. Identifying typology of objects and site space usage can assist in ensuring such applications are applicable to more sites, rather than providing solution to specific cases. More studies are required to ensure the identified typologies are indeed representative of the space usage and relations used in all construction sites.

IMPLEMENTING ALTERNATIVE TECHNICAL CONCEPTS IN DESIGN-BIDBUILD PROJECTS

Douglas D. Gransberg¹, Ghada M. Gad², and Jorge A. Rueda-Benavides¹
¹ Department of Civil, Construction, and Environmental Engineering, Iowa State University, United States
² Department of Construction Management, Bowling Green State University, United States.

Abstract: This paper details the results of two in-depth case studies conducted on agencies that implemented Alternative Technical Concepts (ATC) in conjunction with the procurement of low bid Design-BidBuild (DBB) construction projects. The Missouri and Michigan Departments of Transportation (DOT) each chose to pursue early contractor involvement in DBB projects but used two completely different approaches. Missouri allowed ATCs to be proposed virtually without limitation on seven DBB projects; whereas, Michigan chose to only consider ATCs on the Maintenance of Traffic (MOT) Plan for two DBB projects. The paper found both approaches to be successful, generating tangible cost and/or time savings for each DOT. It also proposes two frameworks for developing ATC procurements using either a limited or full scope approach. The paper’s primary finding is that ATCs can be implemented at any level if the agency thoughtfully develops the project’s solicitation documents. It also finds that limited scope ATCs, like the MOT ones in Michigan provide a mechanism to experiment with the DBB ATC process and gain the required understanding of the mechanics of the procurement without increasing the risk the agency must assume.

1 INTRODUCTION

The rapid spread of alternative project delivery methods for delivering infrastructure projects is the result of the critical requirement to rapidly rebuild the deteriorating transportation infrastructure of the United States (US). Specifically, state DOTs are using design-build (DB), construction manager/general contractor (CMGC), or construction manager at-risk (CMR), and at times design-bidBuild best-value (DBB-BV) contracts to take advantage of the design and construction industry’s ideas for alternative design and construction solutions to highway projects. In 2010, the US FHWA implemented its Every Day Counts (EDC) program, which is designed to identify and deploy technical and procedural innovations that promote the “shortening project delivery, enhancing the safety of our roadways, and protecting the environment... it’s imperative we pursue better, faster, and smarter ways of doing business” (Mendez 2010 emphasis added). The EDC program offers to reduce the amount of state matching funds required for a federal-aid highway project if the DOT employs one or more of the approved EDC innovations. Both DB and CMGC delivery are on that list as are Alternative Technical Concepts (ATC).

An ATC is defined by the FHWA as "a request by a proposer to modify a contract requirement, specifically for that proposer’s use in gaining competitive benefit during the bidding or proposal process... [and] must provide a solution that is equal to or better than the owner’s base design requirements in the invitation for bid (IFB for DBB) or request for proposal (RFP for DB) document.‖ (FHWA 2012). Entertaining ATCs as a part of the pre-award procurement process is one method that has proven to yield novel solutions to
complex design and construction problems on a wide range of projects. ATCs are definitely a smarter way of doing business by bringing the collective experience and creativity of all project stakeholders to bear on a given project.

ATCs have been used on US DB projects since 2002 and as such, are a well-tested approach to soliciting competing technical solutions for a given design problem. Their use in DBB projects was first seen in 2011 when the Missouri DOT (MoDOT), impressed with the quality of their DB projects, decided to include ATCs on certain traditional DBB projects. At a meeting for interested contractors, MoDOT explained its motivation for including ATCs in the DBB project to replace the structurally deficient Hurricane Deck Bridge over the Lake of the Ozarks in the form of the following equation:

"BOLD Approach = Industry + MoDOT = One Team = Best Value" (MoDOT 2011)

The meeting stimulated several bold ATCs including two that proposed to completely realign the bridge from its baseline alignment. The low bidder's ATC realignment permitted it to bid $8.0 million below the engineer's estimate for the baseline design. Two of the five bidders did not propose ATCs and their bids were roughly $10 million more than the low bidder. The results clearly showed the promise found by permitting the construction contractor to make substantive changes to a project's final design and proved that the process accrues tangible savings to both the agency and the taxpayer. Therefore, the objective of this paper is to detail the ATC process applied to DBB projects in Missouri and Michigan. It will also propose a framework for a generic DBB ATC that is founded on the outcome of the two case studies.

2 BACKGROUND

Many of the studies on construction procurement have found that early contractor involvement in the project's planning and design yield benefits to the owner in terms of constructability, which in turn saves both time and cost (Hoffman et al. 2009; McMinimee, et al. 2009; Carpenter 2012; Coblenz 2012; Hitt 2012; Horn 2012). The literature also shows that contractor design input contributes to a more effective design with reduced errors and omissions via the direct application of construction knowledge (Yates and Battersby 2002). Furthermore, West (2012) argues that “contractor design input is [a] benefit... because it enhances constructability and innovation and creates potential for cost savings through effective design solutions.” The Massachusetts DOT (2012) chose to implement ATCs “to avoid delays and potential conflicts in the design.” Taking these findings with the enhanced quality of final construction documents leads to the conclusion that implementing ATCs effectively provides a new level of design quality control through the involvement of the contractor in reviewing the solicitation and design documents and identifying errors, omissions, and ambiguities. In West's (2012) words, the practice creates a “form of price clarification, eliminating confusion and potential misunderstanding by mandating information-rich communications.”

2.1 Confidential One-on-One ATC Meetings

NCHRP Synthesis 455 on ATCs (Gransberg et al. 2014) found that that most agencies implementing ATCs conduct confidential one-on-one meetings where competing contractors are allowed to present ideas for potential ATCs. The objective of these meetings is first to permit contractors to float their ideas for ATCs past the owner and get a quick decision as to whether or not the agency was likely to approve the change. Secondly, if the response is positive, the one-on-one meeting provides a mechanism where the owner and the contractor can discuss the details of the potential change and reach agreement on whether the proposed ATC is “equal to or better than” the baseline design as required by federal regulations. The confidentiality of these communications is the key to success as competing contractors will not offer up their good ideas if they believe the concepts will become known to their competitors (Smith 2012). Randy Hitt, PE of the MoDOT describes his agency's approach to confidential ATC meetings by saying: “Confidentiality in the ATC process is very important for the success of the ATC process. Great care needs to be taken when exchanging files and emails” (Hitt 2012). Another paper written by a contractor expressed the same sentiment from the other perspective: “Trust in the Owner's confidentiality, objectivity and fairness is paramount” (Smith 2012).
In the agencies where one-on-one meetings are not authorized, the competitors were typically asked to submit a written ATC proposal for review and approval. In most cases, there was a deadline established for submission and either a one or two week period for the owner's review and decision to be returned to the competitors. Regardless of the presence of one-on-one meetings, most DOT policies provide for confidentiality of the outcome of the ATC review/approval process.

2.2 Applying ATCs to DBB Procurements

Implementing DBB ATCs entails a shift in the procurement culture to permit contractors to confidentially propose changes to a project’s scope and get the full benefit of their innovation by allowing them to be the only competitor that is allowed to submit a bid on the project as modified by the approved ATC. NCHRP Synthesis 455 (Gransberg et al. 2014) found that guaranteeing confidentiality permits competing contractors to build a competitive edge with their ATCs and is widely used in DB projects. The synthesis also found that it stimulates innovative approaches to delivering a project that were not considered by the agency during the baseline planning and design process.

At this point, it must be noted that the aim of the paper is not to advocate the use of ATCs on every DBB project. The ATCs, like alternative project delivery methods, should be applied to a specific project after careful thought and a determination that the project stands to benefit from the construction contractor’s pre-bid input to the project’s design. In most cases, this means that the transportation agency engineer has found that there are several promising options for the contractor’s means and methods, which once identified, will drive one or more of the details of the final design. Knowing the information before award could conceivably accrue benefits in terms of cost and/or time savings. An example would be designing the size and length of bridge members based on a contractor’s actual reach and pick constraints for a barge-mounted crane.

A second aspect of the ATC method that was found by those DOTs that used the tool is that the decision to include ATCs should be made as early in the project development process as practical. Ideally, it would be made before the project’s National Environmental Policy Act (NEPA) clearance is completed to minimize the chances that public commitments made during the NEPA process do not reduce ATC potential benefits or stifle them altogether. The Missouri DOT learned this lesson on its Hurricane Deck Bridge project and the details of their experience are contained in the subsequent case study discussion. In essence, a project with a high potential for beneficial ATCs must pass through the NEPA process with as much flexibility of final design configuration as possible. This constitutes a shift in the environmental permitting process away from the current mode of “be as specific as possible” to a less restrictive mode that provides the agency as much latitude as possible while remaining in full compliance with the laws of both the State and the Federal Government. The net result is that planners, designers, and construction personnel must be jointly involved in the ATC decision at the earliest point—when the project scope is defined.

Thus, to maximize the value made possible by implementing ATCs, a much higher level of internal collaboration is needed for a longer period of time by the agency. This means that agency planners may need training to recognize the features of a project that make it a good candidate for ATC solicitation. Deciding to change an agency’s culture with respect to environmental commitments requires a certain amount of moral courage and the willingness of upper management to support bold changes in historic agency design standards. It also requires support to allow a low-bid construction contractor to furnish options for changing the design.

2.3 ATC Process Models Found in the Literature

NCHRP Synthesis 455 found that DBB ATCs can be implemented in two different forms. The first, called a “full scope ATC,” allows interested contractors the freedom to propose ATCs on the entire scope of work. The second is called a “limited scope ATC” and specifies those portions of the scope of work on which ATCs are being solicited. Table 1 lists the advantages and disadvantages of both types. To highlight a few, limited scope ATCs may not be able to improve the construction schedule or realize significant cost savings as opposed to full scope ATCs where large number of options are proposed for
time and cost savings. However, the issue of confidentiality and environmental commitments - that could be impacted significantly- is more complex in the full scope compared to the limited scope ATC. In addition, in terms of maintenance of traffic in the limited scope approach, the impact to MOT is easier to measure due to highly focused scope of ATCs compared to the full scope ATC where the entire project might be eligible to modification to optimize MOT and the baseline MOT design may not be compatible with the ATCs proposed. In essence, while both ATC approaches have been implemented successfully, NCHRP Synthesis 455 found that the limited scope ATC was a less radical change to the traditional DBB procurement process and indicated that as DBB ATCs proliferate that most will probably be the limited scope variety (Gransberg et al. 2014).

3 METHODOLOGY

The study utilized two primary research instruments: literature review, including a content analysis of agency ATC solicitation documents, and formal case studies of projects in Missouri and Michigan. The primary objective of the case study protocol was to supplement the knowledge framework created through the literature reviews and agency solicitation documents with the deeper knowledge of the project participants. Literature review and content analysis provide the researcher with the “what” of a given project, but structured interviews with case study project participants provide the “why” for the decisions made and the events observed in the project.
3.1 Case Study Protocol

The literature review and content analysis drove the case study data collection and the sought to identify with information collected in the literature review to validate case study conclusions. The choice of projects to further investigate as in-depth case studies was determined based on the availability of participants and documentation on DBB ATC projects. Only two US states, Missouri and Michigan, have implemented ATCs on DBB projects. At the time of this writing, Missouri has completed roughly ten projects and Michigan has done two. In-depth case studies will serve as a critical source of information in this research. The analysis will be conducted on the following three levels:

1. Analysis of DBB ATC projects of different sizes, different states, and different methodologies as identified in the literature review.

2. Interviews of public transportation agency personnel, contractors, and consultants with DBB ATC project management experience.

3. Published reports of DBB ATC case study projects from the highway sector.

3.2 Case Study Selection

The primary input to the case studies was gathered through structured interviews with agency personnel, contractors, and consultants that have been part of teams involved with DBB ATC projects. The structured interview outlines were developed using the method prescribed by the US Government Accountability Office (GAO 1991). The GAO method states that structured interviews can be used where “information must be obtained from program participants or members of a comparison group… or when essentially the same information must be obtained from numerous people for a multiple case-study evaluation” (GAO 1991). Both these conditions apply to this study; therefore, the tool is appropriate for the research.

The process involves developing a questionnaire that was made available to each interviewee prior to the interview and then collecting responses in the same order using the same questions for each interviewee. The information was gathered using both face-to-face and telephonic interviews. Per the GAO method time is allotted to ensure that the interviewee understands each question and that the data collector understands the answer. Additionally, interviewees were also allowed to digress as desired, allowing the researchers to collect potentially valuable information that was not originally contemplated. The output is used to present the agencies’ perspective on various points analyzed in the subsequent tasks.

The case study details were collected using Yin’s methodology (Yin, 2004). The use of these instruments in conjunction with the comprehensive review of the literature allows the researcher to not only maintain a high level of technical rigor in the research but also follow Yin’s three principles in the process of research data collection: 1) Use of multiple sources, 2) Creation of a database, and 3) Maintaining a chain of evidence (Yin, 2004).

Based on the page limitations for this paper, the Hurricane Deck Bridge Replacement Project in Missouri and the US-10 Rehabilitation Project in Michigan were selected. The fundamental rationale was to be able to compare to a project that utilized a full scope ATC with one that used a limited scope ATC process. Additionally, the Missouri project ATC extensively changed the baseline bridge design and can be compared to the Michigan project where only the MOT plan was changed from the baseline. The result provides a basis for proposing frameworks for each ATC process type.

3.3 Case Study Project Details and Background.

Two case study projects were selected to evaluate the differences in the Missouri and Michigan DBB ATC processes. Table 2 contains a synopsis of each project’s details. It shows that the MoDOT Hurricane Deck Bridge project ATC was the most comprehensive as it not only changed the bridge’s structural design, but also changed its alignment. Alignments of federal-aid highway projects that have received NEPA clearance are considered to be fixed and a change triggers a potential re-review (Hitt 2012). To
compound the complexity of implementing this alternative, MoDOT had chosen to avoid potential design liability issues by advancing approved ATC designs to the point where biddable quantities could be generated. Hence, the issue of confidentiality became very complicated as a NEPA re-review puts the technical details of the ATC into the public domain. Additionally, since three contractors submitted ATCs, MoDOT’s design consultant had to maintain three separate design teams for each of the ATCs to protect against accidental revelation of one contractor’s ATC to another.

MoDOT had several issues that needed to be handled differently than the standard DBB procurement process. For example, to address the environmental issues, MoDOT identified the selected alternative in the Environmental Assessment, while ensuring the environmental document made reference to the ATC process. This is in addition to having FHWA involved in the environmental discussions with MoDOT team from day one. The ATC team had open communication with the environmental office and even disclosed potential designs that could trigger a re-review of the NEPA document if they weren’t originally covered. In terms of design liability, MoDOT decided to assume the design liability of the proposed ATC to avoid creating issues of transfer of design liability and eliminate the need to offer a stipend for the effort costs invested by unsuccessful bidders in ATC design. Since confidentiality for the contractors is considered key to the success of the ATC process, MoDOT took several measures to ensure confidentiality. First, the agency’s design consultant assigned four individual design teams to work on the different ATC designs. The design teams had to also exercise great caution in keeping separate proposals independent of each other. Secondly, MoDOT created an external sharepoint site secure to each contractor engaged in the ATC process. This ensured that the proposers had no idea who the other proposers were and what ideas were being discussed. Finally, confidentiality imposed two major constraints on the normal bidding process, 1) the final proposed improvement could not be revealed to the public until the bidding stage and thus, MoDOT only advertised that they were allowing contractors to propose alternate ideas for construction and 2) MoDOT could not finalize the right of way negotiations as they couldn’t share what the change in footprint impact with the property owners (Hitt 2011).

As for the US-10 project, MDOT provided contractors the opportunity to include pricing for a pre-approved ATC(s) in their proposals. Proposers were allowed to bid either the MDOT baseline design or their approved ATC(s). If the ATCs submitted by the proposers required NEPA re-review or modifications to previously approved permits, the proposer has to bring it up for MDOT and FHWA approval. Since this project presents a "limited scope" implementation of ATC, ATCs on this project were limited to staging and traffic control on US-10 mainline, in contrast to MoDOT Hurricane Deck Bridge project where the contractors were to assume the risk of preliminary and final design costs for their approved ATC. The issue of confidentiality was also addressed in the Notice to Bidders document by stating that “MDOT expressly reserves the right to adopt any specific [Conceptual ATC] CATC or ATC as standard practice for use on other contracts administered by MDOT, whether the CATC or ATC is accepted or rejected....
CATC or ATC shall not be used by MDOT until after the award of this project." MDOT considered all the ATCs submitted as confidential and as such were not to be shared with other bidders. In addition, the review team members were required to sign a confidentiality agreement to guarantee confidentiality (MDOT).

4 CASE STUDY ANALYSIS

4.1 Case Study Procurement Analysis

Table 3 shows that the time required to procure a full scope DBB ATC is roughly 10 months. Whereas, the limited scope DBB ATC was roughly 6 weeks. Thus, it can be concluded that the decision to permit full scope ATCs has a measurably longer time frame to permit interested contractors to generate their alternatives and to permit the DOT time to evaluate and approve those that it finds attractive.

4.2 Case Study Process Analysis

Figures 1 is a generic DBB ATC solicitation, submittal, evaluation and approval process seen in each DOT. MoDOT process occurs in four project development and delivery phases. The process starts with ATCs announcement inclusion on a given project together with the posting of current plans to permit contractors to get familiar with the project and begin developing ATCs. Conceptual ATCs (CATC) are then received and expeditiously reviewed and approved to provide contractors quick decisions on their ideas attractiveness to MoDOT. CATCs are discussed in confidential one-on-one meetings which are then followed by formal ATC submission, evaluation, and approval. Once approved, MoDOT advances the ATC-modified design to a stage where biddable quantities could be produced. It is then the contractor’s decision whether or not to bid the approved ATC. If the contractor wins, MoDOT completes the redesign to finalize the construction documents (FHWA 2014). MDOT uses essentially the same process with the major difference being the amount of time allotted to evaluation and approval as shown in Table 3. Therefore, one can conclude that the amount of time allotted to the ATC process is directly related to the amount of scope that can be changed by ATCs.

4.3 Case Study Discussion

The case studies provide good examples of two different ATC approaches implemented successfully in DBB projects. The key motive for ATC implementation in both is early contractor involvement in generating scope changes and the cooperative effort to find a best value innovative solution. MoDOT’s ATC approach showed that obtaining early contractor involvement is possible on a traditional low bid DBB highway project. Such an approach also was strongly supported by its local design and construction industry partners; in the words of one Missouri contractor, “We elected to pursue ATCs because we felt
we could derive a solution that would be more economical for us to build than the baseline design” (Hitt 2012).

However, based on the two cases, key elements emerge for ATCs successful implementation (1) environmental process, (2) time commitment for project delivery, (3) confidentiality, and (4) design liability. As NEPA came largely into play with an ATC that involved the realignment of the Hurricane Deck bridge, MoDOT had to handle environmental procedural issues in a manner that did not compromise the confidentiality of the ATCs. It also had to maintain high levels of internal collaboration between planners, designers, and construction personnel as well as continuous evaluation impending NEPA commitments against their possible impact on potential ATCs. One of the instrumental factors in an agency’s culture with respect to environmental process change is the willingness of upper management to support fundamental changes in historic agency design standards.

The Figure 1 procurement framework shows that providing contractors adequate time to develop and refine their proposed ATCs is critical to the process. Contractors need more time than the amount in a routine bidding period to explore potential ATCs and to get approvals from the agency to proceed. It is seen how time frames are highly dependent on the scale and type of the project, together with the individual agency and contractor capabilities. Whether the process involves a full or the limited scope approach, confidential one-on-one meetings are instrumental in an ATC process to vet possible ATC concepts. Both agencies addressed confidentiality by different means such as having different teams on different design proposals in MoDOT’s project or the confidentiality agreements used by MDOT. The last important aspect is the issue of design liability for the proposed ATC design. MoDOT assumed full liability of design development in its full scope approach, and MDOT decided to have the proposing contractors fully develop their designs using approved MDOT consultants. Lastly, both DOTs found that permitting contractors to bid the baseline design was important to keep contractors who don’t understand/trust the ATC process in the competition.

5 CONCLUSIONS

The aim of this paper is to detail the ATC process applied to DBB projects in Missouri and Michigan and accordingly propose a framework for a generic DBB ATC founded on the outcome of the two case studies. Two projects were selected; Missouri’s Hurricane Deck Bridge project in and Michigan’s US-10 Rehabilitation project. Both projects implemented ATCs in DBB yet using two different approaches: a limited or full scope approach. MoDOT allowed contractors to propose ATCs without limitation while MDOT Michigan chose only to consider ATCs on the MOT. Through analyzing both projects, three major conclusions are reached. First, both approaches are proven to be successful through generating tangible cost and/or time savings for each DOT. However, limited scope ATCs will prove easier to implement on DBB projects for an agency trying it for its first time as it provides a mechanism to experiment with the DBB ATC process and gain the required understanding of the mechanics of the procurement without increasing the risk the agency must assume. The impact found by the Michigan limited scope approach case was to essentially extend the 30 day bidding period by 12 days. Second, ATCs can be implemented at any level if the agency thoughtfully develops the project’s solicitation documents. The clarity of the instructions and the proposal requirements such as the EPA and permit requirements/constraints are key issues that need to be addressed in the solicitation documents. Finally, the analysis of the two cases emphasizes the importance of confidentiality and one-on-one meetings to the success of the ATC process.

EXPEDITING EMERGENCY CONSTRUCTION PROCUREMENTS: CASE STUDIES IN SUCCESS

Douglas D. Gransberg¹ and Jorge A. Rueda-Benavides†
¹Department of Civil, Construction, and Environmental Engineering, Iowa State University, United States

Abstract: While the law allows public transportation officials to do what it takes to resolve the emergency, they are expected to maintain an extremely careful balancing act between expeditiously resolving the crisis and abusing their authority to circumvent the routine full and open competition process using the emergency as justification. The ability to waive standard procedures comes with the requirement to use that authority both sparingly and wisely. This paper presents analysis case studies of expedited emergency projects from nine states that range from a $550,000 landslide repair to a $234 million interstate highway bridge replacement. The cases also cover emergency projects delivered by design-bid-build, construction manager/general contractor, design-build and indefinite delivery/indefinite quantity contracts. The paper finds that the major factor for successful emergency procurement is for the owner to utilize procurement processes with which it is familiar. It also finds that owners need to allow as much competition as time and circumstances permit to reduce the probability of a substantive protest. Finally, it recommends anticipating an emergency and making advance preparations is the fastest way to react to an emergency and the surest method for avoiding protest.

1 INTRODUCTION

“In both [US] federal and state law, the use of emergency procurement procedures allows for limited competition in selecting a contractor… however, this limitation must be carefully utilized and fully documented” (Perry and Hines 2007 italics added). Herein, lays the heart of the primary procurement dilemma for public officials attempting to expeditiously deliver the design and construction services necessary to resolve an infrastructure availability crisis. The law grants broad latitude regarding suspending statutory competition requirements in an the emergency situation, officials are also expected to the legal tightrope between expeditiously resolving the crisis and potentially abusing the authority to suspend full and open competition while using the emergency as justification. Emergency powers come with the requirement to use that authority both sparingly and wisely throughout the crisis. The New Mexico Department of Transportation (DOT) emergency procedures manual (2007) puts it this way: “Lack of planning does not constitute an emergency.” Another author evaluating the difficulties of emergency procurement puts it this way: “Perhaps a good rule of thumb is, when in doubt, bid it out.” (Houston 2011).

The primary research objective was to identify trends in successful emergency construction project delivery via the analysis of case study projects. Secondarily, the research sought to determine the impact of limiting competition during emergency procurements and identify effective practices for providing as much competition as practical that can be replicated in future emergencies.
2 BACKGROUND

Many of the studies on the deteriorating condition of the North American transportation system find that public agencies must deliver critical infrastructure projects “better, faster, cheaper” (Atzei et al. 1999; Richmond et al. 2006). However, when an emergency occurs and removes an essential piece of the infrastructure such as a major bridge, the alternatives for optimizing the procurement process narrow to the point where only one of the three previous components remain, and that one is time, i.e. “faster.” While “better” (quality) and “cheaper” (cost) are still of concern, they take a lesser priority until service is restored. Then, the public attention often switches to an analysis of value for money from a retrospective viewpoint. The attention often criticizes the procedures used by the agency to restore service as quickly as possible. The result is that public agencies have expended much time and money to develop emergency management plans supported by a preapproved set of expedited procurement procedures.

2.1 Spectrum of Emergencies

The pressing need to expedite the delivery of an emergency project normally arises unexpectedly, and the magnitude of the response can range from very little to a declaration of a national disaster. When the emergency is large enough to make national news like Hurricane Sandy on the US east coast or the Interstate 35W bridge collapse in Minnesota or the 2013 ice storm in Ontario, public officials must implement expedited procurement procedures to restore vital network links with the media scrutinizing their work every night on the evening news. While high profile emergency projects are well-known, the more typical case is a local emergency caused by flashing flooding washing out a culvert on a rural road or a freeway overpass damaged and closed from a traffic accident. These mundane local emergencies sometimes go unmentioned in the news, but are just as critical to drivers traveling through the locality and require the agency to exercise just as much speed to restore service and remove threats to life and property. The difference in the two situations can be the construction industry’s willingness to accept a change in customary rules ensuring free and open competition for construction projects. In major disasters, the publicity encourages a “do whatever it takes” attitude due to the emotions surrounding the event that are rarely present in the localized incidents. Nonetheless, agencies have found ways to successfully resolve both large and small emergency disruptions to network service. Therefore the purpose of this paper is to evaluate the collective experience with expedited procurement procedures to deliver both design and construction services for emergency highway projects.

2.2 Legal Constraints on Emergency Procurements

Based on local statutes, most public agencies are given the power to take whatever action is determined necessary to insure health, safety and welfare of the community in an emergency. For example the Florida statutes (2010) state: “The political subdivision has the power and authority to waive the procedures and formalities otherwise required of the political subdivision by law pertaining to: performance of public work and taking whatever prudent action is necessary to ensure the health, safety, and welfare of the community; entering into contracts [and] incurring obligations...” This verbiage applies to awarding emergency highway contracts by the Florida DOT. Most, if not all, US state codes provide similar authority to ignore routine statutory competition constraints in an emergency where the time it takes to follow the routine procurement process would or could exacerbate the impact to the health and safety of the community.

The United States Code (2000) authorizes public agencies to provisionally suspend its construction bidding regulations for contracts awarded for emergency situations. Normally, the Federal Highway Administration’s (FHWA) requires consultant contracts to be awarded on a competitively negotiated basis to the best qualified offeror based on the Brooks Act (23 CFR §172.5a3) and contracts for construction to be awarded on the lowest responsive and responsible bidder to be approved for federal funds. Additionally, roads designated as eligible for federal-aid are also eligible for federal funds administered by FHWA. Title 23 USC §125 authorizes emergency relief (ER) funding for the “repair or reconstruction of highways, roads, and trails, … that the Secretary finds have suffered serious damage as a result of— (1) natural disaster over a wide area, such as by a flood, hurricane, tidal wave, earthquake, severe storm, or landslide; or (2) catastrophic failure from any external cause.”
Further complicating the mobilization of assets to cope with an emergency event is the requirement for gain approval from and coordinate with resource agencies to meet the requirements of the National Environmental Policy Act (NEPA). The Council on Environmental Quality (CEQ), which issues the implementation guidance for Federal NEPA actions, states: “Where emergency circumstances make it necessary to take an action with significant environmental impact without observing the provisions of these regulations, the Federal agency taking the action should consult with the Council [on Environmental Quality] about alternative arrangements. Agencies and the Council will limit such arrangements to actions necessary to control the immediate impacts of the emergency. Other actions remain subject to NEPA review.” (Perry and Hines 2007). Once the immediate threat to “the health, safety, and welfare of the community” has been resolved by interim emergency repairs, the agency must shift to conventional contracting procedures to award any remaining work (UDOT 2011).

3 METHODOLOGY

The study utilized two primary research instruments: literature review, including a content analysis of agency emergency management documents, and formal case studies of a cross-section of emergency projects. An effort was made in the review of relevant literature to not only seek the latest information but also historical information so that any change over time in emergency procurement practices could be assessed with the current state-of-the-practice. The content analysis of DOT emergency procedure documents from 38 states using a protocol proposed by Neuendorf (2002) constituted the second source of information. Both these instruments supported the third line of independent information: the case studies.

3.1 Case Study Protocol

The literature review and content analysis drove the case study data collection and the sought to identify projects from across the spectrum of emergency transportation projects with procurement aspects of specific interest to the study. The final group of case study projects highlights a specific emergency procurement issue that was address using expedited procurement procedures for emergency project delivery. The case studies were collected using a methodology detailed by Yin (2004). Yin’s approach requires that case study data be collected in conjunction with the comprehensive review of the literature. Thus, it allows the researcher to not only maintain a high level of technical rigor in the research but also follow Yin’s three principles in the process of research data collection: 1). use of multiple sources; 2). creation of a database, and 3). maintenance of a chain of evidence (Yin 2004). Thus, information gleaned from the case studies can be combined with information collected in the literature review to validate case study conclusions.

3.2 Case Study Selection

The primary objective in this paper is to analyze the value of bringing the contractor into the design process. Therefore, the following criteria for the final set of case study projects were applied:

- “Range of project delivery methods – design-bid-build (DBB), construction manager/general contractor (CMGC), design-build (DB), and indefinite delivery/indefinite quantity (IDIQ).
- Range of project types – roads and bridges
- Range of project size – typical small project to mega-project
- Range of project complexity – simple to highly complex
- Range of project location – regionally dispersed
- Range of solicitation type – Invitation for Bids (IFB) to sole source
- Range of payment provisions – lump sum (LS) to time and materials
- Use of incentive/disincentive (I/D) and bonus provisions” (Gransberg and Loulakis 2012)

Case Study Demographics
The study identified nine emergency procurement projects worth more than $290 million in nine states that represent the cross-section of variations on project types, sizes, and project delivery methods. Table 1 is a summary of the case study projects that were sampled for this research. One can see that the projects span from coast to coast and north to south. The case study projects represent the use of four different project delivery methods including a hybrid DBB project with a nested DB provision. The project types spanned the spectrum from the replacement of a washed out culvert to an emergency replacement of an eight lane interstate highway bridge over the Mississippi River.

4 CASE STUDY ANALYSIS

Due to the page limitations for this paper, the salient details of the case studies have been synopsized in Table 2 to permit the reader the ability to easily compare any specific project against all other projects. The analysis of the case study projects shown in Tables 1 and 2 will focus on the comparison of the PDM rationale, procurement, permits, incentives, and tools used to expedite the emergency procurements. These elements are the factors that constitute the elements that must be addressed to allow the agency to expedite the procurement of an urgent or emergency project. Based on the protocol detailed in Section 3, a set of standardized categories was established for the procurement rationale information and the tools used to expedite the procurements. This permits the direct comparison of case study projects and the identification and classification of trends during cross-case analysis. Finally, it should be noted that three of the nine cases involve procurements that anticipated the emergency and put resources in place contractually to be able to rapidly react to an emergency if it occurred or to mitigate the risk that the emergency would be actualized. As can be seen in Table 2’s timeline column, this proactive approach not only provides the ability to immediately react without the need to process environmental permits or acquire right of way, but it also eliminates the risk that the award of the emergency contract will be protested on the grounds that the agency abrogated its responsibility to maintain free and open competition in all procurements.

### 4.1 Case Study Procurement Analysis

Table 2 shows that the need to have the construction contractor’s input during design drives the selection of a project delivery method for an emergency project. Agencies favor CMGC and DB since these methods involve the contractor making substantive input to the design process and purport to improve constructability and construction phasing (West et al. 2012). Caltrans and ODOT did not have the statutory authority to use DB or CMGC, and therefore, both agencies turned to adding large incentives to their DBB contracts as a means of encouraging the contractor to focus on achieving an aggressive schedule (Bai et al. 2006). Maine had authority to use DB but wanted to use in-house design assets, which is functionally impossible in a DB contract. Thus, the agency sought emergency authority to use CMGC to replace the Route 27 bridges (Pulver 2012). New York’s emergency bridge replacement IDIQ was in place when Hurricane Irene washed out the bridges over the Ramapo River (NYSDOT 2007) and as such was able to marry up in-house design assets with the IDIQ contractor that delivered the projects in exactly the same fashion as a typical CMGC project with the contractor identifying immediately available structural steel sections around which the NYSDOT engineers designed (Rueda and Gransberg 2014). This leads to the conclusion that early contractor design involvement is key to not only achieving an expedited delivery but it also facilitates the schedule by designing a project that is highly constructable.

Table 2 also shows that when an agency is unable to obtain an emergency waiver of environmental permitting requirements, the contractor can be given the responsibility for obtaining the permits based on its actual means and methods. The Montana DOT assigned the permit responsibility to its contractor
because the permits would be specific to the means and methods that would be used in the field (MDT 2011). The Utah DOT shared the permitting responsibility with its contractor because of the need to build a temporary access road as quickly as possible to provide egress for the residents that were trapped by the landslide in the valley. A Stream Alteration Permit was required to restore the bed and banks of the creek that is located below the road as well as permits from the county, the US Fish and Wildlife Service and the Utah Department of Wildlife Resources. Lastly coordination was required with the local Native American tribe. To quantify the risk of delay due to permitting, UDOT had the contractor develop two schedules, naming them the “Fast Track” and “Slow Track” permitting packages. These planning packages included right-of-way, environmental documents, and the contractor’s site grading package, which is dependent on both. The Slow Track schedule was 60 days and the Fast Track schedule is 25 days. Permits were received in time to allow preliminary construction to start and accomplish the removal of excess material and to build the temporary access road (UDOT 2011).

Five of the case study projects limited competition to a standing list of prequalified contractors. While still limiting free and open competition, this approach provides more competition than a sole source award and essentially give all potential contractors the chance to qualify for inclusion on the prequalified list before the emergency. Thus, the risk of a protest of award based on restricting competition is reduced and the agency is encouraging as much competition as practical given the urgency of the emergency procurement.

Lastly, every case study project utilized some form of altered or streamlined version of procurement procedures to advertise, evaluate and award the contract. One end of the spectrum was the Florida project that was awarded using FDOT’s standard form modified with seven pages of hand-written “assumptions and clarifications” (Maxey 2006). Minnesota’s process reduced the size of the DB proposal for $240 million bridge project to a mere 20 pages by holding confidential one-on-one conferences to clarify issues in the solicitation and entertain alternative technical concepts (Heitpas 2008). Montana modified its routine lump sum DB contract by adding a unit price item as a means of sharing the geotechnical risk with its design-builder.

4.2 Case Study Incentives Analysis

A recent Strategic Highway Research 2 study found that on complex projects the agency should first identify critical success factors and then incentivize those aspects of project delivery that contribute to success (Gransberg et al. 2013). Table 2 shows that to be the case in only four of the nine projects included monetary incentives. To put this in perspective, three of the cases, Missouri, Montana and New York, were contracts awarded before the emergency occurred and therefore, the contracts were formed without the urgency inherent to contracts procured after an emergency event, reducing the need for incentives and quite frankly, making large incentives more difficult to justify. In these cases, the incentive is in winning the contract. Maine and Utah were other two cases without incentives and both were delivered using CMGC. In CMGC, the contractor is actively involved in forming the final design solution (West et al. 2012) and in both cases, the agency created an incentive for expeditious completion in its contractor selection scheme during procurement. Previous project delivery methods research found that contractors view the possibility of getting future work by satisfactorily completing a CMGC project as the most valuable incentive available in this method, or as stated by one author: “By far the most important incentive that an owner has is the promise of repeat work” (Thomsen 2006). Thus, one can infer that the agency can use the benefits inherent with winning new work as the incentive if it anticipates the emergency, and it can leverage the same incentive after the emergency by selecting CMGC project delivery.

4.3 Case Study Tools Analysis

Gray and Larson (2008) describe project management as “the application of knowledge, skills, tools, and techniques to project activities to meet the project requirements” A recent study defines a procurement tool as “those things that project management practitioners use to ‘do the job’ to execute a process.” (Besner and Hobbs 2008). Thus, the term as used in this paper refers to a specific technique or approach used to expedite the procurement of either design and construction services on an urgent or emergency
basis. Table 3 consolidates the expedited procurement tools show in Table 2. One can see that involving the construction contractor in the design process is the most frequently used tool followed by the use of limited competition and incentives.

</table>

The Utah DOT found that design documents developed in nonemergency CMGC contracts were released for construction much earlier due to contractor involvement (Alder 2007). Additionally, as the contractor is already under contract, the designer no longer needs to produce a full set of biddable construction documents. The agency can direct it to develop its design documents on a feature by feature basis at a point in time where the contractor declares there is sufficient detail for it to release for the trade subcontract work package bids (Alder 2007; West et al. 2012). A previous study on early contractor design involvement (ECDI) found that it yields four specific benefits useful in an emergency procurement:

1. "ECDI permits the DOT to gain access to information regarding available construction means, methods, and materials. This permits the design to be tailored to the immediate need

2. ECDI adds a reality check to the design process via the designer getting immediate feedback on the consequences of design decisions from the entity that is tasked to construct the project. This results in a more constructable project.

3. The use of time-based incentives in emergency projects focuses the contractor on executing very aggressive schedule and to devote as much effort as possible to ECDI as a means to get design packages released for construction in a timely manner.

4. While ECDI does not transfer the design liability, it does produce a higher quality set of design documents with a lower probability of the need for delay due to changes for design errors and omissions." (Gransberg 2013).

Both Table 3 and the subsequent discussion lead one to the conclusion that the involving the construction contractor in the design process is the most effective procurement tool to expedite the completion of emergency project. Additionally, limiting competition reduces the procurement period to as little as one day and if limited to a standing list of prequalified contractors can reduce the risk of award protest. Finally, emergency projects should be recognized as inherently complex and as such, the case studies show that...
aligning thoughtfully developed incentives with critical project success factors also facilitate the expedited completion of the project.

5 CONCLUSIONS

Three major conclusions are reached in this study. The first is the most obvious. The best way to expedite the reaction to an emergency is to anticipate it. The study found two approaches to ensuring that the necessary resources were available to react to an unforeseen event: Missouri’s nested DB provision and NYSDOT’s IDIQ for emergency bridge replacement. It also identified Montana’s approach to nesting a unit price provision inside a lump sum DB contract to provide a means to mitigate the risk to the infrastructure from rock slides. In each case, actions were taken in advance of an emergency in a full and open competition environment and as such did not require emergency waiver of competition statutes.

Secondly, the study finds that selecting a project delivery method like CMGC, DB, or IDIQ which is structured to permit the construction contractor to make substantive input to the emergency project’s design was the most used expedited procurement tool among the case study agencies. The lesson learned here is that the separation of designer and contractor that exists in traditional DBB construction contracts, actually works against the expeditious resolution of an emergency loss of service. Bring the contractor into the emergency project design process, allows the repair and restoration of service to be tailored to that particular contractor’s preferred means and methods and enhances the constructability of the final design solution.

Lastly, maintaining a standing list of prequalified contractors willing to bid on an emergency basis permits the agency to provide as much competition as possible while avoiding the delays associated with running a full open competition solicitation. This conclusion speaks to the political environment rather than the technical aspects of emergency procurements. As with the first conclusion, the standing list acts as an insulator against delays due to protest of award founded on the idea that competition statutes were violated.

EXPLAINING THE INFLUENCE OF CHANGE REASONS ON COST AND SCHEDULE PERFORMANCES

David Grau1,4, Edward Back2 and Nahid Hossain1

Abstract: This research aimed at revealing and characterizing the influence of change events or reasons on cost and schedule performances. The specific objectives were to assess the frequencies of various change reasons with respect to cost and schedule deviations, and to assess the impact intensities of such change events or reasons on performance. Initially, a team of industry experts identified a total of 36 change types and grouped them in 9 major change categories. Then, change log information for 135 completed projects was statistically analyzed to quantify the intensity, frequency, and impact of changes on cost and schedule performances. The most recurrent types of change events for both cost and schedule were associated with issues related to construction productivity; planning; supplier and subcontractor; scope errors and omissions; design or engineering errors and omissions; or engineering productivity issues. In addition, this study quantified the specific impact on cost and/or schedule from a change event or reason. Specifically, this study provides evidence that fairly infrequent change events tend to cause large impacts on performance. The results from this study are likely generalizable, since the retrospective project data was representative of multiple project types, sectors, and organizational roles, among other project facets.

1 INTRODUCTION

Events can have a significant impact on cost and schedule deviations (Grau and Back 2013a; Grau and Back 2013b). As a result, cost overruns and schedule delays are very common in construction projects (Ibbs 2013, 2012; Mulva and Dai 2012). Various construction forecasting methods are used with the intention to ascertain cost and schedule deviations on time, but notably, such methods typically do not provide accurate forecasts (Grau and Back 2014a; Grau and Back 2014b). In reality, different events cause incremental impacts on cost and schedule performances, but those changes are difficult to foresee and their impacts to forecast. If change events could be detected early, such identification would help to minimize impact on performance and also to improve project outcome predictions. Thus, an early recognition of changes is critical to evaluate and implement changes in a proactive manner (Grau and Back 2013b). Importantly, this study tackled the issue of change reasons or events, understood as any unplanned event with a potential impact on cost and schedule.

In reality, the construction industry lacks evidence on the impact of changes on cost and schedule performances or deviations, and on the frequency of such changes. While a perception that the impact of changes vary with the nature of the change reason exists, the reality is that, to date, there is no data to
back up or reject such notion. The extent to which change events or reasons affect both cost and schedule deviations have not yet been documented (Grau and Back 2013a; Grau and Back 2013b; Ibbs 2005; Westersund 2008). As today, change events with high impacts are compensated with the use of large contingency reserves (Ibbs et al. 2008; McEniry 2007). However, we argue that the early recognition, communication, and proactive action to mitigate the impact of changes on performance are critical to minimize their impact. Reactive or late responses can only lead to significant negative impacts on performance, and increase the use of contingency reserves.

Indeed, questions such as: what are the major change reasons for cost and schedule deviations?; or, what are the types of changes that have the most influence on cost and schedule deviations?, have not yet been answered. This study aims at providing an answer to those and other similar questions with the overarching goal to enable construction industry organizations to be timely alert on the change reasons that can have a higher potential impact on performance, and to proactively manage such changes.

2 OBJECTIVES AND SCOPE

This research aimed to reveal the change events or reasons that have significant consequences on cost and schedule deviations. The specific objectives are listed below:

1. To assess the frequencies of various change reasons with respect to cost and schedule deviations; and
2. To assess the impact intensities of such change events or reasons on performance.

The scope of this study is defined as follows: 1) the sample for this study was randomly drawn from projects completed by CII member organizations; 2) the study was performed irrespective of the timing within the project timeline at which a changed occurred; and 3) the study considered the cumulative impacts of changes, regardless of their differences with respect to the controllability of each change.

3 LITERATURE REVIEW

A well-understood impact of change events on project performance should guide both owners and contractors to proactively manage changes. However, while the qualitative literature on changes is large, there is limited evidence on the frequency and impact of changes, as presented in the rest of this section. Those studies with a quantitative facet are mostly limited by the type of projects investigated or by the geographical location (e.g. Middle East) of the projects, and hence such results cannot be generalized.

Indeed, Hanna et al. (1999) quantified the impacts of change orders on craft labor productivity for mechanical trades. The authors collected data from 61 projects, and developed a statistical model to quantify labor productivity loss from change orders. Al-Momani (2000) studied 130 public projects in Jordan, representative of residential and commercial facilities, to examine the causes of delay. The study identified the key factors in delays for public projects as weather conditions, site conditions, economic conditions, delays in deliverables, increase in quantities, and inadequate design. Hsieh et al. (2004) conducted a statistical analysis to find the root causes of change orders, based on data collected from 90 completed metropolitan public works projects in Taipei. The study indicated that issues in planning and design are the key sources of change orders in such projects. In addition, the study identified thirty-five change-order causes within nine categories, and ranked those as per their impact effect. Ibbs (2005) studied the influence of the timing of actual change implementation in the project delivery process on performance. Importantly, the study results determined that changes implemented late in the project timeline have a more detrimental effect on project performance than changes implemented early in the project timeline. In addition, the study proved that changes have a negative effect on craft labor morale and productivity. Assaf and Al-Hejji (2006) investigated the causes of delay specific to large construction projects. The study identified seventy-three causes of project delay. Additionally, the study conducted a field survey among owners, contractors, and consultants to examine frequency, severity, and importance of identified delay causes. Ibbs et al. (2008) conducted a meta-analysis of previous research studies to
show that incremental project changes have significant impact on productivity. Ibbs developed a statistical model to evaluate the effect of changes on craft labor productivity. Sun and Meng (2009) conducted an extensive literature review on construction project change causes and effects, and developed two taxonomies to explain such causes and effects. Ibbs (2012) statistically analyzed change orders from 226 construction projects to identify change patterns, and quantify change impact on project cost, schedule, and productivity. The study found that the entire impacts of a change upon authorization are not well understood by both owners and contractors. As mentioned earlier, these successful studies have not yet provide a generalizable but specific answer to whether or not a relationship exists among change events and, project cost and, schedule deviation, and how frequently such events occur.

4 METHODOLOGY

The research method consisted of three key steps: categorization of change orders, data collection with a survey instrument, and data analysis. First, a detailed review of the existing literature in the topic resulted in a preliminary categorization of change types. The literature review was conducted through key word search, analysis of relevant articles, and further retrieving and analyzing meaningful references in the previously reviewed papers. This preliminary categorization of changes was also contrasted and improved with actual change log categories from 12 industry organizations, and resulted in a broad list of 310 potential change reasons. Through 4 face-to-face research charrettes with a group of 15 industry members over a period of half a year and additional phone call meetings, the list change reasons was sequentially reduced to 36 specific change reasons, and grouped into major 10 types of changes. Table 1 contains the classification of changes by type and category.

Second, a survey instrument was designed to collect general project data on completed projects, their change log data, and also on the corresponding separate impact of changes on cost and schedule deviations, if any. General project data included multiple specific inquiries related to cost and schedule performance, project delivery method, use of incentives, project controls structure (e.g. field vs. home office), among many others. Survey respondents were selected through random sampling within experts on project management and controls affiliated with CII member companies. In total, we collected 135 responses with retrospective data on an equivalent number of completed projects. The aggregate equivalent installed costs for the 135 completed projects was $28.88 billion, with a combined project completion time of about 300 years. Median schedule deviation at completion was 7.91 percent, while the median cost deviation was 5.93 percent. The sample of projects was well distributed between contractors (52%) and owners (48%). Project sector affiliation was 49% for public, 47% for private, and 5% for both public and private sectors. The projects were also representative of multiple organizational roles, as Table 2 illustrates. Notice that respondents frequently selected several organizational roles, so that the sum of the percentages in Table 2 actually exceeds 100%. The projects were also representative of multiple industry sectors, as Table 3 illustrates.

5 RESULTS AND DISCUSSION

Each survey respondent used a 10-point scale (from 1-low to 10-high) to assess the impact of changes in the project on cost and schedule deviations at completion. Respondents separately provided the assessment of change reason types according to the project change log. Table 4 contains the most occurring changes, by frequency of occurrence, with an impact on cost, while Table 5 contains the most occurring changes, by frequency of occurrence, with an impact on schedule. Indeed, order-of-magnitude differences in the frequency of individual change reasons exist. Most recurrent types of change events for both cost and schedule are associated with the following: construction productivity issues; planning; supplier and subcontractor issues; scope errors and omissions; design/engineering errors and omissions; and engineering productivity issues. Virtually any project is likely to face several of these change events. On the contrary, there are other types of change events that show a low recurrence, but, as explained below, tend to have a larger impact on performance.

In order to assess the importance or influence of changes on cost and schedule performance, we defined the metric of average impact effect, which was separately computed for each change reason with respect to cost and schedule performances. Indeed, the average impact effect for a particular change on cost or schedule responds to the sum of the product between impact value (on a 1–10 scale, from low to high) times the corresponding project cost or schedule deviation, divided by the number of project instances with such cost or schedule change (Back and Grau 2013). The average impact effect scores were then grouped by high, medium, and low intensity. Tables 6 and 7 represent the changes with top ten average impact effect for cost and schedule outcomes respectively and their corresponding frequencies.

Indeed, it is observed that the frequency of a change does often have an inverse relation with the severity of its impact on cost or schedule performance. Indeed, changes were observed to have a high frequency of occurrence often show a small impact on cost and/or schedule deviations, while those with a low frequency of occurrence often have a large, or severe impact on cost and/or schedule performances. Among the top 10 change events with them most impact on cost, only two of them occur in more than 10 percent of the projects. Change events with the most impact on cost were: standard, regulatory, and legal requirements; project team integration; procurement processes, natural threats; or project management issues. In addition a similar relationship observed between the low-probability change events and a large impact on schedule exists. Labor disputes, infrastructure or site issues, and permitting problems may seldom occur, but when they do, they are likely to have a high negative impact on project completion time. Among the most influential change events affecting schedule is the occurrence of scope changes. Indeed, scope changes have proven to be somewhat more frequent and observed in fifteen percent of sampled projects. Scope changes tend to have ripple effects on the project delivery process, and fundamentally affect core management functions, such as estimating, planning, and execution. The results indicate that the frequency of a change is inversely correlated to its impact on cost and/or schedule deviations, a notion that may have existed in industry but that had not been previously documented.

A probable explanation for the inverse relationship between frequency and average impact effect is that highly recurrent change events are more easily expected, identified, and addressed by the project team. Infrequent events are not likely to be accounted for during the planning of a project and, hence, when they occur, they are not rapidly addressed and result in a significant negative impact (Back and Grau 2013, Ibbs 2013, Westersund, 2008). These types of infrequent events, though, prove to be the most influential on cost and schedule deviations. Ensuring that potential high-impact events are communicated and addressed as soon as they can be predicted or occur is critical to reduce their impact on performance. The information in this section is useful to industry teams so that they inform how to address underlying change reasons that are associated with revisions to cost and schedule performances and forecasts, and how frequently such reasons can be expected.

6 CONCLUSIONS

Change management plays a critical role in the effort to identify changes early, and evaluate and implement responses to changes in a proactive and effective manner. The later the recognition of a change, the more difficult it becomes to implement corrective actions, mitigate cost and schedule impacts, and accurately and timely forecast project performance at completion. As important as change management is to industry, to date there is a lack of concrete evidence of what the frequency of a change may be, and what its intensity on cost and schedule performances could be.

In order to fill such gap in the body of knowledge, we have statistically analyzed change log information for 135 completed projects to prove the long-held perception that the impact of change is inverse to their frequency, and thus help industry professionals to recognize change events early. Indeed, this study reveals that change events or reasons tend to have significant different consequences on cost and schedule deviations. We found that the frequency of a change does not necessarily directly correspond to the severity of its impact on cost or schedule performances. Specifically, fairly infrequent change events tend to cause large deviations. Also, we have learnt that different change reasons impact cost and schedule performances with different occurrences and intensity. Indeed, some changes were observed to have a high frequency of occurrence with a small impact on cost and/or schedule deviations, while others were observed to have a low frequency of occurrence with a large or severe impact on cost and/or schedule performances. For instance, permitting issues are rare, but, when they occur, tend to have a very significant impact on schedule, but a moderate impact on cost. In summary, we identified change types that are most frequent, and those which are most influential for both owners and contractors, for both cost and schedule.
Overall, this study provides a better understanding of the severity of impacts associated with various change events, and should be used to enhance risk, contingency, and change management practices. Above all, indications of potential changes should be continuously sought and communicated as early as possible. The early recognition, communication, and remediation of changes are critical to decrease their impact on performance. Changes and events will happen, but they must be recognized and proactively addressed by the project team in order to mitigate their impact.

THE INTERFACE BETWEEN BUILDING INFORMATION MODELS AND THE PUBLIC

Raghav Grover¹, Peixian (Ariel) Li¹ and Thomas M. Froese¹,²

² Thomas.Froese@ubc.ca

Abstract: Almost all work to date in the field of Building Information Modelling (BIM) tools has developed software for building professionals: designers, constructors, and operators. However, another important group of potential users is the public. Use cases fall into two broad categories. Pre-construction applications span the design phase and all forms of public engagement during design development, from traditional user-feedback/community engagement processes to innovative applications such as crowd-source design. Post-construction applications include a variety of occupant-centric scenarios, including building dashboards, occupancy-assessments, etc. The relevant technology spans both BIM and social media. The Green 2.0 project aims to develop a middle-ware platform to support a range of BIM-to-public applications, with an emphasis on building energy performance and related “Green” applications. By analogy, if Facebook is conceived as a platform for a public-to-public interaction, and Google Maps as a platform for public-to-geospatial interaction, then the Green 2.0 project aims to provide a platform for public-to-building interactions. This paper describes the problem domain and preliminary work to develop the pre-construction and post-construction application areas for the Green 2.0, BIM-to-Public platform.

1 INTRODUCTION

Building Information Modeling (BIM) is a technology which has caused a paradigm shift in the Architecture, Engineering and Construction (AEC) industry, it has transformed the way buildings are designed, constructed and managed. BIM is moving the construction process from being “lonely” to “social”, in the sense that BIM is enabling professionals: designers, constructors and building managers to easily share information with each other. Another set of potential users is the general public and the occupants of buildings, who can contribute useful information to the building owners, designers and operators. The current performance gap in buildings is twofold. On one hand, the actual energy saving and resource usage like water usage are not as expected (Turner and Frankel 2008). On the other hand, occupants in green buildings have not been shown to exhibit a higher satisfaction compared to those in conventional buildings (Birt & Newsham, 2009; Altomonte & Schiavon, 2013). A building-to-end user interface can help in reducing the performance gap in buildings and can also create a more satisfying indoor environment for the end-users. In the design phase, end-users preferences and opinions can assist the designers and owners to come up with a user-driven design and innovation. Similar, in the post-occupancy phase, the user interactions with the BIM model can help in capturing occupant feedback about the indoor environment in buildings which can be useful for building operators.

In recent years, end user engagement in the product development industry has been gaining importance. Some social media tools like blogging, online forums, video sharing and social networking are turning out to be useful for facilitating this engagement. Crowdsourced design and rapid prototyping are some of the common methods being used in the product development industry. With recent advances in information
technology in the construction industry, 3D modelling and visualization tools like BIM are becoming commonplace. This has created a potential for developing applications that can bridge the gap between the buildings and end-users. In fact, the average North American spends about 87% of his time inside the built environment (Klepeis et al. 2001), hence it is imperative that the building end-users’ design preferences and indoor environment quality feedback should be considered.

The Green 2.0 project, being led by the University of Toronto, is aimed at adding user interaction in design and operation of facilities through using Web 2.0 and gaming technologies with BIM software. The objective of our study is to develop web-based or mobile applications built on the Green 2.0 middleware platform to provide end-users with an easy-to-use interaction interface with the building. These applications will then be tested on the existing and to-be-built buildings in the University of British Columbia (UBC) campus using the Living Lab methodology. This paper describes the problem domain and preliminary work to develop the pre-construction and post-construction application areas for the Green 2.0, BIM-to-Public platform. An outline of the Green 2.0 project is provided in the second section. The third section provides a brief overview of developments in the current building-to-end user interfaces. In the fourth section the conceptual use case scenarios in the design and operation phase of the buildings are discussed. The future work related to this study is presented in the final section of the paper.

2 GREEN 2.0

Achieving a sustainable built environment requires socio-technical solutions. Technology and hardware for green buildings have reached unprecedented levels of advancement, yet the decisions to achieve energy and water savings, ultimately, rests on end-users and other stakeholders. Given that modelling and analysis tools have been developed by engineers for use by engineers, the bottleneck over the life cycle of green building management now lies in the human interaction of end users with the facility during design and operation.

We must match the advanced technical tools with socially-savvy tools that engage people in the design stage to make sure that designers understand their needs and attitudes towards energy usage, and that involve larger communities in the visioning and design processes as expected by new net-native generations of home buyers and building occupants. We also need to fully inform users of green opportunities and their possible role in enhancing the energy profile of their facilities in operation phase.

Green 2.0: a middleware platform for enabling socio-technical analytics of green buildings is a collaborative research project led by the University of Toronto. The project aims at developing a web-based middleware platform to empower professionals from diverse background to create analysis applications while engaging users’ ideas. The platform brings together several core enabling technologies: open BIM for modeling buildings and related project information, social networks and social network analytics for supporting user interactions and investigating the results of this social interaction, energy analysis to model and provide feedback about the impact of various design alternatives, and business process modelling to model users’ activities. The Green 2.0 platform will be open source and free to use, not only open to professional engineers but also available to public users. The Green 2.0 platform provides a base for us to create applications which will give users access to building information and encourage user engagement in both the design and operations phase. The preliminary work on these applications is presented in the fourth section of the paper, Building-to-end user interface.

Research to explore if, when, and how to engage users in building design has been an ongoing subject of research and development. Some researchers have categorized four types of user engagement: unidirectional social research (USR) (information/education), USR (decision support), weak interactive social research (ISR) and strong ISR. Strong ISR, which engage users in all phases of research, is recommended, but studies on ISR projects show that changes are needed in institutional arrangements and organizational settings for ISR (Talwar et al. 2011). Another research project, where novice users were asked to create Business Intelligence information dashboards, found some drawbacks in novice users’ design, such as lack of concepts on categories, lack of consideration in coordinated view, and less consideration on data filtering (Elias and Bezerianos 2011). Therefore, we will collect users’ opinions
when developing the interface but not let the users to design any applications in our research. In this paper, the user engagement refers to using the building-to-end user interface.

To better achieve user engagement, an easy-to-understand building-to-end user interface should be useful (functionally), usable (it is easy to do things), and used (attractive and available) (Glawischning et al. 2011). A number of previous research projects have explored this issue, such as the following two projects:

Robert Zach, et al. developed a Monitoring System Toolkit, MOST, an open-source, vendor and technology independent toolkit for building monitoring, data processing, and visualization (Zach et al. 2012). The toolkit is based on five components: Connectors, Database-Core, Java-Framework, GWT based web interface, Matlab-Framework and thus supports use of building data from various resources. MOST provides a web-based visualization framework to support some use cases such as 3D building browsing. The platform is similar to Green 2.0 platform but the user interaction in MOST focuses on drag and drop and highlighting. One thing that may be valuable is that with the claimed powerful data preprocessing function, the toolkit is allows access to salient and dynamic building information such as zone temperature and energy use, which are the main concerns of building stakeholders including occupants. Although no user applications for presenting such building data were developed, the MOST research team conducted user survey and focus group sessions to investigate the importance of different kinds of information (Chien et al. 2011). The results offer some guidance to the development of our use cases, which will be specifically discussed in Chapter 4.

VIC-MET is a tool developed at Aalborg University in Denmark to involve end-users in the building design process. It offers four different design spaces to enable user-involvement throughout the design process from the mapping of the context to the final solution. Various ICT tools like IHMC CmapTools for conceptual modelling and Ramboll VR Wii for interactive visualization are described in the VIC-MET handbook to support VIC-MET activities in these four different spaces (Christiansson et al. 2011).

The use of social media to present the user with 3D virtual models of the building is another useful method to capture user opinions. In the Finnoo-Kaitaa project, a web portal was used to share project information with end-users and an online forum where registered users can freely propose new ideas and like comment of others. The Nissola Street and railway plan made use of an Internet application that enabled citizens to place comments on different parts of the 3D model while flying through it (Jäväjä et al. 2013). GreenNetwork, developed at UC Berkley, is another social media prototype application integrated in the work environment aimed at promoting a “green work style” amongst the people. It allows people to track their energy use, share this information through social media platforms like Facebook and LinkedIn, and comment on the energy use of their peers (Lehrer et al. 2014). POE 2.0 is a new bottom-up approach towards Post-Occupancy Evaluation (Daltona et al. 2013), it involves analysis of user reviews and comments on social media websites like Yelp, TripAdvisor and ArchDaily. The Smart Campus project being undertaken on four European Universities uses the Living Lab methodology. Their applications are aimed at influencing and transforming the user energy consumption behavior by enabling user interactions with the building. The project expects energy savings of about 20% and 15% of which will be due to user behavior transformation (Nina et al. 2014). These tools and methods have proven to be effective in terms of engaging the users. However, currently there are no applications available that can connect the general public to the BIM model of the facility.

3 CONCEPTUAL FRAMEWORK OF BUILDING-TO-END USER APPLICATIONS

The conceptual framework to develop the building-to-end user applications consists of four steps. First, develop a conceptual process model or algorithm of the application. Use cases will be used to illustrate the requirements and processes that the application will have in this phase. Second, use the use case processes to drive the development of a conceptual data model. This stage will be used to determine how to collect required data and how the application interacts with the data. Flowcharts, process models, and pseudo-code are used to show the processing procedures. Third, programmers will turn the conceptual data model into a detailed implementation-level data models. Fourth, the implementation-level processes
will be programmed around the data model. Our research efforts will be focused on the first two steps. The remainder of this chapter will introduce the work done to date in the first stage.

The focus of the “SocioBIM” applications being developed in our research is on the three different targets areas as depicted in Figure 1. The social net positive target area is aimed at incorporating sustainable values in occupants which results in green behavior amongst occupants. Green and regenerative buildings often focus on achieving a net zero or net positive energy, for example the CIRS building on UBC campus has a net positive energy performance. However, there is not much emphasis on social net positive performance for buildings where occupant’s satisfaction, health and productivity are enhanced by the building environment. The performance gap in buildings often exits due to inappropriate use of the buildings systems by the occupants. These applications will aim at minimizing this performance gap by creating a competing environment amongst the building occupants. In the design and operations phase, these applications will enable occupant feedback and opinions, which will provide useful information for designers, owners and operators.

![SocioBIM Applications](image)

**Figure 1 Target areas for SocioBIM applications**

The applications will be linked to the middleware interface being developed in the Green 2.0 project. The use of these applications is limited to the design and the operations phase. In the next two subsections the conceptual ideas for two of the SocioBIM applications will be discussed.

### 3.1 Use Case in the Design Phase

For the design phase, the primary focus of the SocioBIM application is to present the users with a curated BIM model of the facility extracted from the Green 2.0 middleware. The end-users of the facility are able to easily navigate and walk through in this curated BIM model, similar to the Google Maps street view interface. In addition to navigation, the users have the option of commenting, like/dislike certain parts of the model and can propose some design changes as well. As shown in the use case scenario in Figure 2, users create a profile, access the model and they also enter their design requirements. The data collected is then analyzed by the designers and buildings owners to make appropriate changes to building design. These different user entries will ultimately result in a design evolution of the facility. This application can be used in buildings where end-users are known at the time of design of the facility which is possible in case of high-rise residence, office buildings and academic buildings.
3.2 Use Case in the Operations Phase

A typical post-construction application is a building dashboard. Autodesk is conducting a research named Project Dasher, which is aimed at collecting and displaying occupancy information, but it is not for end users’ involvement in any phase of construction. Real-time building dashboards will visualize information collected from sensors distributed throughout a building. Specifically, occupancy, power usage, heat sources, airflow, and temperature are presented (Autodeskresearch.com, 2015). We will develop a dashboard to present building data for occupants.

3.2.1 What information to present

The results from the MOST research (survey and focus groups) (Chien et al. 2011) demonstrated that users are more interested in knowing about heating/cooling system, electricity, temperature, humidity, illuminance, the number of occupants, and ambient lighting. Users prefer to use laptop and smart phones to get building information. They wish the user interface be simple and clear, easier to interact with. One feedback mentioned the value of “comparison” function of “Oberlin”, which is in accordance with one of our ideas to incorporate a type of “competition pattern” to motivate occupants to reduce energy consumption.

To summarize, our goals are to provide the information that users care most about, illustrate the sustainability of the building and encourage green behaviors. As a protocol to illustrate the ideas above, the dashboards will be presenting these four types of data:

- Electricity usage: This will be divided into Lighting, Devices and Heating/cooling systems;
- Thermal Comport: Temperature and Relative Humidity with votes;
- Health credit: Individual health credit and Average health credit of all the people in the building;
- Energy credit: The energy credit of the working station (room or floor) will be displayed with the average energy credit of all the working stations in the building.
### 3.2.2 How to collect and present data

The building dashboard will use data from building operating system, and Green 2.0 Middleware. The dashboard is web-based. Occupants can get access to it from their own laptop. Each office, each floor, and the whole building can have a big screen showing the dashboards at every entrance. This use case is applicable mainly to office buildings and academic buildings.

### 3.2.3 Functions

The dashboard shows the real-time electricity usage with a pie chart and compares each division with the expected levels. When the usage is over expectation, the usage column and number will turn red to alarm the users. In reverse, it assigns energy credits to spaces where energy usage is below expected levels. A vivid 3D building model with energy usage or room credits of all the rooms in the building is accessible from the dashboard. This provides an intuitive sense of competition. Moreover, occupants can vote on their preferred temperature levels through the dashboard website. Therefore, the building manager or the office manager can adjust the temperature according to people’s needs. With granted rights to vote on temperature, people are encouraged to interact with the building. In addition, people can enter their mode of commute to building, use of stair v/s elevators, etc., in order to earn individual health credits. This is to encourage green behaviors among occupants.

![Diagram of user interactions](image)

**Figure 3.** Use case for end-user interaction during building operations.

### 4 FUTURE WORK

In the following research, the aforementioned conceptual ideas of the SocioBIM applications will be further developed into detailed process maps specifying their requirements and functioning. These process maps will then be used to rapidly prototype these applications in buildings on UBC campus using the Living Lab methodology.

In terms of future work in building-to-end user applications, researches can focus on developing more use cases that are tailored to occupants’ need and trying to connect with big data in social media which can...
make the application not only open to the public but also automatically provide scientific suggestions to
designers and building operators.

5 ACKNOWLEDGEMENTS

The authors would like to acknowledge the support from CANARIE through the Green 2.0 project (PI Prof. T. El-Diraby, University of Toronto), and from the Natural Sciences and Engineering Research Council (NSERC) through the Sustainable Building Science Program (PI Prof. M. Abstract: Various energy prediction tools and methods are widely used in the design process to reduce the energy consumption of buildings. It is also well known that not only the system selection but also the synergies of these critical system selection decisions have impact on building energy performance. However, these decisions are incorporated into simulations without synergies are considered early in design process. These late evaluations cannot go beyond the projection of energy performance that is already selected for design. Thus, this is a need for a decision support system that stimulates the integration of decisions to achieve higher levels of energy efficiency compared to considering individual measures. In the light of these indicators, this paper presents a critical review of energy conservation measures (ECM) used in retrofit project case studies. The individual impact of changes to these critical ECMs is modeled in EnergyPlus and eQuest. A simplified energy prediction methodology fed by a process model, and the possible synergies are presented. The prediction range is tested in three case studies with different energy performance levels. The calculation algorithm relies on determining individual system performance relative to the ASHRAE standard. This relative system performance evaluation is also useful in defining the scope of system retrofit by comparing options with the standard baseline. It assists collaborative design teams to evaluate the individual impact of system decisions and overall energy saving prediction rate earlier in the design of a variety of deep retrofit projects.

1 INTRODUCTION

Approaches to support decision making prediction in energy performance include checklists, databases, and forward and inverse modeling. It is well known that integrated system upgrades result in significantly more energy reduction rates than standard approaches. However, these synergies between decisions are not communicated to all team members in order to be able make energy-efficiency decisions early in the design process. In a typical energy efficient retrofit design, decisions are entered into simulations without collaboration to document and predict the energy performance of design. These late evaluations cannot go beyond the projection of energy performance of what has already been selected for design. Thus, there is a need for a simplified energy analysis methodology to provide instant comparative performance evaluations and to improve decision making by interdisciplinary design teams.
This paper reviews energy efficiency initiatives and measures in retrofit projects and then presents three case study projects that informed the development of a new approach to comparative energy outcome analysis in deep retrofit projects. The key features of the new approach are presented and the benefits over conventional approaches highlighted.

2 ENERGY EFFICIENCY INITIATIVES

2.1 Energy Efficiency Metrics

The energy performance target of a retrofit design affects the criteria used for system selection. These selections are usually based on energy conservation measures (ECMs). An ECM is intended to improve the energy efficiency of building infrastructure, including heating, cooling, and ventilation systems, utility systems, roof, and windows. This is achieved by an engineering investigation to identify potential replacements of, or upgrades to, existing systems that enhance energy efficiency (Kunselman 2013).

In order to evaluate the performance of ECMs, it is important to quantify their impact on building performance. One of the most common quantitative energy comparison measures is energy (Btu) per square foot, energy (Btu) per occupant, and cost per square foot (PNNL 2012). Designers usually make comparisons by using the Btu/sqf per year. These comparisons generally rely on various energy simulation tools, databases and checklists. According to a study done in 2007, there are 330 energy performance evaluation initiatives available using different measures of performance outputs (WBDG 2014). These initiatives include websites, technical publications, software, databases, checklists and matrices. From the literature review on performance evaluation metrics of energy efficient buildings, the most common units of analysis for energy efficiency are as follows:

- LEED Scorecard: Certified, Silver, Gold, Platinum (USGBC 2005),
- Normalized Annual Energy Consumption and Energy Use for heating in kWh/m2 (Rey 2004; Zhu 2006), Annual Electricity Use in kWh/m2 (Rey 2004),
- Energy and Time consumption Index (ETI) (Chen et al. 2006),
- Energy Saving by Retrofitting expressed by (1- Energy/ Energy Baseline) % (Gholap and Khan, 2007).

For the purposes of this paper, the energy percentage reduction output measure defined by Gholap and Khan (2007) for energy performance comparisons was used.

2.2 Energy Efficiency Initiatives

As mentioned before in the scope of building performance evaluations; checklists, technical publications/standards, and software are the most popular initiatives. These initiatives carry different levels of information and are more beneficial to a certain design phase than others. With the use of different units of analysis, the performance evaluation methodology also varies.

2.2.1 Checklists

Checklists and rating systems provide a holistic performance evaluation in addition to energy performance. One of the most common green building rating systems is the Leadership in Energy and Environmental Design (LEED™) program that was developed by the United States Green Building Council (USGBC). This program aims to provide third-party verification that a building or community was designed and built using strategies aimed at improving performance across all the metrics that matter most: energy savings, water efficiency, CO₂ emissions reduction, improved indoor environmental quality, and stewardship of resources and sensitivity to their impacts (USGBC: What LEED™ is 2010). 10 bonus credits are available, four of which address regionally specific environmental issues. This individual type of approach provides more flexible and reliable results for green building performance. There are also
different types of certifications for different types of buildings, such as Core and Shell, and Commercial Interiors.

### 2.2.2 Technical publications and Standards

**Technical publications and standards** prepared by professional societies, national laboratories, and academicians are also used in the design process as a benchmark and recommendations. The outcomes of these studies are improved on year by year to improve the energy efficiency of buildings. American Society of Heating and Air-Conditioning Engineers (ASHRAE) has developed the ASHRAE 90.1 standard to provide minimum requirements for the energy-efficient design of buildings except low-rise residential buildings (ASHRAE 2007). Various versions of this standard are widely used in the building industry. As seen in an analysis done by a national laboratory (PNNL 2011), ASHRAE 90.1-2010 standard targets a minimum requirement of 19% lower energy use than ASHRAE 90.1-2007, and 24% lower than ASHRAE 90.1-2004. In this research, ASHRAE 90.1-2007 is used as a common baseline to compare case studies. It is on continuous upgrades every three years. The current version is ASHRAE 90.1-2013.

In addition to providing minimum requirement standards, ASHRAE is delivering performance and process related recommendations. ASHRAE 189.1 is targeting higher energy efficiency levels for the design of High-Performance, Green Buildings except Low-Rise Residential Buildings. In addition to these efforts, ASHRAE delivered Advanced Energy Design Guide 30% to 50% to explain and show a way and recommendations to achieve 30% and 50% savings relative to ASHRAE 90.1. Briefly, this guide provides critical ECMs under four main categories: optimize orientation and glazing, use efficient building systems, use efficient energy producing systems, and engage occupants (ASHRAE 2011). These ECMs include energy measures for envelope, lighting, HVAC water and air side, renewable sources, and plug and process loads. This specific technical publication is designed to provide recommendations to achieve 50% energy savings when compared with the minimum code requirements of ASHRAE Standard 90.1-2004. It also gives hints on an efficient process with key design activities as organized below (Table 1).

2.2.3 Modeling Techniques

The use of modeling techniques has increased year by year in order to predict a relative energy efficiency rate to building performance standards. There are four times more building performance simulation (BPS) tools than nearly 15 years ago. However, the increase in tools used by architects in early design is not as high as the increase in the engineering tools used for system design later in the design process (Attia et al. 2012). In particular, the ECMs and user interfaces are specialized according to certain systems and disciplines. In this paper, the aim is to provide a list of ECMs that are meaningful for architects, engineers, and project managers in a collaborative decision making environment.

With regard to energy consumption analysis techniques, there are two types of prediction methods. First, inverse modeling is commonly used more in academia, which is used to predict building parameters such as ECMs by energy use and drivers with statistical models. Secondly, forward modelling is commonly used more in industry to predict energy use by building parameters and environmental drivers such as weather using energy models. There is a need for more case studies to provide valid statistical models rather than energy models. Thus, the forward modeling technique was used due to a limited number of case studies. Also, one of the objectives of this research was to understand the practical context and approaches for the decision making environment of the deep retrofit design process. In-depth process evaluation was prioritized over energy evaluation, which is defined as comparative performance of alternatives rather than precise energy consumption prediction.

Since there are around 400 energy modeling tools (DOE Website 2013), designers are willing to use the most realistic prediction tools. However, these tools are not only specialized based on expertise and experience, but also on specific design phases. A study shows that only 1% of BPS tools carry pre-design information (Attia et al. 2012). This shows that the aim of using the tools is to predict the performance of already selected design alternatives. Another study shows that starting energy simulation at the conceptual design phase has greater impact ability on the level of energy efficiency performance than schematics and starting even later at design development phase provided significantly lower level of green performance outcomes (Gultekin et al. 2013).

Figure 1: Pearson's correlation analysis results showing the effect of starting to use energy simulations at various phases of design on high-performance green index (Source: Gultekin et al. 2013)

Since the goal of this paper is on improving the collaborative design decision making environment, the focus was placed on the early phases of design. Performance analysis was undertaken with a simplified comparative energy comparison rather than energy prediction.

There is still room for improvement in terms of the energy predictions of forward modeling tools. A study compared three widely used energy simulation tools; DOE-2, DeST, and EnergyPlus (Zhu et al. 2013) by using three case studies (simulated cases). Figure 2 shows the discrepancy of annual heating and cooling loads (kWh) with the use of the same building parameters, environmental drivers, and occupancy behavior.
Figure 2: Prediction comparison of DOE-2, DeST, and EnergyPlus in annual heating and cooling load of same building (Source: Zhu et al. 2013)

Even though these there still discrepancies in the performance prediction of these three tools, they are pretty detailed in terms of ECM parameters and calculation algorithms. Since the focus of this study is on a comparative analysis of ECMs, the impact of particular ECMs was tested by simulation using EnergyPlus. For this analysis, DOE Commercial Reference Building’s EnergyPlus data was used to simulate certain technical criteria (NREL 2010). For retrofit comparison basecase, a medium sized office building in Zone 5A (RefBldgMediumOfficePre1980_v1.4) climate region by using State College typical meteorological year TMY weather data. ASHRAE 90.1 Prototype Building Specifications was used as as base case (PNNL 2014). For the selection of critical technical criteria, simplified energy simulation tools that use the most critical ECMs to predict energy were reviewed. Energy-10, developed by National Renewable Energy Laboratory (NREL), was one of the rare early design tools that provides annual energy use information, cost breakdown, and ranking of energy efficiency strategies (Deru et al. 2010). Another simplified energy model is Design Advisor, developed by MIT (2007), which also provides ECM inputs such as: zone configuration, building orientation, room, window, wall, thermal mass, occupancy, and ventilation rates. Its aim is also to improve the understanding of ECMs for various disciplines with a simplified user-interface.

These tools still require the input of form, zone, orientation, occupancy, and internal loads. This study is limited to a specific region, form and building type, and excludes orientation and zoning impacts in energy performance analysis.

3 RETROFIT CASE STUDIES

In this research, case studies have been found appropriate to gain first-hand experience of the current approaches being adopted and to understand the practical context for decision making in retrofit projects. Three case study projects in Pennsylvania were investigated. Two of the projects were superior examples in terms of the collaborative design process and new technologies used, while one was a typical project that represents the traditional retrofit process.

Two of the case studies, Energy Innovation Center (EIC) Retrofit Project and Energy Efficient Buildings Hub (EEB Hub) Retrofit Project in Pittsburgh and Philadelphia respectively are deep retrofit projects. Both projects are best practice examples regarding the collaborative project delivery process and energy efficiency technologies used. The decision making is transparent due to the aim of delivering showcase projects in terms of energy efficiency technologies and techniques used as well as the process followed. The third case study was of an academic building (HHD) on a university campus, which provided an example of a traditional retrofit process; this enabled the identification of differences from the more modern approaches in the other two case studies through the cross-case analysis.

Case studies are selected purposefully to reflect the various levels of energy efficiency, process followed, and tools used. For the energy performance data, the case studies represented different levels of ASHRAE 90.1 and LEED targets. The two showcase projects represented an integrated project delivery approach based on contractual and informal project processes. The EIC followed a typical design-build approach with the early involvement of the contactor in the design process, while the EEB Hub project was an example of an integrated design process as part of an informal integrated project delivery (IPD) process. On the other hand, the HHD building represented a fragmented design process with a lower
energy efficiency target as a result of a design-bid-build delivery process. Additionally, the use of various simulation tools in different projects with different efficiency levels is beneficial for our simplified energy performance prediction test comparisons (Table 2). The multiple source calculation algorithms improve the validity of our energy performance range prediction.

3.1 Case Study Data Source

Case studies are the main data source of this research. Since the number of case studies is limited, construction projects were selected purposefully and compared with literature. The decision making environment and decision scope in the case studies were tracked by attendance in the project team meetings. The variety of energy simulation tools provided us to range our predictions with different algorithms. The simulation tools that are used for case study predictions are TraneTrace, Hourly Analysis Program (HAP), and eQuest.

4 CALCULATION ALGORITHM

After the key decision points were sequenced into a process model, certain steps that required decision support were refined. The refinement criteria were defined as energy efficiency performance and available technical criteria tracked in project participant interviews and documents.

4.1 System Algorithm

Related critical technical criteria from the key decisions point of view were collected from project documents and reports for all the case studies as follows.

ECM1. Natural Lighting Hours
ECM2. Interior Lighting Power Density
ECM3. Window-Wall Fraction
ECM4. Wall R-Value (assembly)
ECM5. Roof R-Value
ECM6. Window U-Value
ECM7. Shading
ECM8. Daylighting controls
ECM9. Ventilation Rate
ECM10. Chiller Efficiency
ECM11. Boiler/Furnace Efficiency
ECM12. Heat Recovery
ECM13. AHU Fan Type
ECM14. Pump Type
These ECMs were individually tested on Commercial Reference Building model (NREL 2010) as a baseline by using EnergyPlus v8.1 and the energy reports of EEB Hub Project that were created by eQuest. ECMs are taken from energy reports and created after the discussions in expert workshops. Input parameters such as u-value, COP, cfm/sqf are tested in EnergyPlus, and the output parameters such as natural lighting hours %, daylighting controls are taken from eQuest reports.

Finally, the individual system parameter efficiency represents the individual system efficiency (1- Energy/Energy Baseline)% (Gholap and Khan 2007) is used as a proportion of change in the case study and test options at certain key decision point as in Table 3.

4.2 Algorithm Testing for Defining Range

Since the focus is on comparative energy performance rather than predicting energy consumption amounts, precision was not of prime concern. Based on the energy simulation, the results of EEB HUB, EIC and HHD (38%, 53%, 23%) are tracked in project reports submitted by project team members and compared with energy predictions by adding up individual system parameter efficiency ratings (e.g. 33%, 44%, 19%) The proposed prediction deviates 5%, 9%, 4% from the energy efficiency rates documented in reports, respectively. The precise average of deviation of three projects is 5.82% lower than the reported numbers. The prediction range was rounded to 10% more or less than the DSS prediction, which covers both the average and largest deviations that can result from the impact of interdependent measures.

In EEB HUB prediction calculation, the deviation is 5% which is lower than the average. The calculated prediction and reported performance gap is lower than the average performance deviation. There are two main reasons for such close prediction. First, all baselines and proposed performance criteria of ECMs were captured and documented well during the design of the project. Secondly, there are commonalities between the list of critical ECMs and test project ECMs while setting up the calculation algorithm. The list of tested case study parameters is documented in Table 4.

</tbody>
</table>

In the EIC prediction calculation, the deviation is 9% which is higher than the average. The prediction and reported performance gap is higher than the average performance deviation, but still in the range of 10% projected energy performance range. The prediction gap can be resulted from the uncertainty of baseline assumptions, which is mark as (*). These baseline criteria were not precisely documented due to inaccessibility of energy model, and flexibility of the project goal and system selections. Since the project is a green demonstration showcase, the interdependencies of the flexible system schedule enabled much higher efficiency than individual system performance. The list of tested case study parameters is documented in Table 5.

</table>
In the HHD prediction calculation, the deviation is 4%, which is lower than the average. The prediction and reported performance gap is lower than the average performance deviation. The prediction gap can be caused by the assumptions (*) made for baseline comparison. The preciseness of the baseline criteria is interrupted with inaccessibility of energy model, and unavailable proposed model parameter. Additionally, 5% ASHRAE 90.1 conversion difference is subtracted from 2004 version 2007 of ASHRAE according PNNL’s recommendation. The list of tested case study parameters is documented in Table 6.

5 CONCLUSIONS

A simplified comparative energy performance analysis methodology for deep retrofit designs has been presented. This study contributes to an integrated design process by providing critical decision stages with regard to energy performance, and describing the resolution of system decision conflicts by adding criteria impact. This relative system performance evaluation is also useful in defining the scope of system retrofit by presenting a comparison of options relative to a standard baseline. It assists collaborative design teams to evaluate the individual impact of sub-system decisions earlier by identifying potential synergies between sub-systems in the design of deep retrofit projects. The limitations of this research are as follows:

- Synergies are tracked for the future step, but not calculated.
- ECM impacts are calculated with a single energy model single tool and an energy analysis report with single set of decisions.
- Modeling level of detail is accepted as it is in Commercial Reference Building model. Zoning, occupancy, building type measures are accepted as constant. The prediction will improve with the reflection of these variables impact.
• The number of deep retrofit case studies is limited to create a complete list of all technical criteria. This study focused on tracking the critical technical criteria which are defined by project team members of three projects and literature review.

• Load calculation is analyzed based on final building energy load, not based on sub-systems such as heating, cooling, and lighting. Even though the impact of system on load type varies, the source of energy is accepted as electricity.

The future step of this study is developing a decision support system that provides guidance to interdisciplinary teams to analyze their decisions during retrofit design process. This tool will enhance system-based decision making process by comparing their proposed decision alternative individually and energy consumption reduction rate relative to a certain baseline.

Abstract: The concept of Civil Integrated Management (CIM) was developed to facilitate better utilization of data and information that would enable effective decisions for transportation agencies. It is important to select appropriate intelligent technologies or tools and use them efficiently. Moreover, data needs to be collected, stored, and managed wisely so that it could be used throughout the life cycle of a transportation facility and even for the next reconstruction cycle. This makes it necessary for agencies to have electronic document management (EDM) systems, so that they can manage and share their data with other stakeholders in an efficient manner. Though EDM systems have been implemented and their benefits are well understood in the building construction industry, they are not as common in the transportation design and construction industry, and there are only a few leader state DOTs implementing EDM at agency wide level. Since there are differences between the building and the transportation industry, it is desirable to analyze early examples of implementation from the transportation industry in order to achieve further progress. The purpose of this paper is to present and analyze current state of the EDM systems within the state DOTs that lead with regard to EDM implementation. During a United States National Cooperative Highway Research Project Domestic Scan effort, seven state DOTs and their contractors collaborated to present their extensive experience on CIM related practices and tools. Of these seven, four distinguished themselves with leadership in the area of EDM systems implementation while others were leaders in other areas. In this paper, those four agencies who are leaders with regard to the EDM systems implementation are analyzed and their practices are documented in detail.

1 INTRODUCTION

Electronic Document Management (EDM) systems have become more crucial to the transportation industry as more advanced tools and automated process have been adopted. Prior to the adoption of EDM systems, piles of paper plans or other documents had to be handed back and forth within agencies and/or between various parties. Considerable time and cost were spent on printing out and shipping hard copy documents during the duration of a typical project. Nowadays, with the adoption of EDM systems, personnel form various stakeholders can easily submit documents to the same platform, and other users involved with the project or a particular task can view the submitted documents and provide comments, concurrence and approvals. Furthermore, certain engineering products, such as 3D models must be delivered electronically, because they cannot be easily converted to hard copies. EDM systems eliminate the need for printing and shipping documents among various parties (Sulankivi et al. 2002). Moreover, the
documents or models might be stored in the system as permanent record if necessary, so that stakeholders can extract and use them in the future.

Especially after the release of Moving Ahead for Progress in the 21st Century (MAP 21) legislation, many leading transportation agencies started using various advanced tools such as EDM system, 3D modeling, GPS, GIS, automatic machine guidance and others. Also, programs such as Every Day Count (EDC), which is facilitated by Federal Highway Administration (FHWA) in the United States, is meant to encourage the adoption of various innovative methods and tools. E-construction, one of the topics under EDC-3, specifically addresses the importance and benefits of using EDM systems (FHWA 2015).

This paper presents the results associated with the EDM system obtained from the National Highway Cooperative Research Program (NCHRP) Domestic scan project 13-02 Advances in Civil Integrated Management (CIM). The final report of this project is expected to be released during the second or third quarter of 2015. During this scan study, panel members visited seven leading states to explore current practices related to CIM. Content analysis method was adopted to analyze the EDM system related presentations and documents provided by host agencies. It is found that EDM systems, as one of the major components of CIM, are helpful in increasing communication efficiency among various parties and retaining data integrity and transparency during the project duration. EDM systems adopted by four transportation agencies and their functionalities are analyzed in this paper.

2 BACKGROUND

Common tools used by agencies or companies to support electronic collaboration include document management, file sharing, emails, calendars, discussions, polling, and instant messaging (Munkvold and Zigurs 2005). Study results from 2003 indicated that about half of the larger contractors were already using project collaboration technologies to some extents in the US (Issa, Flood, and Caglasin 2003).

During the project duration, a large number of documents are usually produced, such as design drawings, schedules and estimates, meeting minutes, bill of quantities, and others. There has been several attempts at the standardization of those documents involved various industrial organizations in various countries. As word and CAD applications became more commonly adopted in the industry, traditional hard copies began to be replaced with digital forms of documents which can be distributed out by email or other tools. Subsequently, the EDM systems evolved with the capability to retain all of the latest documents that were generated during a project on the same web server (Björk 2006). Such systems could be created by an agency or company’s in-house staff, project participants, or a third party (Bjork 2003), and these systems were either developed at project/team level or at enterprise level (Munkvold and Zigurs 2005).

The role of metadata in EDM systems is important, as the directory structures embedded within the metadata could help mitigate potential damage that would result from loss of data or documents. Also, document searches become easier and more precise with the directory structure that can be devised from metadata (Tough and Moss 2003). The standardization of metadata and data storage is very important, as it could provide considerable convenience for downstream users (Bjork 2003).

Based on the case studies conducted by Sulankivi et al. (2002), the use of EDM systems resulted in 29 work days’ savings and avoided 1700 days of delay in information distribution, which together saved 17,300 USD for one single project in Finland. Major qualitative benefits of using EDM systems include easier document distribution and publishing, easy access to the latest updated versions of documents, and easy access to real-time information (Sulankivi et al. 2002). On the other hand, there are some challenges associated with the use of EDM systems. In a study conducted by Mohamed and Stewart (2003), it was indicated that considerable training and support related to the EDM system would be necessary for users. Becerik (2004) indicated that lack of studies on illustrating the EDM systems’ benefits resulted in the slow development and popularization of the EDM systems. In addition, Munkvold and Zigurs (2005) recommended that the EDM systems should be developed in a way that users can easily adapt to them. Otherwise, users might tend to select the older ways of performing work tasks. Also, guidelines and support should be developed to instruct new users about how to implement such systems.
3 METHODOLOGY

A content analysis approach was adopted as the major methodology to establish a better understanding of current practices on the implementation of EDM systems. The analyses were conducted as part of US Domestic Scan Project 13-02 that was entitled Advances in CIM which is managed under the auspices of the NCHRP 20-68A U.S. Domestic Scan Program. Scan team members were chosen from among leading state DOTs who have interest in adopting CIM related practices and tools in addition to the FHWA representatives. Scan team members, along with a subject matter expert (SME, the second author) and his assistants (the first and third authors), developed a set of amplifying questions relevant to the topics of interest including EDM system. These questions were then sent to the target agencies and their contractors and consultants. When scan team members visited the leading state DOTs, presentations were provided by the host agencies in response to the questions. Detailed notes were recorded during the presentations and interactions between scan panel members and host agencies. In addition, supplemental documents were also provided by the host agencies to assist panel members in better understanding their usage of certain tools. These notes and supplemental documents were systematically analyzed to provide the findings.

As previously mentioned, EDM is one of the major components of CIM. Various agencies or companies are using various EDM systems produced either by their in-house employees, project partners or commercial software developers. Four state DOTs who served as host agencies in this study were selected for detailed analysis, as they have relatively mature EDM systems and extensive experience in using such systems. Presentations and documents related to EDM were reviewed using the content analysis method (Elo and Kyngäs 2008, Neuendorf 2002). For Iowa DOT case study, additional documents obtained from Iowa DOT’s official website were also analyzed. In Section 4, the content analysis results associated with the EDM systems used in four target agencies are summarized and presented.

4 FINDINGS

4.1 Utah DOT

Utah DOT is currently using an application called Interchange which was developed using a Microsoft SharePoint platform. This program contains segments that were developed for different groups of users and also for different phases of projects. Additional segments are still under development. The program can not only be used by DOT personnel, but also can be used by their local contractors. This construction portal is adopted for 18 construction projects so far, and Utah DOT is planning to have all construction projects use this portal by the end of 2015. Some of the major capabilities provided by this program include document submission, task management, meeting minutes, and design review.

Through this program, various groups are able to submit their documents or design models to the same platform. When documents are being submitted, users can make selections with regard to the document filter, type, and subtype. This initial setup selection allows documents to be better organized within the system, making it easier and faster to search and manage documents. Users can assign other attributes to documents such as document event date and due date, phase, and others, and they can also specify which personnel within which group can receive the submitted document. Thus, when the documents are submitted successfully to the system, recipients are notified immediately.

Task management is another important function of this program. The schedule of various project-related tasks will be shown on a task calendar, which reminds users to perform the required tasks within the expected due dates. Tasks that are not completed yet are marked as open tasks, and users can view task status, due date, and responsible personnel for each open task. Users can not only view their own tasks, but also view tasks assigned to their group. Each open task is closed once it is finished.

Meeting minutes can also be tracked by this program. Meeting minutes can be recorded including other related information such as creator, meeting organizer, time, location, type, and attendees. At the same time, tasks can be assigned through meeting minutes if necessary. Utah DOT also tried to integrate this
meeting minutes stored in this program with other applications such as the agency’s email platform, however their attempt was unsuccessful due to data integration issues.

More importantly, this application allows for better tracking comments and responses, which makes design review process more effective. Usually in Utah, design reviews occur at 15%, 30%, 60%, and 90% of design. Design packet that needs to be reviewed can be uploaded to the system based on the planned milestones. When uploading the design documents, the system provides various options such as which disciplines are supposed to review the submitted materials and by which date the review is expected to be completed. Then, reviewers can provide their comments before the designated due dates, and subsequent responses will be created by design documents creators to address those comments. Each review document will be coded by different colors based on each division’s review status (e.g. not needed, no response, in progress, complete, etc.). When changes are made to the design documents, the responsible disciplines will also be notified to review the changes. Usually, solutions to proposed comments will be addressed in the next design review meeting. Between each design review meeting, project managers will also have intermediate meetings to track the design progress. Exceptions might occur when design-builders ask for reduction of the number of submittals or meetings, and decisions for approving such requests will be made based on actual cases. Compared to the traditional design review process where piles of paper need to be handed back and forth, this digital communication method increases work efficiency and flexibility as well as maintaining a digital record of comments and responses occurred during design reviews.

4.2 Michigan DOT

Michigan DOT requires all electronic documents submitted through ProjectWise platform (Bentley Inc. 2014) and kept up to date. The only exceptions are delivery tickets for hot mix asphalt (HMA), concrete, and aggregates, which are stored as hard copy documents. Contractors are responsible to coordinate electronic document submittals by their subcontractors, suppliers, fabricators, and others that are involved in the construction process. Failure to upload documents to the system will result in delayed payment.

In order to better manage all submitted electronic documents, there are rules developed for document format, folder structures, and user authorizations. For example, contractors need to sort and place their files into the following folders: correspondence, materials, payrolls, shop drawings, and sub-contractor in box. Michigan DOT also provided training courses on the use of their EDM system for their contractors. In general, by using this electronic document management system, all information could be stored in one place and stakeholders have easy access to the most up to date project-related data.

The level of authorization is determined and monitored to ensure that personnel can access files when necessary while maintaining the security. For example, the project team cannot view information in contractors’ inbox until the documents are submitted to the system. After contractors submit their documents, an audit trail will be attached to each file to achieve transparency. At the same time, restrictions are in place to prevent consultants or contractors who have competitive relationships from seeing each other’s proprietary information or intellectual property.

Additionally, Michigan DOT uses and accepts digitally encrypted electronic signatures. Digitally encrypted electronic signatures are not scanned copies of handwritten ones, but rather electronic “objects” containing unique identities, password, and date/time. Most commonly adopted software for placing digital signatures for Michigan DOT EDM system is Adobe Acrobat. Each user will have a unique digital identification (ID) and password. Before placing an electronic signature, the user is required to provide his or her password. After the signature is placed digitally, the electronic document will become a signed original file which has the same legal effect as a paper document with a handwritten signature. In terms of signature validation, document recipient can check whether the electronic signature is placed by an expected signer and whether the document is sent from an agency/company’s email account. If the signer has previously been verified by the system, there will be a green mark besides his or her signature. If the signer is new or cannot be verified, there will be a grey question mark besides his or her signature.
Michigan DOT developed a detailed instruction document for placing and verifying digitally encrypted electronic signatures.

4.3 New York State DOT

New York State DOT requires all project related electronic documents to be stored in its EDM System which is built on a ProjectWise platform (Bentley Inc. 2014). Project related electronic documents to be stored normally included studies, permits, mapping, plan sheets, digital terrain models, reports, control, calculations, photos, correspondence, and other items. Emails involving project-related decisions are also expected to be stored in the system. DOT personnel, consultants, or contractors are required to follow specific instructions for document naming conventions, categories, and formats to ensure that the documents can be better organized, managed and retrieved.

This system contains DOT’s DataSource and archive DataSource. DataSource is composed of various documents, folders, and their supporting database. Documents for active projects will be submitted to DOT’s DataSource (NYSDOT 2006). There are specific rules developed for folder and subfolder structures within the DataSource. Official project records will be created based on electronic documents that reside in DOT’s data source. After projects are completed, documents in DOT’s DataSource will be moved to archive DataSource by a data manager, so that they become permanent records.

In order to ensure system security, access is limited to stakeholders who have proper authority based on work groups’ responsibilities in various phases of a project. Read and write access will be given only to work groups that have active roles in a particular phase of a project. The rest of work groups without active duties will only have read access to a project. A regional data manager will be responsible for providing and changing each work group’s access as the project moves forward. For non-department personnel such as consultants, contractors, and partners, only the minimum access required for their work will be provided. Employees of an outside company will only have read and write access to their company’s designated folders.

All documents retained in the system are kept up to date. When a document is checked out, it means someone has downloaded the file for revision work and other personnel cannot make changes to this file at this stage. When the revision work is completed, this document will be checked back into the system. Alternatively, users can select update server copy option to upload the most recent version to the server and keep the document checked out for further work.

Attributes assigned for each document are important for organizing and searching information. When searching for a document, documents with attributes matching the search criteria will be displayed for users. Thus, when uploading a document, all appropriate attributes applicable to a document should be assigned by the document creator. In addition, information could be automatically generated in MicroStation based on the document attributes resided in predefined tags.

The archiving process is another important part of data management. Documents that are used to create officially approved project records should be included in the archiving process. Data owners are expected to determine which documents should be kept and which documents can be deleted and then convey their decisions to the data manager. At each stage of a project (e.g. scoping, design, and construction), there are rules developed for key data that must be stored in the archive. When project is completed, all project data should be moved to the archive DataSource.

4.4 Iowa DOT

Iowa DOT’s EDM system was developed using a Doc Express platform (Info Tech, Inc. 2015). Iowa DOT offers instructions for contractors and suppliers about how to use this system for electronic file storage and sharing (Iowa DOT 2015). Through this system, contractors can manage their contracts and associated documents systematically. They can view and sort their contracts based on their own preference, and they can choose to receive real-time notifications (e.g. ready to be processed, rejected, etc.) or request a summary report for all of their contracts and/or ones added in their favorite lists. Under each contract, they can select various virtual “(file cabinet) drawers” named based on document
categories for managing their documents, including Contract Documents, Pay Items, Payrolls, Contract Modifications, Working, Shop Drawings, and Signatures.

Documents are submitted to their appropriate drawers. DOT and prime contractors can open the submitted documents in the drawers to which they have access. Subcontractors and suppliers can only open documents submitted by their own companies, though they can see a larger list of documents. Documents will be electronically signed when submitters check the electronic signature box. Once documents are submitted to the system, no changes can be made to the documents’ contents. Comments can be added to those documents by other personnel or document creators.

The Contract Documents drawer is the place for storing documents related to a particular contract. This drawer is mostly used by DOT personnel, but there are also cases where the prime contractor needs to submit documents to this drawer. DOT users or the prime contractor can make comments on the submittals in this drawer. Likewise, the Pay Items drawer is used for storing pay item documents associated with a particular contract. DOT personnel mark the submittals as received or audited. The status of audited indicates that the materials users have audited the item and no further checking is needed.

Contract modifications (or change orders) are made in the FieldManager application (Info Tech, Inc. 2015) and then submitted to the Contract Manager drawer. Once contract modifications are submitted to the system, users who have access to this drawer will receive notifications immediately. The prime contractor needs to review the submitted documents and provide signatures if they approve those submittals. All associated activities could be tracked down through the system. The time, date, and personnel’s role associated with each transaction are visible to users with access. After all signatures have been collected, contract modification will be approved in FieldManager.

Payrolls sent from subcontractors can be certified by the prime contractor and then submitted to the Payrolls drawer by the prime contractor. The submitter can open and view the submitted payroll documents, but users associated with the prime contractor can only view the list of submittals. Also, only selected DOT personnel involved with the contract are given the access to those payrolls.

The Working drawer is designed for sharing documents that are produced during working process and should be continuously updated until the final version is completed. Once a document is finalized in the Working drawer, it will be published by a DOT user to its appropriate location (a specific drawer). As for the Shop Drawings drawer, it is the place to which shop drawings should be submitted. The prime contractor is the only user authorized to submit drawings to this drawer. Personnel who are supposed to review the documents can either open or download the drawings in this drawer and make comments if necessary. The Signature drawer is mostly used by DOT personnel and contains documents that need to be signed by one or more people.

4.5 Discussion and Comparisons

Generally, the EDM products described above are designed with three different approaches which could be categorized as:

- General purpose workflow and file storage solution (e.g. Microsoft SharePoint Platform)
- Document access solution originally developed to meet the needs of design groups (e.g. ProjectWise)
- Document management solution designed mainly for transportation construction agencies (e.g. Doc Express)

The original purpose and approach for the development of these products were somewhat different, so they all come with their own unique capabilities, characteristics, and IT support demands. However, there are common functionalities shared, such as:

- Document submission
- Electronic signatures
- Document access based on the predesignated level of authority
• Document sharing
• Document format and structure standardization
• Document searching based on the assigned attributes
• Creation and modification tracking
• Instant notice to related users

These functionalities appear to be adequate for supporting most transportation agency needs for electronic document management. Moreover, the communication process between various stakeholders becomes easier and faster when an EDM system is implemented. Despite the differences of these EDM implementation approaches, they have proven to be efficient in organizing and managing electronic documents within the same agency and exchanging documents amongst the agency, designers and contractors. In cases where current products could not support an agency's needs, modifications were made by collaborating with software developers or assigning in house or consultant programmers to produce a solution addressing agency needs. Overall, stakeholders provided positive feedback on the adoption of EDM tools for the purpose of data storage and exchange. In one case, a contractor trade association proactively encouraged the use of the EDM tool for file exchange.

During the application of these EDM tools, some challenges were also identified as below: (1) interoperability issues between various software applications and hardware are always challenging; (2) An insufficient budget is often initially allocated for purchasing and updating hardware and software applications; (3) It is difficult for agencies to decide whether to use an existing commercial product or to develop a customized in-house product; (4) Stakeholders outside the agency, such as contractors, might have difficulty accessing the system due to stringent protocols required to penetrate agency firewalls; and (5) It is often be difficult to obtain quick and effective specialized IT assistance within the unit that needs help, especially if IT support has been highly centralized (for example provided on a state wide basis).

5 CONCLUSIONS AND RECOMMENDATIONS

The EDM systems have become more commonly used in the transportation construction industry, as they help to better manage and share documents produced throughout the project life cycle. Currently, various companies or agencies are using various EDM systems which might be produced by their in-house staff, project partners, or third parties such as a software vendor. All these products are designed to help improve the digital communication process and increase work efficiency by reducing the time spent in handing hard copies of documents among various parties. Each product might have its unique characteristics and ways to support its users during the project duration or daily company operations. The intention of this study is not to conclude which product is better than the others but rather to present the functionality and real practice of EDM systems adopted within some leading transportation agencies.

It is important for agencies and companies to determine which product might fit their demand better or if they need to develop their own unique product. No matter which product they are using or planning to use, critical issues need to be considered include standardization of document submission and sharing, proper level of user authorizations, long term storage, training programs, IT support, and others. Essentially, the EDM systems are tools that can make the work process easier and faster. Discussions with host agencies indicated that as employees become more familiar with the systems, their work efficiency increases and they come to greatly prefer the EDM systems to the traditional work process.

Nowadays, technologies are evolving quickly. The transportation design and construction industry, which has not adopted EDM systems as fast as the building design and construction industry, can review these case studies and select the tools that will increase their productivity and quality of work. The EDM systems are basic tools that should be used not only at project level, but can also be useful at enterprise level. Feedback from using current EDM systems should be kept and sent to program developers for further improvement. Furthermore, more communication should occur among agencies or companies, software developers, and researchers to share lessons learned and exchange ideas. Collaboration between researchers, developers and industry practitioners to deliver more useful products and
disseminate best practices can be helpful. Together, with everyone’s efforts, technologies can continue to be improved and become more beneficial for the entire transportation design and construction industry.

Acknowledgements

Most of the material in this paper is based on presentations and documents obtained during Scan 13-02 Advances in Civil Engineering Management (CIM) supported by National Cooperative Highway Research Program (NCHRP) 20-68A US Domestic Scan Program. Scan team members included John Adam of Iowa DOT, Katherine Petros and Brian Cawley of the US Federal Highway Administration, Rebecca Burns of Pennsylvania, Duane Brautigam of Florida DOT, Julie Kliwer of Arizona DOT, John Lobbestael of Michigan DOT, Stan Burns and Randall R. Park of Utah DOT, David Jeong of Iowa State University; the scan team was supported by Harry Capers, Jake Almborg, and Melissa Jiang of Aurora and Associates, P.C. Lawrenceville, NJ. Their assistance in analyzing the information obtained from the visits is gratefully acknowledged. We would like to sincerely convey our thanks for the support provided by the Iowa, Michigan, Utah, and New York State DOTs.

A PROCESS FOR THE ASSESSMENT OF INFRASTRUCTURE RELATED RISK DUE TO NATURAL HAZARDS

Abstract: The determination of network related risks for transport infrastructure systems, such as road or railway networks, is a challenging task. Due to such complex systems, it is generally impossible to abstract the global behavior from the analysis of single components, especially under conditions such as failures or damages. People who manage infrastructure have to handle these risks. The proposed overarching risk assessment process is constructed in a way so that computational support can be constructed in modules. This allows to couple the process with detailed sub-processes to achieve varying levels of detail in the risk assessment. The use of the overarching risk assessment process is demonstrated by using it to evaluate infrastructure related risk due to natural hazards for an example region in Switzerland.

1 INTRODUCTION

Transport infrastructure is a key element for the economic growth and development and it plays a fundamental role in the modern world. Over the past decades it has become obvious that the analysis and understanding of large-scale infrastructure networks is important for research, engineering and society. The failure or damage of an infrastructure system could cause huge social disruption. It could be out of all proportion to the actual physical damage (Vespignani 2010). Thus, understanding the phenomenon of failure is critical for evaluating the systems risk and vulnerability and for designing robust infrastructure (Schneider et al. 2011). People who manage infrastructure, herein referred to as infrastructure managers, have to handle these risks. Each infrastructure manager relies on his own risk management processes. These processes are systematic, timely and structured processes that when followed will provide the infrastructure manager with a better understanding of what may go wrong with the system in which the infrastructure is embedded, the probability of this happening and the associated consequences. This risk assessment process is particularly challenging for managers of infrastructure networks, due to the large number of scenarios that need to be analysed in order to assess the risks appropriately, the spatial and temporal correlations between these events (MOVE 2011), and the correlation between event occurrences, or so called cascading events (Garcia-Aristizabal & Marzocchi 2011).

In addition to the challenges in the physical world, the process is made even more complex because the risk assessment process requires that persons work together from many different disciplines who each
has their own discipline based approaches to risk assessment that are not always harmonious with those in other disciplines. This makes it so that independent risk assessments from different persons are not always easy to aggregate to a level that is useful for the infrastructure manager.

The overarching process presented in this article is meant to be helpful to infrastructure managers who want to assess the infrastructure related risks due to natural hazards. It is to be used to help bring together people from many different disciplines so that they can provide information in a way that will be useful to an infrastructure manager. It has been specifically developed to deal with road and rail infrastructure networks but it is believed to be generally applicable to all types of infrastructure networks. The proposed overarching process is meant to fit within the risk management process of any infrastructure owner. This process is developed so that it can be coupled with detailed sub-processes to achieve varying levels of detail in risk assessment. This flexibility ensures that the overarching process is applicable for different types of infrastructure, different types of hazards, different levels of detail in the assessment, different sizes of regions, different types of regions and different levels of abstraction. It is also developed to ensure that the temporal and spatial correlation of events can be considered.

The work was carried out in the scope of the European project INFRARISK, with the aim to develop reliable stress tests to establish the resilience of European road and rail network infrastructure to rare low frequency extreme events and to aid decision making in the long term regarding robust infrastructure development and protection of existing infrastructure. This article is a summary of Hackl et al. (2014). Additional information also can be found in the report Adey et al. (2014) which was submitted as a deliverable in the INFRARISK project. The work builds on that done for the Swiss Federal Roads Authority in 2005 (Adey et al. 2009; Adey et al. 2010).

2 METHODOLOGY

The overarching risk assessment process is based on ISO 31000 (2009), including different principle activities: communicating and consulting, establishing the context, and identifying, analysing, evaluating, treating, monitoring and reviewing risk. Beside the basic concepts of ISO 31000, the proposed framework has been extended to allow explicit consideration of the spatial and temporal correlation between hazards as well as the modelling of the functional interdependencies between multiple objects in the infrastructure networks, including physical dependencies, cybernetic dependencies, geographical dependencies and the modelling of impacts. The process is described using generic definitions of sources, hazards, objects of the network and the network itself, which eases the application to different decision-making situations. It is constructed keeping in mind that for many decision-making situations it will be desired to have the process be computer supported, for example to model specific parts of the system. It has also been constructed keeping in mind that different decision situations will require the use of different types of models and models that will provide different levels of detail. In the following, a brief overview of the different sub-processes of the overarching risk assessment is given.

2.1 Problem Identification

The first step is to identify the question to be answered. This step includes the generation of preliminary thoughts on the area to be investigated. It is only once this question is identified that a meaningful risk assessment can be conducted. It will affect the system definition, the requirements of the assessment in terms of both input, e.g. man-power, and output, e.g. the accuracy of the results or the number and types of scenarios to be investigated. It will also affect the scope of the assessment and the level of detail.

2.2 System Definition

The system representation is a model of the relevant part of reality used for the evaluation and consists of all relevant realizations of stochastic processes within the investigated time period. It includes sufficiently good representations of the hazards, infrastructure, and consequences, as well as the interaction between them so that it can be reasonably certain that there is an appropriate understanding of the system and that the risks and the effectiveness of the strategies can be determined.
The system to be modelled includes all things required to assess risk, including the natural environment, e.g. amount of rain, amount of water in rivers, the physical infrastructure, e.g. the behaviour of a bridge when subjected to high water levels, and human behaviour, e.g. traffic patterns when a road bridge is no longer functioning. As it is necessary to model the system over time, it is necessary to also model the spatial and temporal correlation between events and activities within the investigated time period. This includes the consideration of assumptions, agreements as to how the system will react in specific situations, and drawing fixed system boundaries where it is clear that the things outside the considered system are not being modelled. It also includes the consideration of cascading events.

2.2.1 Boundaries

By establishing spatial boundaries, the part of the natural and man-made environment to be specifically modelled is determined. In addition to the definition of the geographical space, this includes specification of where the objects are located, where the events and hazards can occur and where the consequences could take place. It is usually easy to specify the possible locations of the events, hazards and objects. It is more difficult to, however, determine how they are related, e.g. heavy rain causes a flood hazard. This becomes even more difficult when the location of possible consequences is to be specified. Consequences can be far away from the location of the events, hazards, and infrastructure, and may be outside the direct area of responsibility of the infrastructure manager (e.g. the collapse of a highway bridge on a trans-European highway network can have consequences on the free flow of goods in many countries). By establishing temporal boundaries, the time period over which risk is to be assessed is fixed, as well as how this time period is to be subdivided for analysis purposes. With respect to time, the system representation can be made either: static or dynamic. In the case of a dynamic representation, the model evolves over time whereas in the case of a static representation time is not explicitly modelled.

2.2.2 Elements

It is proposed to group the system elements from initiating events to the events that are considered to be quantifiable and no further analysis is required. It is considered that the element types can be further grouped as either elements to which no value can be directly assigned or elements to which a value can be assigned. In the assessment of risk related to infrastructure due to natural hazards, one can label these further as “hazard elements” and “consequence elements”. Although the number of element types to be considered vary depending on the type of problem and the desired level of detail. Each element type is considered to correspond with events, which can be considered to have a probability of occurrence. Five basic element types, or event types, that should be regularly considered are:

Source events, or initiating events, are events, such as rainfall, tectonic plates movements, ground movement etc. The occurrence of such an event does not necessarily mean that a hazard will be triggered.

Hazard events, or loading events, are events related to any earlier event that may lead to consequences. A hazard always has a source event. It may also trigger another one (e.g. earthquake triggers landslide). Most hazards evolve through space and time and interact with their environment. The time frame can vary from a few seconds (e.g. earthquake) to over a few days (e.g. flood) to several months (e.g. drought). The area that is affected can range from very local, to global. In defining the hazards to be considered it is important to define the intensities of the hazards to be considered. This should include consideration of the return period of the hazards to be used, e.g. 1/500 year flood or earthquake, and the loads to which the infrastructure will be subjected, e.g. the amount of water in the river during a flood, the magnitude of ground motions during an earthquake, the amount of displaced soil during a landslide.

Infrastructure events include all the objects and the condition states of these objects to be considered, e.g. a bridge collapse is an infrastructure event. How the infrastructure networks to be modelled are subdivided into infrastructure objects depends on the specific problem and the level of detail desired in the risk assessment. For example, a 10 km road link may be modelled as one element, although it consists of 3 bridges, 4 road sections and a tunnel, or it may be subdivided to explicitly consist of all eight of these objects. If more detail is required then each object could be subdivided. For example, one of the bridges could be seen as being composed of columns, bearings, decks, etc. In the development of the
system representation it is important to consider which infrastructure objects are affected by which hazard and how the states of these objects may change over time. This is a difficult task as in many cases many objects could be affected but the effect might range from very small, e.g. yielding of a reinforcement bar in a bridge during an earthquake, to very large, e.g. collapse of the bridge. An example of a value that could be assigned to this element type may be the cost of reconstruction of the infrastructure object if damaged. This value depends on the level of damage that might happen and how the infrastructure manager plans to intervene on the object if it is damaged. Sometimes these are referred to as direct consequences, although this terminology is not used consistently. For more in-depth analysis, one might decide to not assign values directly to infrastructure elements and to model the human activities involved in restoring the infrastructure, which would allow a substantially higher level of detail in terms of the costs related to multiple objects in a network being affected simultaneously.

*Network use events* include the states of use of the infrastructure network that might occur. For example, due to a tunnel collapse the freight corridor between Rotterdam and Genoa is closed and no vehicles can travel on it. The probabilities of these events occurring are particularly difficult to estimate as their occurrence depends on spatial and temporal correlation, and physical relationships between initiating events, hazard events and infrastructure events. Network use events can lead to cascading events, as can the other events. To be clear on the distinction between infrastructure and network use events, an example of a value that can be assigned to a infrastructure use event is the cost of deviating traffic around a closed road, whereas an example of a value to be assigned to a network use event is the cost lost travel time due to the closed link. Of course, the value assigned is highly dependent on the flow of traffic if the road is closed which in turn depends on the decisions of many persons in society. For more in-depth analysis, one might decide to not assign values directly to network use events and to model the human activities involved in redirecting traffic, which would allow a substantially higher level of detail, i.e. societal events.

*Societal events* include the actions of persons or groups of persons. For example, due the freight corridor between Rotterdam and Genoa being closed 50% of goods is put onto trucks, 40% of goods is diverted over other train routes and 10% is not delivered. In order to model the actions of persons or groups of persons it is often beneficial to group them into categories based on their general behavior, which in turn is coupled with how their behavior is to be modelled. Societal events may lead to other societal events. If a societal event is not an intermediate event then no value needs to be assigned to it. If they are, however, a terminal societal event, then a value needs to be assigned to the event.

![Network Use Events Diagram](image_url)

**Figure 1:** Example of a simple event tree for risk assessment of infrastructure networks

As the events from the initiating event to the event upon which a value is placed forms a causal chain it is convenient to think of them in the form of an event tree, where each chain of events is represented by a path in the event tree. To build the tree it is necessary to determine the intensity measures to be used to
define the events to be investigated, e.g. the water height above which a flood event is considered to have occurred. At each branch in the event tree a decision is required to determine the value of the intensity measures, which allow classification of the event. The number of intensity measures used to describe the events depends on the problem being investigated and the level of detail required in the analysis. A very simple example is given in Figure 1.

As can be deduced from this simple example, there is an infinite number of ways to represent reality. Due to this, particular care needs to be used in the development of an appropriate system representation. The necessary detail to be used depends on the specific problem and the level of detail desired. If events at any level, or complete ranges of the values of intensity measures are excluded, it should be explicitly explained and documented why, because in the following risk assessment, the risk coming from those hazards cannot be taken into account.

### 2.2.3 Relationships

In order to estimate the likelihood of each subsequent event in the causal chain of events appropriate models of the relationship between them are to be developed. For example, in order to determine the amount of water coming in contact with a bridge during a flood, it is necessary to model how the water which falls as rain reaches the river, taking into consideration, for example, the amount of water that seeps into the ground or evaporates, or is held in temporary retention ponds.

The amount of effort to be invested in this depends on the exact problem and the level of detail desired. For example, in some cases it may be sufficient to use one dimensional vulnerability curves based on expert opinion to estimate the amount of damage that a single object might incur during an earthquake. In other cases, it may be desirable to use multidimensional vulnerability curves based on detailed finite element models to estimate the amount of damage a large dam might incur during an earthquake. In general, extra effort should be spent to achieve more detail when it is suspected that the results will add additional clarity for decision-making. If additional clarity is not provided the extra effort is not worth it.

Although specific examples are given here, the general thoughts apply to all system elements, i.e. initiating events, hazard events, infrastructure events, network use events and societal events. If possible the availability of data to be used to model the relationships should be taken into consideration in determining the level of detail to be used.

### 2.3 Risk Identification

In the previous step emphasis is made on identifying the correct system elements to be used in the risk assessment and how to model the relationships between these. In its most extensive form the definition of these elements and relationships will provide all possible scenarios, or risks. As it is unrealistic to attempt to quantify all of these it is necessary to identify the specific scenarios that are to be part of the risk assessment. Each branch in Figure 1 is a scenario which has an associated risk.

The identification of the scenarios should be done in this step without an explicit estimation of their probability of occurrence or putting a value on the consequences. The starting point for the development of this set of scenarios is all combinations of the system elements in the system representation. It is useful in the identification of scenarios to first determine for who the risk assessment is to be done, and then to:

- start with the initiating events and think through how the infrastructure will be affected and then how humans will react to this,
- to start with the consequences and think through how the infrastructure would have to behave to something to cause these consequences, and
- to start with infrastructure behaviour and think in the other two directions.

Comprehensive identification of relevant scenarios is critical, because scenarios excluded in this step will not be included in further analysis and may result in an underestimation of risk. To minimize the possibility of this happening it is important that experts in each area are involved.
2.4 Risk Analysis

The analysis of risk has to do with estimating the probability of occurrence of the scenarios and the value of the consequences of the scenario if it occurs. It is only through doing this that an infrastructure manager can decide if action needs to be taken and if multiple options are available, which one is the best. It can be done using a qualitative or a quantitative approach. In both cases, however, the goal is to gain a better understanding of the probability of occurrence of a scenario and the consequence of that scenario.

Risk analysis, as with risk identification, can be undertaken with varying degrees of detail, depending on the specific problem, the information, data and resources available. Analysis can be qualitative, semi-quantitative or quantitative, or a combination of these, depending on the circumstances. The certainty with which both the probabilities of occurrence of each of the scenarios and the consequences can be estimated, as well as the sensitivity of these values to the modelling assumptions, need to be given appropriate consideration in interpreting the results. Indicators of the sensitivity of these values are the divergence of opinion among experts, the availability of information, the quality of information, the level of knowledge of the persons conducting the risk analysis, and the limitation of the models used.

2.5 Risk Evaluation

Risk evaluation has to do with verifying the meaning of the estimated risk to persons that may be affected, i.e. stakeholders. This is true regardless if a qualitative or a quantitative approach is used. A large part of this evaluation is the consideration of how people perceive risks and the consideration of this over- or under-valuation with respect to the analyst’s point of view used in the risk analysis step of the risk assessment. Through the risk evaluation there is the possibility to bring into the risk assessment aspects that have not been explicitly modelled in the risk analysis step. The risk evaluation step help to bring decision makers closer to finding a solution that is more acceptable to all stakeholders.

One possible result of this step is that the risk analysis needs to be redone with more detailed system representations, improved models and different values. Another possible result is that it is decided that the risks are acceptable and no exploration of possible interventions are required (ISO 31000 2009).

3 EXAMPLE

In this section, the use of the overarching process is demonstrated by using it to evaluate infrastructure related risk due to natural hazards for an example region. For the sake of simplicity, the example is presented in a sequential manner, although the process itself is highly iterative. The results of this example should be treated with care since only very simple physical models are used to evaluate the risk.

3.1 Problem Identification

The target area is located around the city of Chur, the local capital of the easternmost Canton of Switzerland, Graubünden. Chur is located in a valley between several mountains with many watercourses draining into the main river Rhine. The addressee of this risk assessment is the city administration being interested in damage, cost and other consequences resulting from a rare flood event. It is here important to note that this example was made using public data and was not done in collaboration with, or for, the city of Chur. The results, although they are realistic and serve to demonstrate how the methodology works, are not to be used for other purposes.

3.2 System Definition

3.2.1 Boundaries

The spatial boundary of the system has been selected to be that shown in Figure 2. The risk assessment is done for a flood hazard with a return period of 500 years. The occurrence of this hazard takes three
days. To compare the risk with other cities and regions, the losses resulting from this analysis are converted into an average annualized loss.

![Figure 2: Overview of the area of interest.](image)

### 3.2.2 Elements

**Source event precipitation**: The model of precipitation was constructed using the precipitation data from a historical event which occurred in year 2007 and is scaled in such a way that it corresponds to a precipitation event resulting in a flood with a return period of 500 years. **Hazard event flood**: The model of the amount of water on each land surface area and in the rivers was developed using a set of interrelated tools. **Infrastructure event hospitals**: In the area of interest, only one institution is present for ambulant care, the hospital of the Canton of Graubünden. **Infrastructure event road segments**: Since road geometries for the target area can have lengths up to several hundred metres, these are partitioned in such a way that a spatial analysis can be undertaken on a feasible resolution. **Network use events**: The road network for the target area is extracted from the VECTOR25 dataset. Each road is represented by a linear geometry with assigned attributes on their type (swisstopo 2014).

**Societal events**: Societal events are how the traffic behaves on the network when it is not fully operational. It is estimated using traffic simulations to estimate how much additional time is required to travel from anywhere in the hospital catchment area to the hospital.

### 3.2.3 Relationships

**Source-Hazard-Interaction**: For reasons of simplicity and efficiency only a simple hydrological model for the runoff calculation is used. The ModClark model (Kull & Feldman 1998) is used to estimate the discharge during the precipitation event. **Hazard-Infrastructure-Interaction**: To estimate damage resulting from inundation, simple damage curves are used from Deckers, et al. (2010). **Infrastructure-Society-Interaction**: It is assumed that if infrastructure is damaged that it would be restored to the condition it had prior to being damaged. The unit values used are taken from Kutschera (2008). **Infrastructure-Network-Interaction**: Since this connectivity changes during the scenario due to node failure, for each time step a distinct network had to be created. **Network-Society-Interaction**: The quantification of consequences related to travelling across the network resulting from the failure of infrastructure network nodes was undertaken in terms of the following non-exhaustive list of examples: travel time costs (e.g. man hours of work time lost), vehicle operating costs (e.g. increase of fuel needed), accident costs (e.g. number and type of injuries/deaths), environmental costs (amount of additional nose/pollution) (Adey et al. 2012).

### 3.3 Risk Identification

The target area has been historically prone to the mentioned natural hazards flooding and landslides. Information on past events are stored in the database "Unwetterschadens-Datenbank" (Hilker et al. 2009) In addition, two more recent projects, AquaProtect and SilvaProtect (Losey & Wehrli 2013) provide model based information on regions vulnerable to floods and landslides. For the sake of simplicity, only one scenario is considered. This scenario is comprised of the following events: Source event is rainfall, the hazard events are floods, defined as being more severe as the largest volume of water expected in the main river expected in 500 years. The infrastructure events are derived from the road sections and
hospitals being in specified damage states. The network use events are derived from the different combinations of damage states of the different infrastructure objects. The societal events are derived from modelling the traffic flow results from the different network condition states.

3.4 Risk Analysis

For the risk analysis of the considered scenario a quantitative approach is used. In order to aggregate risk that has been estimated based on the specific scenario, it is necessary to ensure that they are directly comparable and that they are not double counted. The value associated directly to the condition of the infrastructure objects, are added. It is assumed that the maximum damage predicted throughout the three-day period is the amount of damage that needs to be repaired. Based on the cost associated with the single objects for each time step, the development of the total losses for the whole region of interest can be calculated. The costs related to the disruption of traffic on the road network are estimated by counting the number of additional hours of travel time that is required on the network while the network is not fully operational. In this case study it is also assumed that all road sections are restored to normal immediately following the three-day period.

![GIS results of the example for the time steps 20 and 38.](image)

Figure 3: GIS results of the example for the time steps 20 and 38.

Figure 3 exemplarily illustrates the results of this process. Here, for each type of event a pair of maps illustrates one stage of the overarching process in left-to-right order. To illustrate the change of the system, the upper maps represent the state of the system for time step 20 and the lower maps for time step 38. The source maps show heavy rainfall over the region of interest, which decreases towards the end of the simulation period. The hazard maps show the maximum inundation depths of the resulting flood for each surface area until the respective time step. It becomes apparent that the maximum inundation depths increase with time, which therefore leads to increasing damages of affected infrastructure objects. This causes rising reconstruction costs, which is shown in the element maps for the Haldenstein region. The road networks functionality is reduced as shown in the network maps. Here, red road segments indicate that they are isolated from the green main network. Impassable road segments are not shown. This reduced network state results for some regions, in particular in the northern and south-western parts, to be cut off from important infrastructure objects. For example, it is impossible for people in these areas to get to the hospital in Chur as indicated by the society maps.
3.5 Risk Evaluation

In this paper, risk evaluation is not performed. If a complete risk management process is being conducted this work would need to be done in conjunction with the city administration of Chur. The results coming from the risk analysis would support this task in order to plan further analyses, safety measures or risk treatments.

4 DISCUSSION

The example demonstrates that the proposed overarching risk assessment process is useful to assess infrastructure related risk due to natural hazards. Computer systems can highly accelerate its distinct steps so that the results can be delivered to infrastructure managers in a timely manner. However, in order to refine the results, the methodology needs to be applied to a greater number of scenarios. The process can be used for a wide range of different problems at different levels of detail. In addition, the changes over time and interactions between different events can be modeled as shown in the example. Although the proposed overarching risk assessment process can be used conceptually for all kinds of different problems, its usefulness depends on the quality of available models and data. Often the physical models do not take into account interaction with their environment. For example, if a bridge collapses, the cross-section of the river will be changed, too.

In the presented example a relatively deterministic point of view was chosen. In order to take the numerous uncertainties into account a probabilistic approach seems more suitable, especially when dealing with natural hazards. If one associates a probability of occurrence with the occurrence of the particular precipitation then one could quantify the risk. A more sophisticated example will require the consideration of the not only the probability of occurrence of different rain patterns, but also given the rain fall patterns, the probability of different water run-off events, different levels of water in different parts of the rivers, different behavior of the infrastructure objects in the network, and different behavior of the vehicles on the network. It would also require consideration of larger periods of time, in which multiple rain events occur and perhaps even different types of source events that may result in consequences.

In the expansion of the example to do this there are substantial hurdles with respect to the infinite number of scenarios possible, the uncertainties associated with many different models to be used to make approximations and the temporal changes in the probabilities of event occurrences.

5 CONCLUSIONS

This article describes a generic overarching risk assessment process as well as an example of how it can be used and how it can be implemented using a GIS framework. Even in its current form it is believed that this process would be useful to infrastructure managers in the assessment of their infrastructure related risks due to natural hazards. It is applicable for different types of infrastructure, different types of hazards and different types of consequences and can take into consideration both simple and complex system representations. The overarching risk assessment process will be further improved by taking into account multiple scenarios, including multiple initiating events, multiple hazards, multiple infrastructure events, multiple network use events and multiple societal events. It will also be expanded to deal properly with the spatial and temporal consideration in the estimation of the probability of occurrence of scenarios and the establishment of the scenarios. More work is required to emphasis the human interaction in conducting the risk assessment.

Abstract: Building sector in most countries around the world requires large amounts of heating and cooling energy. Indeed, building cooling loads due to solar gains are responsible for approximately half of global cooling load. In addition, windows are considered as one of the important sources of energy loss in buildings. In order to minimize this loss, shading devices can be installed in the exterior part of the window to reduce solar heat. The objective of this study is to investigate the simultaneous effect of glazing, shading materials, and configuration of shading devices on total building energy consumption in different climate regions in the United States. To achieve this objective, a typical residential building was selected to assess the effect of the aforementioned parameters on total energy consumption in five main climate regions. A series of simulations were conducted using EnergyPlus simulation program to quantify energy consumption in each scenario and determine the most energy efficient glazing and shading materials as well as configuration of the shading device. Different types of window glazing (including clear, Low-Iron, Ref-B tint, Low-E clear and Low-E tint with 6 mm thickness) as well as different materials for shading devices (including PVC, aluminum and wood) were considered in this study. Moreover, the effect of five different shading device configurations, including horizontal and oriented overhang, vertical fin and combination of them were investigated. Results showed installing vertical fins and horizontal overhang shading devices in buildings located in Miami and Atlanta do not have a significant effect on annual energy consumption. However, combining these two overhang shading configurations will reduce energy consumption. In addition to shading configurations, it was found that Ref-B tint glazing material along with wood shading material reduced annual energy consumption by approximately 11.6% in Miami. However in Atlanta, total energy consumption was reduced by approximately 7% in the case of using Low-E tint glazing material along with wood shading material. No significant decrease in energy consumption was observed in cold climates.

1 INTRODUCTION

The total energy consumption in U.S. buildings has increased in recent years. Building energy consumption had increased by 48% for the period between 1980 and 2009. In 2009, residential buildings consumed 20.99 quadrillion Btu energy which is equivalent to 54% of building sector energy consumption as well as 22% of total primary energy consumption in the United States (Kelso 2012). One of the major sources of energy consumption in buildings is associated with space cooling and heating systems. In the United States, heating and cooling energy consumption is equal to 43% and 52% of the total energy consumption in residential and commercial sector, respectively. Building sector in most countries around
the world requires large amount of heating and cooling energy demand. Indeed, cooling load due to solar gains is responsible for approximately half of the global cooling load in both residential and commercial buildings. According to Residential Energy Consumption Survey (RECS), heating and cooling energy consumption was reduced by 10% in the U.S. residential buildings from 1993 to 2009 (2009). To continue this reduction trend, different parameters such as more efficient equipment, better insulation materials and more efficient windows can be used in buildings.

Windows are considered as one of the main sources of energy loss in buildings. Windows are mostly used as the architectural devices that connect the interior space to outdoors. Therefore, they absorb solar radiation and transfer the captivated heat inside the buildings. The three sources of solar radiation on exterior surface result from sun direct radiation, sky diffuse radiation as well as buildings and adjacent surface reflected radiation. Exterior shading devices are one of the building elements that can restrict the direct solar radiation and decrease the effect of the reflected and diffuse radiation (Stack, Goulding, and Lewis 2000). The main advantage of using shading devices is to restrict solar radiation (Stack, Goulding, and Lewis 2000). Effective shading devices should control solar radiation before heating up the fenestration and should provide large shading area for summer, while allow for maximum solar radiation absorption in winter.

Recently, it has been found exterior shading devices can reduce energy consumption and improve thermal comfort of buildings. Moreover, they provide a great view for the occupants by reducing glare (Norbert Lechner 2008). Several studies have been investigated the relation between shading devices and energy consumption. Peebles (Peebles 1940) conducted one of the very first works to investigate the effect of shading devices on energy consumption through an experimental study. It was found that shading devices with different colors can reduce building energy consumption. The results of the study showed that light color shading devices decrease heat gain by about 55% and 40% in the summer and winter, respectively. In another study conducted by Emery et al. (Emery et al. 1981), they found that the performance of shading systems in reducing building energy consumption significantly depends on climate condition. According to this study, the effect of climate on the performance of shading device systems was investigated for three cities in the United States and it was found that fixed overhangs and fins had the most reduction in energy consumption. In a similar study, Harkness (Harkness 1988) investigated the effects of various parameters including window areas and sunscreen projection on cooling energy reduction in Australian buildings. He found that use of single pane clear glass with exterior precast concrete overhangs and fins decreased the cooling energy loads by 50%. In another study conducted by Tzempelikos and Roy (Tzempelikos and Roy 2004), the effect of fixed and movable shading devices on thermal comfort and visualization was investigated. An office building with a large glass area in Montreal was selected as a case study in this work. It was found shading properties and location have significant effects on heating and cooling loads as well as thermal comfort. The simulation results indicated that exterior shading devices with small transmittance and high reflectance can reduce cooling loads by 60%. Kim and Kim (J. Kim and Kim 2010) conducted a series of simulation to compare exterior and interior shading devices in terms of energy performance and view. It was found that exterior shading devices reduce cooling and heating loads by 20% and 12%, respectively, and provide a better view compared to interior shading devices. Kim et al. (G. Kim et al. 2012) compared various exterior shading devices in terms of heating and cooling energy saving for residential building in South Korea. According to this study, the great impact on energy reduction occurred by changing the slat angle of shading devices. The slat angle range was between 0° to 60°. Smaller window area was covered with shading devices when the slat angle was reduced. Therefore, the occupant’s view and energy consumption were improved.

The objective of this study is to investigate simultaneous effects of glazing and shading materials in addition to the configuration of the shading devices on total building energy consumption in different climate regions in the United States. To achieve this objective, a typical residential building was selected in this study to assess the effect of these parameters on total energy consumption in five climate regions in the United States. A series of simulations were conducted using EnergyPlus simulation software to quantify energy consumption in each scenario and determine the most energy efficient glazing and shading materials besides configurations of the shading devices. Different types of window glazing materials (including clear, Low-Iron, Ref-B tint, Low-E clear and Low-E tint with 6 mm thickness) along
with different materials for shading devices (including PVC, aluminum and wood) were considered in this study. Moreover, the effect of five different configurations of shading devices, including horizontal and oriented overhang, vertical fin and combination of these configurations were studied in this paper.

2 METHODOLOGY

The objective of this study is to investigate the effect of various shading devices and glazing materials on residential building energy consumption in five climatic zones in the United States. Five different types of shading devices, three different shading materials and five glazing types were studied. Different scenarios were compared together to find out the most efficient combination for each studied climate zone. A detailed flowchart for simulation steps is shown in Figure 1.

Figure 1: Framework of the simulation model.

2.1 Selection of Representative Locations

Energy consumption varies significantly from building to building located in different climate regions. Climate is one of the most important factors in selecting effective exterior shading devices in terms of energy savings (Khezri 2012). According to Energy Information Administration (2005), the climate regions in the United States categorized into 5 main categories (see Figure 2) based on the last 30-year average heating degree-days (HDD) and cooling degree-days (CDD). The geographical information of the representative cities are summarized in Table 1.

2.2 Building model

A typical residential building (see Figure 3) was selected in this study to evaluate the effect of various shading designs and materials on total energy consumption in different climate regions in the U.S. The studied building was a one-story detached house with a height of 3.2 m and a total floor area of 130 m². The total window to wall ratio is 18.87 where the height and width of the windows are equal to 1.4 m and 1.2 m. The Ecotect (version 5.6) was used to build the building’s geometry and then it was imported in EnergyPlus for energy consumption simulation. All envelop properties, schedules and equipment (lighting system, HVAC system, etc.) were defined in EnergyPlus. The inside temperature was set to 20 and 24°C in winter and summer, respectively.

Figure 3: Typical Residential Building, (a) Floor Plan; (b) and (c) 3D model.

2.3 Glazing type

Building energy consumption can be affected greatly by glazing properties and shading configurations. In this study, the effect of five different types of glazing as well as five shading configurations considering shading depth and shading materials on building energy consumption were studied. The five studied glazing systems were Low Iron, Ref-B tint, Low-E clear, and Low-E tint with 6 mm thickness. To evaluate the performance of these glazing systems, a control case with no shading devices was simulated for each climate zone to identify the best-performing glazing type which served as the control case to evaluate shading performance.

2.4 Exterior solar shading devices

2.4.1 Shading depth

The depths of shading devices are different in each climate regions depending on the solar altitude angle. Solar altitude is the angle between the sun’s ray and the projection of that ray on a horizontal surface. It is a function of a location’s longitude and latitude. One important design principle for exterior shading
systems is that they can block out direct sunlight for most of the time in a year. In winter, the sun is low in the sky and its ray is considered as a source of heating while in summer the sun position is comparatively higher. Therefore, solar altitude in summer was used to calculate shading depth according to Equation 1 (Rungta and Singh 2011). The results of shading depth are shown in Table 2 below.

\[ \text{Shading depth} = \frac{\text{window height} \times \cos (\text{solar azimuth-window azimuth})}{\tan (\text{solar altitude})} \]

2.4.2 Exterior Shading Types and Materials

In this study, the effects of five different types of exterior shading systems (Figure 4) on total building heating and cooling energy load were investigated. The shading depths for each type except shading Type 1 were calculated in previous section. The shading depth of Type 1 was considered the same depth as other types in each climate regions. By comparing the results of various exterior shading configurations, the more efficient configuration that is able to reduce energy consumption was determined for each climate region. In addition, the effect of different shading materials including PVC, aluminum, and wood on building energy consumption were investigated.

![Various exterior shading configurations](image)

Figure 4: Various exterior shading configurations

2.5 Parametric study

A parametric study was conducted to compare the performance of different exterior shading designs and materials and also glazing materials in a typical residential building in five major climate regions in the United States. A typical residential building with no shading device was considered as a control house. Energy simulation was conducted for each scenario to calculate annual heating and cooling loads. The results were then compared to the base case energy consumption to determine the most efficient glazing material in each climate region (see Figure 5). Then, the effect of different types of shading devices and materials on annual energy consumption was investigated for each scenario. The results were compared with the control case energy consumption to determine the efficient scenario for each climate region. The simulation process is illustrated in Figure 6.
3 RESULTS AND DISCUSSION

3.1 Efficient Glazing Materials

To identify the optimal glazing type in terms of energy consumption, a building with clear glass windows was first modeled for each climatic region and the results were compared with other types of glasses as mentioned above. Figure 7 shows the total energy consumption of all studied glazing types. It should be mentioned that clear glazing was considered as the control case. Results showed that the studied glazing types do not have significant impact on total energy consumption in different climatic regions. This is explained by the fact that glazing materials with different coating basically have the same amount of U-value and the window to wall ratio is small. In Miami, the best performing glazing type was Ref-B tint which reduced the annual cooling energy demand by 1.14 MWh. Comparing to the control case with clear glazing, Ref-B tint saved 7.6% in total energy consumption. In Atlanta, Low-E tint reduced total energy consumption by about 4.1%. For all other studied locations, the reduction in energy consumption was not significant.
3.2 Efficient Shading Properties in Each Climatic Region

Installing shading devices on windows will reduce the amount of beam solar radiation passing through and, hence, reduce the amount of heat gain. As it can be seen in Figure 8, in all selected cities, shading 4 and shading 2 with best performance glazing material and wood as a shading material, respectively, have the most and the least window heat gain reduction compared to the clear glass case without shading. The window heat gain and loss for each climate with best performance glazing material, various shading device types, and wood as a shading material are shown in Figure 8. In all locations, window heat gain was affected by installing different shading devices, but the window heat loss did not change significantly because shading devices reject window solar gain effectively depending on shading configuration.

3.2.1 Hot-Humid climate zone

Miami was selected as the representative city of hot-humid climate zone. Energy consumption on heating and cooling between the 15 investigated cases for Miami were compared and the results are shown in Figure 9. By adding exterior shading devices on top of the windows in building in Miami, the maximum reduction in solar radiation absorbed by windows was decreased. In Miami, the great energy consumption reduction was achieved by placing shading 4 while the total energy consumption for clear glass case without shading was 14.8 MWh.
The energy consumption with shading 4 along with wood material and Ref-B tint as an efficient glazing material was 13 MWh, which was a reduction in the annual energy consumption by about 11.6%. Shading device 4 increases the shade area of window and restricted excessive solar beams and consequently the cooling energy consumption was reduced. In addition, heating energy demand in Miami is not too much due to weather condition, so it did not have a significant impact on the annual energy consumption.

![Graph showing energy consumption comparison](image)

**Figure 9: Annual energy consumption of various variables in Miami**

### 3.2.2 Mixed-humid climate zone

Atlanta was selected to simulate the effect of exterior shading devices in mixed-humid climate zone. As Figure 10 shows, the total annual energy consumption in a building having shading device 4 along with wood as a shading material and Low-E tint as a glazing material is 11.95 MWh which reduced the annual total energy consumption by about 7.1% in comparison with clear glass case with no shading.

![Graph showing energy consumption comparison](image)

**Figure 10: Annual energy consumption of various variables in Atlanta**

### 3.2.3 Marine climate zone

For marine climate zone, Seattle was selected as a representative location. According to Figure 11, the total annual heating and cooling energy loads in a building with shading 3 and Low-E clear as a glazing material is 10.1 and 2.1 MWh, respectively and for clear glass case with no shading is 9.98 and 2.77 MWh. Therefore, it was found that replacing clear glass with Low-E clear glass result in 4.2% reduction in energy consumption in Seattle. Also, the energy consumption is not affected much by shading materials in this climate zone.

![Graph showing energy consumption comparison](image)
3.2.4 Cold and very cold climate zone

As Figure 12 shows, in Chicago and Duluth (climate zone cold and very cold), the best performance was achieved in Duluth for a building having shading 2 along with Low-E clear as a glazing material. For a building with Low-E clear glass in Duluth, heating and cooling energy consumption were 21.6 and 2.1 MWh, respectively and for the control case were 21.88 and 2.55 MWh. In Chicago for shadings 3 and 4 with Low-E tint as glazing material, heating and cooling energy consumption respectively were 13.93 and 4.3 MWh and for clear glass case with no shading were 13.85 and 5.08 MWh. In comparison with control case, total energy consumption was reduced by about 3.69%. As shown in Figure 12, shading device does not have a significant impact on energy consumption in cold climates.

3.3 Shading properties guideline

A numerical simulation was conducted to study the impact of exterior shading types, shading and glazing materials on annual energy consumption. After identifying the best performing glazing types for all locations, a series of simulations were conducted to study the impact of different shading types and shading materials. Table 3 summarizes best scenarios among 15 cases with different combinations of shading devices and shading materials in each climate zone.

4 CONCLUSIONS

This study investigated the impact of various shading devices and glazing materials on total energy consumption of a typical residential building in different U.S. climate regions. In this study, five different shading devices (horizontal and oriented overhang, vertical fins, and combination of these two), five glazing materials (clear, low-iron, Ref-B tint, Low-E clear, and Low-E tint with 6 mm thickness) and three different shading materials (PVC, aluminum and wood) were considered as potential fenestration elements. In all climate regions, exterior shading devices reduced cooling energy consumption compared to the buildings without shading. The results of this study can be used as a guideline to select the most efficient shading types for various U.S. climate zones. It was concluded in hot climate zones, shading properties and materials play a key role in cooling energy consumption due to restricting the solar beams. In cold and very cold climate regions, installing exterior shading devices can reduce the cooling demand in summer and increase heating demand in winter. Therefore, no significant reduction in total energy consumption may be resulted.

Abstract: Precedence Diagram Method (PDM) has gained the widest acceptance in the scheduling practice in the last decades due to its modeling flexibility over other existing techniques, and to the relative simplicity of its mathematical background. The four basic precedence relationships have been serving planners for more than half a century. However, even this model is not flexible enough; proper modeling of overlapped activities seems to be a never-ending debate. Different practical and theoretical solutions have been proposed during the years for better modeling overlapped activities. The most promising among them is the development of a new type of relation that can connect any two arbitrary points of the related activities. These relations can be called point-to-point relations. Different authors in various ways have proposed similar solutions. To the best of our knowledge, the literature on the mathematical model of PDM using this new relation is lacking. Main results of the paper are: 1) standardized discussion of the different approaches to point-to-point relations; 2) proper mathematical model of PDM with point-to-point relations; 3) introduction of the algorithm that can handle point-to-point relations with both minimal and maximal lag to define the earliest and latest feasible time policy.

1 INTRODUCTION AND LITERATURE REVIEW

Widely used network techniques are more than half a century old. The results of Fondahl, (Fondahl 1961), Roy (Roy 1959), (Roy 1960), IBM (IBM 1964) and many others have led to the present form of the Precedence Diagram Method, the prevailing network technique of our times. PDM has hardly changed during the decades in spite of the critiques it has received about its modeling capabilities. Proper modeling of overlapping activities seems to be a never-ending debate when traditional precedence relations are used, (Douglas et al. 2006) because traditional endpoint relations are simply not suitable for describing this kind of logic. Different solutions have been proposed using the traditional precedence relations; but fragmentation of activities and developments based on this idea (Tarek & Menesi 2010) seem to be the best theoretical solution despite the arising practical problems, namely the multiplication of the number of activities and precedence relations. Probably the fragmentation technique has given the idea of connecting the inner points of the activities, which will be discussed in this paper. These point-to-point relations connecting the internal points of the activities seem to be theoretically more suitable for modeling overlapping activities – especially if continuous activities are assumed - as multiple relations are allowed between the activities. To the best of our knowledge four partly parallel works regarding point-to-point relations can be found: Kim (Kim 2010, 2012) calls his new relations bee-line relations and the graphical representation Bee-line Diagram (BDM), while Francis and Miresco (Francis & Mireco 2000, 2002) call their new relations temporal functions and they call their graphical representation method
chronographic approach. Plotnick (Plotnick 2004) calls his method Relationship Diagramming method (RDM) using the term of ‘event’ for the internal points. Ponce de Leon (Ponce de Leon 2010) uses the term Graphical Diagramming Method (GDM) and connected internal points are called embedded nodes. Despite the differences in terminology and definitions, e.g. bee-line and RDM relation does not allow a lag between the connected inner points, maximal lags are defined only in the work of Francis and Miresco, the concept behind all these works is the same. All these improvements regarding the relationships can be seen as a new type of precedence relation that can substitute all traditional precedence relations, as it will be shown later. The goal of this paper is twofold: firstly, to remedy a common shortcoming of these works (authors have failed to present the mathematical model); secondly, to show that traditional precedence relationships can be derived from the general point-to-point relations discussed in this paper. A proper mathematical model and the algorithm will be introduced using standardized technical terminology. The new point-to-point relation can be seen as a generalization of traditional precedence relations. It will be shown that the existing traditional precedence relations are special cases of the point-to-point relations; they connect the endpoints of the activities instead of the internal points.

2 THE MATHEMATICAL MODEL

2.1 Notations

Let a directed acyclic graph be given with one start (s) and one finish node (f). Let \( N = \{1,2,\ldots,i\ldots,j\ldots,n\} \) stand for the set of nodes also called activities. \( A \) will define the set of arcs, also called precedence relations. The ‘super’ relation defined later can have minimal or maximal lags, therefore \( A_{\text{min}} \) and \( A_{\text{max}} \) subsets are introduced for differentiating relations with minimal and maximal lags. In the algorithm, relations with maximal lags will be transformed into relations with minimal lags. In this case \( A^* \) denotes the set of relations. An activity \( i \) is defined by its start and finish points \( P^i_s, P^i_f \), shortly \( S^i \) or \( F^i \), or by any of the two aforementioned points and its duration \( d^i \). Additional points of the activities can also be defined. \( P^i_k \) stands for the \( k^{th} \) point of activity \( i \). The relative place of the \( k^{th} \) point of activity \( i \) is defined by the time span \( (t^i_k) \) from the start point of activity \( i \) \( (P^i_s) \). A relation can be defined between any \( l^{th} \) internal point of activity \( j \) and any \( k^{th} \) internal point of activity \( i \) by defining the time that must elapse between the two points \( (z^i_k j_l) \). Therefore this ‘super’ precedence relation can be defined either by the points and the lag as \( (P^i_k; P^j_l, z^i_k j_l) \) or by the relative positions of the points and the lag \( (t^i_k; t^j_l, z^i_k j_l) \). Explanation can be seen in Fig. 1. Lags can be defined using production volumes as well.

![Figure 1: Explanation of notations and the the 'super' precedence relation. \((t^i_k; t^j_l, z^i_k j_l)\)](image-url)
Let the time when a point is accomplished be called point or event time and denoted by $T_i$. This way $T_i^S$ stands for the start, and $T_i^F$ stands for the finish of activity $i$. Table 1 shows how the traditional relations and bee-line relations can be derived from the new ‘super’ relation. Transformation of temporal functions (Francis & Miresco 2002) and RDM relations is obvious so this is not presented here. If instead of time, the names of the points of the activities are used for describing the relation, then even the same notation can be used. (e.g. instead of SS100 days (S; S; 100 days) can be used.) Based on the above notations the following model can be defined.

Table 1: ‘Super’ relation can be used instead of traditional and bee-line precedence relations

</tbody>
</table>

2.2 The model

The first two conditions tell that all precedence relations must be satisfied. [1] describes the precedence relations with minimal lags, while [2] describes the precedence relations with maximal lags.

$$[1] \quad T_j^l - T_k^i \geq z_k^j l, \quad \forall (P_k^i; P_j^l) \in A_{min}$$
$$[2] \quad T_j^l - T_k^i \leq z_k^j l, \quad \forall (P_k^i; P_j^l) \in A_{max}$$

By definition $T_k^i = T_k^S + t_k^i$ and $T_j^l = T_j^S + t_j^l$, therefore [1] and [2] can be modified as:

$$[1^*] \quad T_j^S - T_k^i \geq z_k^j i - t_k^i + t_j^l, \quad \forall (P_k^i; P_j^l) \in A_{min}$$
$$[2^*] \quad T_j^S - T_k^i \leq z_k^j i - t_k^i + t_j^l, \quad \forall (P_k^i; P_j^l) \in A_{max}$$

The finish of the activities can be calculated according to [3]. Activities are assumed to be continuous [4]. Let’s set the start of the project to zero. [5]

$$[3] \quad T_i^S + d_i = T_i^F, \quad \forall i \in N$$
$$[4] \quad T_k^i - t_k^i = T_k^S, \quad \forall i \in N \quad \text{and} \quad \exists P_k^i \quad (P_k^i \text{ exist})$$
$$[5] \quad T_0^S = 0$$

The $T$ policy that satisfies $[1^*], [2^*], [3], [4], \text{and} [5]$ is called a feasible time policy. An infinite number of feasible time policies exist, but the objective of the model is to find that/those time policy/policies where the project duration is the minimum, that is

$$[6] \quad T_F^i - T_S^i \rightarrow \min \quad \text{that is} \quad T_F^i - 0 \rightarrow \min \quad \text{that is} \quad T_F^i \rightarrow \min$$

This model is an LP model, so any LP solver can be used for solving it, furthermore, based on the simplistic structure of this LP problem different efficient primal dual algorithms can be developed. The solution shown below is based on the modification of the simplistic and widely used CPM/PDM time analysis. This approach is probably the easiest to digest for planning engineers.
3 ALGORITHMS

3.1 Point-to-point relations with minimal lag

The goal of the algorithm is to find the optimal time policy, the earliest and the latest out of the existing – sometimes millions of – optimal time policies. The earliest optimal time policy is denoted by \( E_i^S \) and \( E_i^F \). The latest optimal policy is denoted by \( L_i^S \) and \( L_i^F \). The applied algorithm has two phases. The result of the first phase is the earliest optimal time policy, while the result of the second phase is the latest optimal time policy.

Let’s suppose for the sake of simplicity that only relations with minimal lags are allowed in the network. In this case, the earliest start and finish of an activity \( j \) can only be calculated, if the earliest start dates for all its predecessors are known. As all precedence relations must be satisfied, the early start of a given \( j \) can be defined by the maximum of the shifts caused by the preceding relations of activity \( j \), that is:

\[
E_j^S = \max \{ E_i^S + t_{ik} + z_{kj} - t_{jl} \mid \forall (P_i^k;P_j^l) \in A_{\text{min}} \} \tag{7}
\]

To start, an activity with known predecessors has to be found. In the beginning, only the start activity satisfies this condition: all of its predecessors are known because it does not have any. After these introductory thoughts, the steps of the first phase, that is the steps aiming to find the earliest time policy, can be summarized as follows:

**Step 1**
- Let \( E_i^S = -\infty \) and \( E_i^F = -\infty \) \( \forall i \in N \); Let \( E_S^S = 0 \); Let \( g := 1 \).

**Step 2**
- **REPEAT**
  - \( g := g + 1 \)
  - Choose an activity \( j \) from the unknowns \( (E_i^S = -\infty) \) with known predecessors only.
  - **IF** there is no such activity then **GO TO** Step 3
  - \( E_j^S = \max \{ E_i^S + t_{ik} + z_{kj} - t_{jl} \mid \forall (P_i^k;P_j^l) \in A_{\text{min}} \} \); \( E_j^F = E_j^S + d_i^j \)

**UNTIL** \( g = n \)

**Step 3**
- **IF** \( g < n \)
  - **THEN**
  - STOP (There is a loop in the network.)
  - **ELSE**
  - \( p = E_F^F \) (Project duration is the same as the early finish of the finish activity.)

During the backward pass, the latest optimal time policy will be defined. It is completed by working from the terminal activity to the initial activity in reverse direction of the arrows. It is based on the observation that the late activity times of an activity can only be calculated, if these dates are known for all of its successors. As all successor relations must be satisfied, the late start of a given \( i \) can be defined by the maximum of the shifts caused by the succeeding relations of activity \( i \), that is:

\[
L_i^S = \min \{ L_j^S + t_{jk} - z_{kj} - t_{jl} \mid \forall (P_j^k;P_i^l) \in A_{\text{min}} \} \tag{8}
\]

The rules of the backward pass can be summarized as follows:

**Step 1**
- Let \( L_i^S = \infty \) and \( L_i^F = \infty \) \( \forall i \in N \); Let \( L_S^F = p - d_f \); Let \( g := 1 \).

**Step 2**
- **REPEAT**
  - \( g := g + 1 \)
  - Choose an activity \( i \) from the unknowns \( (L_i^S = \infty) \) with known successors only.
  - \( L_i^S = \min \{ L_j^S + t_{jk} - z_{kj} - t_{jl} \mid \forall (P_j^k;P_i^l) \in A_{\text{min}} \} \); \( L_i^F = L_i^S + d_i^j \)

**UNTIL** \( g = n \)

(Note: Loop detection is not necessary during the backward pass.)
3.2 Point-to-point relations with mixed lags

Calculations with mixed lags require more computational steps. Maximal relations have to be transformed into minimal relations first. Comparing conditions [1] and [2], it can be seen that the difference between a relation with minimal or maximal lags lies in the direction of the operand. Transforming a relation with maximal lag into a relation with minimal lag requires a simple multiplication by -1.

\[ T^l_j - T^l_k \leq z^l_j \quad \forall (P^l_k;P^l_j) \in A_{\text{max}} \quad \cdot (-1) \]

\[ T^l_j - T^l_k \leq - z^l_j \quad \forall (P^l_k;P^l_j) \in A_{\text{max}} \]

This is nothing else but a relation from \( j \) to \( i \) with a negative minimal lag (see Fig. 2).

![Figure 2: Point-to-point relation with maximal lag a) and its minimal equivalent b)](image)

Traditional precedence relations with maximal lags, and their transformed equivalent minimal lags can be found in Table 2.

<table>

</table>

* Transformed equivalents go in the opposite direction

However, converting relations with maximal lags into their equivalent minimal relations can result in so-called transformation loops. In Fig. 3 it can be seen that there is a loop between B and C.

The simple time analysis presented in 3.1 cannot be used in case of loops. One can easily check it by selecting the activities. E.g. during the forward pass activity A has to be chosen first. After that none of the activities can be selected, B has two predecessors but only A is known and C is not; C has two predecessors but only A is known and B is not, so the algorithm will stop here.

In case of loops, different algorithms exist to find the longest path. We will use the modified version of the algorithm developed by Bellman (Bellman, 1958) and Ford (1956) for finding the shortest path between any two points of a cyclic graph. The algorithm is based on the idea that during the forward pass all activities are calculated using the dates of their predecessors even if those have not taken their final dates yet. When all activities have been calculated this way, it has to be checked whether there have been changes in activity dates or not. If the answer is yes, then the entire calculation must be repeated again and again, until we come to the results we had in the previous iteration. In every iteration, at least
one activity takes its final value, so after maximum \( n \) iterations we get the results. Usually much fewer iterations are necessary. If the \( n^{th} \) iteration still brings changes, then the network cannot be solved due to the maximal relations that probably impose logic on the network, which contradicts the minimal or other maximal lags. E.g. imagine that \( B \) can start minimum five days after the finish of \( A \) (\( F;S;5 \)) point-to-point relation but another relation describes that \( B \) should start maximum 4 days after the finish of \( A \) (\( F;S;\text{max}4 \)).

Figure 3: Transformation of relations with maximal lag into their minimal equivalent can result in loops.

This definite contradiction cannot be solved. In this case, the value of the transformation loop will be positive, and the result for the project duration will increase by at least this value in every iteration even after the \( n^{th} \) iteration. The steps below summarize the forward pass:

**Step 1**
- \( E_i^{s} = -\infty \) and \( OLD_E_i^{s} = -\infty \) \( \forall \; i \in \mathbb{N} \); Let \( E_i^{i=0} = 0 \) and \( OLD_E_i^{i=0} = 0 \); Let \( h=0 \); Let \( No_of_Iter=0 \)

**Step 2**
- \( REPEAT \)
  - \( There\_were\_changes:=\text{FALSE}; \; No\_of\_Iter:=\; No\_of\_Iter+1 \)
  - \( REPEAT \)
    - \( h:=h+1 \)
    - Select any \( j \) activity that has not been selected in this iteration yet
    - \( E_j^{s} = \max \{ OLD_E_j^{s}; (E_i^{s} + t_{ik} + z_{kl} - t_{jl}) \; \forall \; (P_i^k;P_j^l) \in A^* \}; \; E_j^{f}=E_j^{s}+d_j \)
    - IF \( E_j^{s}> OLD_E_j^{s} \) THEN \( There\_were\_changes:=\text{TRUE} \)
  - UNTIL \( h=n \)
- \( Let \; OLD_E_i^{s}=E_i^{s} \; \forall \; i \in \mathbb{N} \)
- \( UNTIL \; No\_of\_Iter>n \; or \; There\_were\_changes:=\text{FALSE} \)

**Step 3**
- IF \( No\_of\_Iter>n \) THEN There is no solution. (There is a loop with positive value.)
- IF \( There\_were\_changes:=\text{FALSE} \) THEN we arrived to a feasible optimal time policy (All activity dates remained unchanged after two iterations.)

The rules of backward pass can be summarized as follows:

**Step 1**
- \( L_i^{i}= -\infty \) and \( OLD_L_i^{i}= -\infty \) \( \forall \; i \in \mathbb{N} \); Let \( L_i^{i=0} = E_i^{i=0} \) and \( OLD_L_i^{i=0} = L_i^{i=0} \); Let \( h=n \);

**Step 2**
- \( REPEAT \)
  - \( There\_were\_changes:=\text{FALSE}; \)
  - \( REPEAT \)
Select any \(i\) activity that has not been selected in this iteration yet
\[
L_i^S = \min \{ OLD_L_i^S; (L_i^S + t_{i-k} - z_{i-k} - t_{i-l} \land (P_{i-k},P_{i-l}) \in A^*) \}; L_i^F=L_i^S+d_i
\]
IF \(L_i^S > OLD_L_i^S\) THEN \(There\_were\_changes:=TRUE\)
\(h:=h-1\)
UNTIL \(h=0\)

Let \(OLD_L_i^S=L_i^S \land i \in N\)
UNTIL \(There\_were\_changes:=FALSE\)

Notes to the algorithm:
- Loop detection was done during the forward pass, so there is no need for that during the backward pass.
- Any order of activities can be used during the algorithm, which can largely modify the number of iterations. Here we used the ascending order of activities during the forward pass and the descending order during the backward pass. In the optimal case, the first iteration presents the results and the second iteration will validate this, in the pessimistic case, \(n+1\) iterations are necessary.
- Following the optimal order of the forward pass will be the worst during the backward pass, and vice versa.

4 SAMPLE PROJECT

4.1 Sample project: only minimal lags are allowed

A small sample project is shown in Fig. 4 a) consisting only of relations with minimal lags. Results can be seen in Figure 4b), calculations can be tracked below.

Forward pass:
Only activity A can be selected. \(E_A^S=0\); \(E_A^F=E_A^S+d_A=0+6=6\)
Only activity B can be selected. \(E_B^S = \{(E_A^S + t_A^A + Z_A^A - t_B^B)\} = \{(0+3+0-0)\} = 3\); \(E_B^F=E_B^S+d_B=3+6=9\)
Only activity C can be selected. \(E_C^S=max\{(E_A^S + t_A^A + Z_A^A - t_C^C);(E_B^S + t_B^B + Z_B^B - t_C^C)\} = \{(0+6+4-0);(3+2+2-0)\} = 10\); \(E_C^F=E_C^S+d_C=15\)
Only activity D can be selected. \(E_D^S=max\{(E_B^S + t_B^B + Z_B^B - t_D^D);(E_C^S + t_C^C + Z_C^C - t_D^D);(E_C^S + t_C^C + Z_C^C - t_D^D)\} = \{(3+6+3-0);(10+3+0-0);(10+4+0-1);(10+5+0-2)\} = \{12;13;13;13\} = 13\);
\(E_D^F=E_D^S+d_D=17\)

Early dates for all activities have been calculated, the forward pass is finished. (See Fig. 4)
Figure 4a) Sample project with minimal lags.  
Figure 4b) Results of the calculations.

Backward pass:

Only activity D can be selected. \( L_D^F = 17; L_D^S = L_D^F - d^D = 17 - 4 = 13 \)

Only activity C can be selected. \( L_C^S = \min((L_D^S + t^D_2 - z_{C0}^D - t^C_0); (L_C^S + t^C_1 - z_{C1}^D - t^C_1); (L_D^S + t^D_0 - z_{C3}^D - t^C_3)) = \min((13 + 2 - 0 - 5); (13 + 1 - 0 - 4); (13 + 0 - 0 - 3)) = \min((10; 10; 10)) = 10 \)

\( L_C^F = L_C^S + d^C = 10 + 5 = 15 \)

Only activity B can be selected. \( L_B^S = \min((L_D^S + t^D_0 - z_{B0}^D - t^B_0); (L_C^S + t^C_0 - z_{B2}^C - t^B_2)) = \min((13 + 0 - 3 - 6); (10 + 0 - 2 - 2)) = \min((4; 6)) = 4 \)

\( L_B^F = L_B^S + d^B = 4 + 6 = 10 \)

Only activity A can be selected. \( L_A^S = \min((L_B^S + t^B_0 - z_{A3}^B - t^A_3); (L_C^S + t^C_0 - z_{A6}^C - t^A_6)) = \min((4 + 0 - 3); (10 + 0 - 4 - 6)) = \min((1; 0)) = 0 \)

\( L_A^F = L_A^S + d^A = 0 + 6 = 6 \)

Late dates for all activities have been calculated, the backward pass is finished. (See Fig. 4)

4.2 Sample project: both minimal and maximal lags are allowed

A small sample project is shown on Fig. 5a) consisting of relations with minimal and maximal lags. The network with the transformed maximal relation and with the results is shown in Fig. 5b). Due to the transformation loop, the iterative algorithm has to be used.

Any order of the activities can be used. Here we use the A;B;D;C order for the forward pass. The calculations can be followed in Figure 6. Boxes of those activities that have been changed during the iteration are filled with grey.

Iteration #1

\( E_A^S = \max \{ \text{OLD}_E^A_s \} = 0; E_A^F = E_A^S + d^A = 0 + 6 = 6 \)

\( E_B^S = \max(\text{OLD}_E^B_s; (E_A^S + t^A_3 + z_{A3}^B - t^B_0); (E_C^S + t^C_0 + z_{C0}^B - t^B_2)) = \{-\infty; (0 + 3 + 0 - 0); (\infty + 0 - 2 - 2)\} = 3 \)

\( E_B^F = E_B^S + d^B = 9 \)

\( E_D^S = \max(\text{OLD}_E^D_s; (E_A^S + t^A_0 + t^B_6 + z_{B0}^D - t^B_0); (E_C^S + t^C_0 + z_{C0}^B - t^B_2); (E_A^S + t^A_6 + z_{A0}^B + t^B_0); (E_C^S + t^C_0 + z_{C0}^B - t^B_2); (E_A^S + t^A_7 + z_{A0}^B - t^B_0)) = \{-\infty; (3 + 6 + 3 - 0); (-\infty + 3 + 0 - 0); (-\infty + 4 + 0 - 1); (-\infty + 5 + 0 - 2)\} = 12 \)

\( E_B^F = E_B^S + d^D = 16 \)

\( E_C^S = \max(\text{OLD}_E^C_s; (E_B^S + t^B_0 + z_{B0}^C - t^C_0); (E_A^S + t^A_3 + z_{A0}^C - t^C_0)) = \{-\infty; (3 + 2 + 2 - 0); (0 + 6 + 4 - 0)\} = 10 \)

\( E_C^F = E_C^S + d^C = 15 \)

Figure 5a) Sample project with mixed lags.  
Figure 5b) Transformed network with the results
Iteration #2

\[ E^A_S = \max \{\text{OLD}_E E^A_s\}; E^A_F = E^A_S + \Delta T = 0 + 6 = 6 \]

\[ E^B_S = \max(\text{OLD}_E E^B_S; (E^B_S + t^A_S + z^B_S)t^A_S; (E^C_S + t^C_S + z^C_S)t^C_S) = \{3; (6 + 0 - 0); (10 + 0 - 2 - 2)\} = 6 \]

\[ E^B_F = E^B_S + d^B = 12 \]

\[ E^D_S = \max(\text{OLD}_E E^D_S; (E^B_S + t^A_S + z^B_S)t^A_S; (E^C_S + t^C_S + z^C_S)t^C_S) = \{12; (6 + 6 + 3 - 0); (10 + 3 - 0); (10 + 4 - 0); (10 + 5 - 0)\} = 15 \]

\[ E^D_F = E^D_S + \Delta T = 19 \]

\[ E^C_S = \max(\text{OLD}_E E^C_S; (E^B_S + t^A_S + z^B_S)t^A_S; (E^C_S + t^C_S + z^C_S)t^C_S) = \{10; (6 + 2 - 0); (6 + 4 - 0)\} = 10 \]

\[ E^C_F = E^C_S + d^C = 15 \]

No activity dates have changed in the course of iteration #3; therefore the forward pass is finished. For the backward pass the D; B; C; A sequence is selected. Calculations can be followed below.

### Iteration #1

\[ L^D_S = \min(\text{OLD}_L L^D_S); (\text{nil}) = 15; \quad L^D_F = L^D_S + \Delta T = 19 \]

\[ L^B_S = \min(\text{OLD}_L L^B_S; (L^D_S + t^D_0 + z^B_S + t^B_0); (L^C_S + t^C_0 + z^C_S + t^C_0)) = \text{min}(\infty; (15 + 0 - 3 - 6); (\infty + 0 - 2 - 2)) = 6 \]

\[ L^B_F = L^B_S + t^B = 12 \]

\[ L^C_S = \min(\text{OLD}_L L^C_S; (L^B_S + t^B_0 + z^C_S + t^C_0); (L^D_S + t^D_0 + z^C_S + t^C_0); (L^D_S + t^D_0 + z^D_0 + t^D_3); (L^D_S + t^D_0 + z^D_0 + t^D_3); (L^D_S + t^D_0 + z^D_0 + t^D_3)) = \text{min}(\infty; (6 + 2 - 2 - 2); (15 + 0 - 0 - 3); (15 + 1 - 0 - 4); (15 + 2 - 0 - 5)) = 10 \]

\[ L^C_F = L^C_S + t^C = 15 \]

\[ L^A_S = \min(\text{OLD}_L L^A_S; (L^C_S + t^C_0 + z^A_S + t^A_0); (L^B_S + t^B_0 + z^A_S + t^A_0)) = \text{min}(\infty; (10 + 0 - 4 - 6); (6 + 0 - 0 - 3)) = 0 \]

\[ L^A_F = L^A_S + t^A = 6 \]
Activity dates have not changed during the iteration. Calculations are finished. Results of the backward pass (and the forward’s as well) can be seen in Fig. 5b.

5 DISCUSSIONS AND FURTHER RESEARCH

A new ‘super’ precedence relationship based on the results of Francis & Mireco and Kim has been discussed in the paper. It has been shown that the traditional precedence relations (SS, SF, FS and FF with either minimal or maximal lags) could be derived from the new relation. It has also been shown that different results of parallel works e.g. bee-line relations can also be derived from this new ‘super’ relation; therefore claiming these results as a new technique is a wrong approach. This new relation forms a connection between two arbitrary points of two activities; therefore the name point-to-point relation fully describes the nature of this new relation. Following this logic, the traditional precedence relations, which could be called endpoint relations, form a subset of point-to-point relations as they connect the endpoints of the activities. Point-to-point relations affect the very fundamentals of network techniques, therefore all definitions, generalizations, problems based on the ‘old’ precedence relations must be checked and modified accordingly, if necessary, including the definitions and calculations of floats, the definition of the critical path, the classification of critical activities (Weist 1981) (Hajdu 1996) (Walls & Lino 2001), the algorithms for resource optimization etc. To our best knowledge, this work has not been done yet.

Abstract: Lean construction principles are not yet well known to the Egyptian construction industry. Introducing lean principles is often reported to be faced with considerable resistance to change. In this research, the authors follow the action research methodology to apply some lean construction tools on an ongoing construction operation in Giza, Egypt. The operation at hand is the manufacturing and installation of steel fences and gates in a new residential complex. The operation involves material procurement, off-site manufacturing, off-site finishing, transportation, installation and on-site finishing activities. The investigated sample includes four steel workshops, two painting workshops, and an on-site installation crew. The lean construction tool applied is value stream mapping. The main challenges faced by this operation are customer’s demand fluctuation and a resisting craftsmen culture. The customer demand unforeseeable fluctuations (1) affect the subcontractors’ ability to order large quantities of materials from the suppliers with sufficient lead-time; (2) results in an unstable cash flow to the subcontractors; and (3) generates an unbalanced workload distribution among the on-site and off-site crews. The supervisors of the workshops and on-site crews attempted to adopt some operation plans that according to their experience is best suited for mass production. These plans incorporated many wastes and needed significant modifications to respond in time to the fluctuation of the customer’s demands. Hence, value stream mapping is investigated as a possible solution to the aforementioned challenges. The authors succeeded to change and improve the operations of some participants, cutting the response time to customer demands by half in some cases. However, the authors failed with other participants, mainly because the craftsmen and their supervisors showed a significant resistance to change their operations design. This paper describes the lean construction initiatives, their results, and the main barriers and potentials identified through this research project.

1 INTRODUCTION

Lean construction seeks to maximize the generation of customer value by driving out all forms of waste, ensuring ‘right first time’ quality, reducing timescales and minimizing cost (Koskela 2004). Lean thinking offers an alternative method of project management to the construction industry. Lean construction is more efficient on complex projects with high uncertainties as well as fast track projects. There are several differences between the lean construction management approach and traditional project management. Following are some of these differences (Sicat 2012):

- The role of control in lean construction is to maintain a reliable flow, in contrary to the traditional after-the-fact variance detection,
Lean management focuses on the whole process to maximize value rather than optimizing each activity in isolation,

- Lean construction utilizes a pull planning approach, and
- Lean construction focuses on reducing variations at an early stage.

A key principle of lean thinking is the identification and systematic elimination of process waste at every stage of the value chain (Koskela 2004). Generally, the work done in any process to provide a product or service is classified as one of three activity types: (1) value adding; (2) essential but non-value adding, which is only needed because of current practice constraints; and (3) non-value adding, which is pure waste and should be eliminated immediately.

To identify the level and type of waste within a process, eight categories of waste can be defined, as follows (Koskela 2004):

1. **Transportation**, unnecessary movement and handling of goods,
2. **Inventory**, poor planning and control of inventory leading to excessive stocks,
3. **Motion**, excessive or unnecessary movement of people, and poor layout of tools,
4. **Waiting**, idle resources (people and/or plant) waiting for information or other resources,
5. **Over-production**, producing more than is required and/or ahead of time,
6. **Over-processing**, double handling of items, materials, etc.,
7. **Defects**, non-'right first time' quality requiring rework, and introducing extra time, and
8. **Skill misuse**, wasting or not effectively tapping into available skills, expertise, and knowledge.

Lean construction principles and applications are new to the Egyptian construction industry. A recent survey conducted in Egypt showed a current lack of awareness of lean construction, where 55% of the respondents are almost not aware of lean construction and 40% were at best only moderately aware (Gamal 2013). On the other hand, there is a great potential for adopting lean principles, where 55% of the respondents reported high potentials to use new management techniques.

Value stream mapping (VSM) is one of the essential lean practices, which has resulted in significant improvements in the manufacturing, military, and healthcare sectors, and has recently attracted interest in the software engineering community (Khurum 2014). VSM visualizes the entire production process throughout the enterprise. It represents both the materials and information flows. As defined by Rother (1999), value stream is the collection of all the activities required to bring a group of products through the main flow from raw materials to the end user. Furthermore, VSM enables documenting the relations between the activities and controls.

There are a number of reported attempts to leverage value stream mapping to improve construction processes. For instance, Roberto Arbulu et al. (2003) presented a case study within which VSM was used to re-engineer the construction supply chain for pipe supports used in power plants. Haitao Yu et al. (2009) developed a systematic approach that is based on VSM to analyze and formulate a lean production model for the home building industry. Chein-Ho Ko, and Shun-Chi Li (2014) used VSM to enhance submittal reviews for public construction projects by proposing a pull system instead of the traditional push system. Rosenbaum et al. (2014) used VSM to simultaneously assess production and environmental wastes over the execution stage of construction projects, and presented a case study of a reinforced concrete hospital in order to improve its production and environmental performance. Banawi and Belic (2014) used VSM as part of their delay analysis framework, in order to improve exterior construction processes. They applied their model to a case study of 53 residential units. Frandson et al. (2012) used VSM as one of the documentation tools in their study to analyze the workflow of complex projects.

In this paper, we attempt to use VSM to model and improve a number of processes in steel and painting workshops for manufacturing and painting steel products, including metal fences and gates. The studied construction operation involves material procurement, off-site manufacturing, off-site finishing, transportation, and on-site installation and finishing activities. The motivation to apply VSM to this operation was the reported long response times to the customer needs. Due the nature of the case study project, the customer demand was unpredictable and fluctuating. This unpredictable demand affected the
subcontractors’ ability to order large quantities of materials from the suppliers with sufficient lead-time, while the subcontractor’s mass production approach required large batches of materials to reduce the products unit costs. The demand fluctuations also resulted in an unstable cash flow to the subcontractor and generated an unbalanced workload distribution among the on-site and off-site crews. The following section describes the adopted research methodology to address this challenge.

2 RESEARCH METHODOLOGY

The studied project in this paper is a residential compound developed in Giza, Egypt. This paper focuses on the operation of manufacturing and painting steel products, which include side chain linked fence panels, back fence panels, and metal gates. The subcontractor responsible for this operation is Rawasy. The objective of this study is to propose and implement operational improvements that would reduce the subcontractor’s response time to meet the developer’s needs.

In order to achieve this objective, this research project adopted a four-phased action research methodology, which starts by developing a current state VSM for these processes that depicts the supply of raw materials, manufacturing processes in steel workshops, painting processes in painting workshops, and assembly on site. Second, the wastes within these processes are identified, and the process performance in terms of response time, cycle time, and inventory is reported. Third, a future state VSM is proposed and applied in order to eliminate processes wastes. Finally, the research findings are analyzed and discussed.

Table 1 shows the components and symbols of the VSM models developed to analyze this operation. The following subsections present the developed current and future state maps.

3 CURRENT STATE VSM

The objective of the current state VSM is to represent the actual state of the studied operation. This includes identifying and assessing the constituent processes/task, inventories between these tasks, crews and equipment, raw and manufactured materials transportation, and information flows. As shown in Figure 1, the current state VSM represents three lines of production, which are required to produce three product families; fencing side chain linked panels, fencing back panels, and pairs of steel gates. The production of each product family is sequentially conducted at three sites; the steel workshops, painting workshops, and on-site assembly locations. The production is distributed among four steel workshops, two painting workshops, and one on-site assembly team. Further, there are four suppliers and vendors providing the needed materials to the workshops and the on-site team. These materials include steel, wire mesh, accessories, and painting materials.

The customer sends monthly installation schedules to the subcontractor, who in turn uses these schedules to determine the required response time to meet the client’s needs. Accordingly, the subcontractor translates those schedules into weekly manufacturing schedules to the suppliers, workshops, and on-site assembly team. The steel workshops start the operation by conducting the three tasks of cutting, assembling, and mesh finishing, as shown in Figure 1.

These products are then shipped to the painting workshops, which conduct five tasks, including stocking, sanding, first coat application, second coat application, and wrapping. The finished products are then shipped to the work site for installation, finishing, and inspection. The current state map shows the cycle times of each task and the inventory durations as well as the response time as the key performance indicator for each of the three product families. For example, the batch size for the side chain linked panels (the first product family) is 100 panels and manufacturing response time is 8.1 working days. These achieved response times could not meet the customer’s needs. Accordingly, process improvements were required to the current state (for instance, as represented by the two Kaizen Bursts in the first product family). The proposed and implemented improvements are reported in the following subsection; the future state VSM.

Figure 1: Current State VSM
4 FUTURE STATE VSM

The use of value stream mapping enables visualizing the materials and information flows and identifying sources of wastes. Accordingly, a series of process improvements were proposed and implemented in the three product families, as shown in the future state VSM in Figure 2. The developed future state VSM was proposed to half of the workshops (i.e. two steel workshops and one paint workshop), whereas the remaining workshops continued to adopt the current state VSM. All the changes in the manufacturing process were implemented and tested in two consecutive batches in these workshops.

For space considerations, this subsection will discuss the details of the improvements implemented for the side chain linked panel (the first product family), whereas the improvements in all product families are demonstrated in the future state VSM in Figure 2. For improving the response time for producing the side chain linked panel, five improvements were made based on analyzing the shortcomings of the current state VSM, as follows:

- Decrease the batch size of the side panels from 100 to 35 panels,
- Combine assembly and mesh production processes in the steel workshops into one work cell,
- Combine the stocking and sanding processes in the painting workshops into one work cell,
- Combine the two coating processes in the painting workshops into one work cell, and
- Eliminate the wrapping process in the painting workshops.

Current processes adopt a mass production approach characterized by production wastes, such as large work-in-progress inventories, which in turn result in long response times. The first change is designed to gradually move from the current mass production approach as close as possible to a one-piece flow approach in order to minimize the production wastes associated with mass production. To this end, the production batch size was reduced from 100 panels to 35 panels, which is the minimum batch size that assures no waste in both material and transportation.

In the current state, each process in the steel workshop used to process the 100 panels before moving them all to the following process, which delayed the production and created large in-process inventories. In the improved future state, the assembly and mesh production are combined into a single work cell, eliminating their in-process inventory. Further, a pull system is implemented between the processes in the steel workshop (as indicated in Figure 2), where each processed panel is moved right away to next process to minimize the lead time and in-process inventories. These modifications decrease the inventory time and inventory amount significantly, where the inventory was reduced from 5 days for entire 100 panels to 2.9 days for only 35 panels.

Similar improvements were implemented in the painting workshop, where the first four processes are combined into two work cells, as shown in the future state VSM, eliminating in-process inventories. A supermarket pull system was also introduced between these two work cells with an 80% threshold. Furthermore, the wrapping activity was removed, because it added no value to the customer. These changes decreased the inventory time and amount in the painting workshops from 3.1 days per 100 panels to 1.2 days per 35 panels with almost no additional cost.
Figure 2: Future State VSM
5 DISCUSSION

In this study, the response time corresponds to the lead-time of producing a batch of the fence panels and gates. As shown in Figure 3, the abovementioned improvements resulted in reducing the response time by about 50% in the three product families, as follows:

- The side panels: The response time decreased from 8.1 days to 3.9 days,
- The back panels: The response time decreased from 7.1 days to 3.6 days, and
- The gates: The response time decreased from 7.1 days to 3.7 days.

The reported improved performance was achieved in one steel workshop and one painting workshop. However, the other steel workshop showed significant resistance to change as will be discussed in this section. The following paragraphs discuss (1) success factors; (2) observed barriers; and (3) reported impacts on other metrics.

First, based on the researchers’ observations, there were three main factors of success; (1) setting clear goals and cascading them throughout the subcontractor’s organization and to the workshops; (2) the willingness of the crews to accept change, which represents a learning culture; and (3) the nature of proposed changes, which was characterized by their low cost and no need for advanced technologies. Regarding the first factor, in the case study at hand, it was clear to the subcontractor’s management that reducing the response time is a top priority. Accordingly, various processes needed to be changed to fit this organizational goal, as discussed in the previous section. As for the second factor, the two workshops that successfully adopted the proposed improvements were both characterized by a very skillful foreman and a crew of semi-skilled young workers, who showed complete obedience to their supervisor. For these two crews, the changes in the processes were designed and verified with their foremen’s aid and consultancy, and the changes were then implemented with minimal resistance from the workers. Third, the proposed process improvements did not come at a noticeable cost and did not need the use of advance technology. This is an important aspect to facilitate the adoption of such changes in a relatively primitive and cost-conservative working environment.

The main observed barrier to implementing the proposed improvements was a culture of resistance to change, as experienced with the other steel workshop. It is noteworthy that the resisting crew is the one with the most skilled workers, which might explain why they showed the least cooperation and the most resistance to any change in their usual processes, especially that these changes were proposed from an outsider to the crew.
The implemented process improvements affected two other metrics; the products quality and manufacturing time per piece. First, the products quality generally improved. For instance, in the traditional mass production approach, defects might not be detected until a complete batch of 100 panels is produced. In the proposed approach, defects are identified and addressed early in the value stream. On the other hand, the manufacturing time per piece (unit lead-time) showed an increase by an average of 27% in the proposed approach, as follows (and as shown by Figure 4):

- Regarding the side panels: manufacturing time per piece increased from .65 hours to .89 hours,
- Regarding the back panels: manufacturing time per piece increased from .57 hours to .8 hours, and
- Regarding the gates: manufacturing time per piece increased from 5.7 hours to 5.9 hours.

![Figure 4. Manufacturing time per piece before and after the changes](image)

From the management perspective, the increase in the overall production time is an acceptable cost to the decrease in the response time in the operation at hand. This increase might be attributed to the learning curve effect, where the modified processes were only tested on two consecutive batches.

6 CONCLUSIONS

This paper presented an action research project, which involved designing, implementing, and testing an improved construction operation process using value stream mapping. The studied operation involved the production of three product families of fence panels and metal gates. A current state VSM was first developed based on actual observations. Second, sources of waste were identified and process improvements were proposed. Third, a future state VSM was developed to encompass and implement these changes. Fourth, the improved processes were evaluated. This research project represents the first attempt to apply value stream mapping to the Egyptian construction industry.

The results showed the superior performance of the improved process in terms of response time to customer's needs (which is the main target of this research) and the products quality. On the other hand, the manufacturing time per piece showed an increase, especially in the fence panels production. It was observed that with a clear delineation of organizational goals and discussing them in a respectable and involving manner to the working crews, a valuable enhancement is achieved to the whole operation and to the relations among its members. It is noteworthy that most of the value added is achieved through the use of the most simple and inexpensive changes. However, a resisting culture to change remains a main barrier to such improvements.

7 ACKNOWLEDGEMENT

The authors would like to acknowledge the support of the workshops foremen and their crews in designing and testing the proposed changes. The authors would like to express their gratitude to Mr. Abd Al-Hakeem Al-Soory, Mr. Magdy Hanna, and Mr. Hany Mahmoud.

Abstract: Best-value is a procurement method that combine price and non-price factors when selecting a contractor or design-builder. While, several researchers have evaluated the impact of best-value selection on project outcomes—such as cost, schedule, and quality—there are a limited number of studies that qualitatively evaluate the experience of different parties on projects that have been procured through best-value. To address this knowledge gap, this study aims to explore project stakeholders’ experience, team interactions, and behavioral patterns during best-value project execution. To achieve these objectives, three healthcare-construction case studies were selected and in-depth phone interviews were conducted with representatives of owners and contractors. The interviews were transcribed and a content analysis was implemented to explore the relationship between the procurement method and the team’s behavior in those projects. Three themes of team behavior emerged from the study, including innovation, partnering, and problem solving. The results of the interviews indicate that best-value selection encourages innovation, enhances partnering, and facilitates problem solving. The results also demonstrate that the time required to go through contractor selection and project scope development are major challenges of projects procured using best-value selection. To achieve successful completion of a project, one should: provide early project planning that includes clear definition of each party’s responsibilities; provide proper training; involve end users; and provide proper details in request-for-proposals. This research makes a cross comparison between the findings of this study and the existing literature related to best-value. The results of the study provide new insights regarding the team-building process through best-value selection. Furthermore, this study provides a basis for future data collection and quantitative analysis to compare various procurement methods and provides a foundation for exploring team integration in construction projects.

1 INTRODUCTION

One of the major decisions that an owner should take in the process of acquiring a new capital facility is to choose an appropriate procurement method. Traditionally, low-bid selection has been favored by public owners as a standard method for procuring construction projects as a means for efficiency, transparency, and corruption prevention (Boukendour and Hughes 2014). However, low-priced products or services can fall short of owners’ expectations and may cause adverse relations between client and contractor as well as low profitability for the contractor (Yu and Wang 2012, Horstman 2013). Owners in both the public and private sectors can choose best-value procurement and introduce non-price procurement factors that may negate the shortcomings of low-bid procurement. (Yu et al. 2013).
Best-value is a procurement approach aimed at getting the highest value and customer satisfaction for the lowest price. A review of best-value procurement practices for design-build transportation projects revealed that the approach demonstrates flexibility for owners since it allows for the consideration of factors that are specific to each project (Gransberg et al. 1999; Scott et al. 2006). The best-value approach deviates from traditional procurement methods by using other key factors such as past performance, relevant experience, and quality management plans as well as bid price in the contractor evaluation and selection. In addition, researchers observed that projects procured using the best-value approach consistently satisfied owner’s expectations regarding price and quality. The best-value system is viewed as a balance between the consideration of price and qualifications. Abdelrahman et al. (2008) showed that best-value is useful for the owner and the project due to the reduction in cost growth from 5.7% to 2.5% and a reduction in claims and litigation by 86%. Best value motivates stakeholders to choose this procurement method since it has the potential to eliminate waste, drive better and safer projects, improve quality, emphasize value for money, increase time savings, and lower life-cycle project cost.

Although previous studies indicated that best-value selection can provide significant benefits for some projects in terms of cost, time, and quality, there is no study that specifically seeks to understand the details of what happens during the project, specifically in terms of interactions among team members. To address this knowledge gap, the purpose of this qualitative study was to explore the behavioral changes of stakeholders in best-value projects in the U.S. construction industry. The main research questions of the study were: How does best-value procurement influence stakeholder behavior in the design and construction industry? What challenges have owners/designers-builders/contractors faced through the best-value process? What steps can be taken to improve best-value implementation in construction industry? What did the stakeholders learn from being involved in a project procured using best-value? By addressing these questions, this study will help practitioners and researchers to explore team behavior in best-value projects. The following sections elaborate on this research’s methods, analyses, and conclusions.

2 RESEARCH METHODOLOGY

2.1 Qualitative Method

To achieve the objectives of this study, we needed to hear the stakeholders’ voices about best-value’s impact on the behavioral pattern and collaborative interactions. To obtain a nuanced and detailed understanding of the issue, we chose a qualitative approach and case study as the main research methodology. The qualitative approach attempts to make sense of, or interpret, phenomena in terms of the meanings people bring to them (Denzin and Lincoln 2011). In addition, conducting a case study provides a suitable qualitative technique for this study because it helps to answer “how” questions and to capture the details of particular groups in a real-life context (Yin 2013).

To select cases and gain access to reliable sources, we used a large project delivery database developed by the Construction Industry Institute (CII) and the Charles Pankow Foundation (CPF). This database includes projects’ data from more than 200 building projects from across United States; such data were collected from a request to more than 8500 project managers in the past two years. To limit the scope of the study, we decided to focus on healthcare facilities because hospitals were some of the more challenging projects in the database to design and construct (Franz 2014). Here, we define healthcare facilities as hospitals, clinics, medical offices, and nursing homes. Purposeful sampling was used to select three healthcare projects that were procured using best-value selection. We then implemented a multi-case design in this research, within which we conducted case studies on three different projects. The process and criteria to select these projects were important since the participants needed to be knowledgeable about or have enough experience regarding the central phenomenon (Creswell and Plano Clark 2011). With these considerations in mind, the selected healthcare projects were chosen based on delivery method, project type, owner type, procurement, and team chemistry—Table 1.

To reach the most knowledgeable people in a project, we used an effective type of purposeful sampling called “Snowball Sampling.” In this method, participants or informants for whom contact information is available will be asked to use their social networks and refer the researcher to the most informative person who can contribute to the study (Bernard 2013, Palinkas et al. 2013). To enhance the validity of the study, data were collected from multiple cases. For each case study, at least one owner and one contractor representative were interviewed, which helped research team to collect and compare information from multiple sources (Yin 2013).

After finding the best contacts, phone interviews were formulated according to five distinct sections: (1) a brief summary of research background, objectives, and research method; (2) a consent question for participation; (3) an opening questions to capture the participant’s perception of central phenomenon; (4) seven questions clustered around behavioral changes related to the best-value selection process; (5) five concluding questions to obtain best practices, challenges, and the interviewee’s lessons learned. There were two separate interview protocols for owners and for design-builders. Since the qualitative research is interpretative research (Creswell 2009), we made sure that all participants were acquainted with the topic; however the questions did not lead interviewees to a specific direction.

We conducted seven semi-structured interviews to gain insights from the experience of the project stakeholders in a best-value project. In total, 253 minutes worth of interviews were audio-recorded and transcribed. To protect the anonymity of the participants, projects’ name and interviewees’ personal information were coded. A comprehensive content analysis was then conducted on transcriptions using MAXQDA 11 software to identify and analyze preliminary themes and codes. More than 60 codes were defined in this process, most of which were “In-Vivo” quote and theory codes. Two independent coders analyzed the preliminary list of codes to remove redundant codes, combine similar codes, define new codes, and compare the codes with the current body of knowledge to maintain consistency. This iterative process led to defining three main themes related to behavioral pattern: innovation, partnering, problem solving; and two other themes including implementation challenges and best practices. In the next step each themes was analyzed in details to answer the research questions.

2.2 Validation and Reliability

Many perspectives exist regarding the methods of validation in qualitative approach. We consider “triangulation” as a valuable means of assessing the accuracy of the findings. In triangulation, researchers include corroborating evidence from various sources and methods to shed light on a perspective (Creswell 2013). To triangulate our interview results, we interviewed multiple stakeholders in each project and considered both the owner’s and the builder’s perspectives. Similarly, in qualitative research, “reliability” often refers to the stability of multiple coders’ responses in data sets (Creswell 2013). Our focus on reliability here was on inter-coder agreement. We used multiple coders to analyze transcript data separately. The list of codes and themes were developed in an iterative process.
3 FINDINGS

The qualitative analysis revealed that early involvement is one of the most important features when using a best-value approach as procurement method. Early involvement was found to have significant impacts on the behavioral patterns of the stakeholders. The construction industry is highly fragmented in part due to a lack of communication among designers and contractors. The traditional delivery practices—such as design-bid-build—also promote separation of design and construction processes. Such a separation hinders design and construction knowledge exchange; consequently, the potential for innovation will be reduced as contractors have no input for design decisions. To address these limitations and to integrate construction knowledge into the design process, many owners prefer to use integrated delivery systems that provide overlap between design and construction (Beard et al. 2001). Project delivery methods that use design-build or integrated project delivery, such as those in the three case studies, necessitate the use of best-value or qualifications-based procurement because the builder is hired before the design is done. These innovative systems are characterized by the involvement of contractors in early stages of projects. One of the participants mentioned:

The nature of these integrated delivery methods requires considering factors other than cost, because the selected constructor will be responsible for some sections of design. Therefore, to employ alternative delivery methods, owners need to purchase combined design and construction services through best-value rather than low-bid selections (Beard et al. 2001). In all case studies investigated here, project participants had some sort of early involvement; therefore, it became important to study the relationship between time of involvement and team behavior. In total, three themes were identified: (1) innovation; (2) partnering; and (3) problem solving. Moreover, other important information which were mentioned by stakeholders categorized in two groups including challenges and best practices. These themes and their related codes are discussed in more detail below.

3.1 Innovation

One of the important benefits of best-value selection noted in interviews is its ability to encourage innovation in a project. While, leadership and top management plays a critical role in creating an atmosphere of innovation in a project, it is important to pre-qualify team members and seek people who are enthusiastically looking for better solutions. One of the owner stated that relationships are far more important than a transactional contract in creating an atmosphere of innovation:

“[…] I learned that… tapping people’s intelligence is far better than holding them to a contractual [sic] terms and conditions. I learned that people, when challenged, will clearly step to the plate, and, and when they do that, and they innovate, that they have a much more satisfying life and, and job, […]”

As mentioned before, best-value selection is required with early involvement of various parties unless a purely qualifications-based selection is used. According to interviewees, the early involvement of project stakeholders can facilitate adoption of innovative ideas in many ways. First, in traditional procurement methods, contractors have to start a project with a project design that is almost complete; however, the design can have constructability issues and require contractors to request several change orders. In contrast, in best-value selection, because a small portion of design is frequently provided, the contractor has more control over design, and as a results, cost and schedule control become much easier. As one of the owner noted that:

“[…] successful offer came in with a three month improvement on the project schedule that was laid in the RFP; there was some scheduling innovation using building information modeling, […]”

In addition, early involvement of contractors in the design-phase and the selection of parties based on their safety performance provide opportunities to enhance safety using innovative ideas. One of the owner mentioned that:
“[…] one of the things that [early involvement] enabled was a fresh and frank discussion and dialogue on how project safety was going to be... treated. And that led to some innovative methods to work on project safety, and that of course all contributed through the relationships and the teamwork in that particularly important area for us contributed directly to the amazing project safety success, which again, don’t [work] if you copied it, but it was … over 2.7 million man hours of construction with zero loss time incidents. […]”

Including specialty contractors in the design process can also provide several benefits for the project. For example, Franz et al. (2013) conducted comparative case study analyses to investigate the impact of specialty mechanical-contractor design involvement in the healthcare industry. They found that increasing the involvement of mechanical contractors in design-phase can reduce cost growth, schedule growth, and safety incidents, and can improve the HVAC system performance. Our findings indicate that one of the benefits of engaging trade partners in the early stage of a project is to avoid re-work. The results of interviews supported this theory and indicated that including the trade partners can reduce the amount of rework in construction projects and can lead to cheaper, faster, and safer projects. For example, one of the design-builder stated that:

“[…] having the team involved, including the trade partners, and having the leaders that were going to manage the field operations involved in the design, we only drew things once. That was our goal to only draw things one time. […]”

Furthermore, utilizing best-value selection for hospitals provides a unique opportunity for owners to achieve higher quality. Flexibility in best-value selection allows owners to incorporate the latest technology in their facilities and to create a capability for tomorrow's growth. Such traits could further add to the value of the process.

### 3.2 Partnering

Partnering is an effective tool for improving the productivity of stakeholders, achieving cost effectiveness, providing opportunities for innovation, and decreasing confrontational interactions in construction projects (Wong and Cheung 2005). The role of partnering and trust-based relationships has become an important foundation in innovative delivery methods for achieving successful projects (Pena-Mora and Harpoth 2001). Some of the design-builders highlighted the importance of this long-term partnering in selecting teams in best-value selection:

“The team first was build based on prior positive experience working together. So … we assembled the team based on the fact that we have collectively worked together and been successful before… all decided to come together because we had previously been able to work together, and... make money together and deliver high quality work together.”

Building trust among various team members is necessary for establishing a long term and effective partnering relationship (Wong et al., 2005). The interviewees repeatedly mentioned that best-value selection enhanced trust among project teams; for example, one of the interviewee called the best-value project as “Nirvana, full of honesty.” Considering that trust is pivotal attitudinal point in a collaborative environment and that there is a positive relationship between partners’ trust levels and their partnering success (Wong and Cheung 2005), best-value selection can facilitate collaborative decision making in a project.

### 3.3 Problem Solving

It was found that people who were involved early in the project and selected based on criteria other than cost could offer alternative solutions for equivalent results that ultimately provided more values to the owner. Several other studies verify these findings (Mendelsohn 1997, Jergeas and Put 2001, and Arditi et al. 2002). Making major decisions early in the project provided more time for project stakeholders to make
decisions related to uncritical activities. Such flexibility in time provided confidence in the project team. For example, one of the design-builder stated that:

"[...] One example is... structural steel. Because we were involved early, and we were... having full visibility of the, the design process, we were able to have the confidence that the... basic layout of the building had been settled, and we could order structural steel, and be able to start structure early while still allowing for full time to design the interior, because we had confidence that the basic structural grid had been settled. That ultimately resulted in saving... it ultimately was 6 months overall for the project, but just the structural steel alone gained the project 2 months by being able to order earlier. [...]."

According to interviewees, best-value selection also allows team members to work together and discover their strength and weaknesses, this can have positive impact on problem solving. One of the design-builder mentioned that:

"[...] we worked for nine months together before we started actual construction. In those 9 months, we had opportunities to... have growing pains in our relationship. [...] when we got to the construction phase, we were able to build upon the lesson learned, the relationships, the problem solving that we did early on during the design phase, and, and... better problem solve later when the stakes were higher at the time of construction. [...]."

Some interviewees stated that when the team is formed early in a project, the hierarchy of authority becomes clearer from the beginning, which leads to easier problem solving. People in such a project were able to develop an understanding that they needed to solve problems without escalating them. Even when they had to raise an issue with the ultimate decision makers, they believed in the commitment of the decision maker to find the right solution. More importantly, when a decision was made, the team would accept it and move forward. Some interviewees named this phenomena as "trust between parties." One can infer that using early involvement jointly with best-value selection provides an opportunity to establish trust between parties and facilitate problem solving. Furthermore, interviewees consistently mentioned that early involvement can provide better team experience in a project. Such an experience can lead to higher commitment from team members to project goals.

3.4 Implementation Challenges

Best-value selection provides several benefits for both owners and contractors; however, there are some challenges in implementing this procurement method. While previous studies mentioned legal barriers in best-value implementation (Hilger 2009), the identified challenges through interviews provided unique perspective on potential barriers to successful implementation of best-value selection. For example, although the current literature portrays that the use of the best-value can reduce both time and cost growth (Scott et al. 2006), the findings of the interviews provided us with evidence that owners and contractors assume timing will be a challenge. One of the owner stated that they had a challenge to allocate enough time for the evaluation of proposals:

".... In the sense of the process it takes us to go through a best-value process, [it] takes a lot longer than if you just use cost. So for me, when I best-value a piece of equipment, I have to look at the, that equipment, plus all options to go along with that equipment, and I look at 3 or more different vendors. So in order to evaluate all of those vendors that provide me a quote for a piece of equipment, I have to go through each one of those and evaluate it..."

Another contractor said that in order to achieve best-value, they had to change a piece of the equipment. This change required them to go back out to several different vendors again and gain more information to achieve what they expected. Also, one of the representative of end user group stated that while this change impacted project time and cost, they could achieve long-term benefit:
“...it had a domino effect. Once we changed that piece of equipment, then it made major changes to the construction site. Best-value, for the next 50 years, […]”

Most of the participants stated that although selecting contractors based on best-value process can be time-consuming, the results paid off. In order to develop a better team and better partnering culture, and to get more value for the ultimate user, it was better for owners to take their time to select the right partner, and then to let the team self-form and develop a trust-based relationship. One of the owner noted that:

“... [it is believed that] The time required to go through the full best-value process, will result in a longer overall project time-line. This project proved that that is not always the case, and that the, the savings in time during execution often more than make up for... the extended procurement timeline up front.”

Another challenge in best-value procurement stems from a vague definition of parties’ responsibility, which can lead to higher expectations. For example, a contractor noted that the owner sometimes expected them to make the decision that gave the most value to the client without recognizing that even under best-value procurement, there are still ultimately some business decisions:

“[...] sometimes the owner expects that you’re going to… give them some scope for free, because… you promised that you were going to give them best-value.”

On the other hand, an owner stated that sometimes the contractor or design-builder do not have enough incentives to reduce project cost:

“[...] contractors or design builders... expect that because they were selected as best-value, that... there should never be any pressure on price. So that, ‘hey, you selected me because I was best-value, so now that... I need you to cover this cost, you should not complain because you already told me that you selected me ‘cause I was better than the competition.’”

In these cases, stakeholders need to adhere to their contract. One of the stakeholders suggested that providing a clear definition of each party’s responsibility would help to reduce relationship problems.

Another challenge in a project procured using best-value is related to scope development. Proper scope definition proved to be primary factor that impacts cost, time, quality, and relationship (Cho and Gibson 2001, Gransberg et al. 2006). The best-value procurement provides flexibility for owners to build a final product that provides highest value for them; however, the results of interviewees indicated that such flexibility can lead to scope creep. One should note that a design-build delivery method executed under best-value procurement can affect the project scope since the project criteria are usually identified in a broad, generalized manner rather than a narrow, specifically defined one. The detailed planning should be available in the request for proposal, since the chance for a portion of the proposal to not meet an owner’s objective is fairly high, resulting in either a change to the scope or a reduction in scope to meet the budget. In addition, the process of risk assessment during the pre-contract procurement phase can reveal programming flaws or incompatibilities, creating a change that could result in a bidding addendum prior to the award of the contract (Hilger 2009). One of the design-builder explained the difficulty of defining scope in a best-value project:

“Scope definition and expectations is probably one of the more significant challenges. You know, having the, the balance between properly defining the scope, while allowing true flexibility for the design builder. It’s … an intricate challenge. “

3.5 Best Practices

According to interviewees, to get the most benefits from best-value selection, there is a need for appropriate and early project planning that includes clear definition of each party’s responsibilities, authorities, and hierarchy structure. For example, the design-builder should have enough authority to
influence design decisions; alternatively, by developing an appropriate reward system from the beginning, contractors would have incentives to meet all required outcomes and even surpass owner’s expectations.

While best-value provides an environment for project team members to collaborate, there is a learning process for each team member who is participating in this process. Training is an essential tool for formally communicating changes in policies to a wider audience as part of project implementation. The process to deploy procedure and train staff should introduce the basic concept and procedure, and should provide open communication to further promote best-value implementation. Furthermore, staff turnover and loosing key personnel in the middle of a project highlights the importance of regular training to make sure that all parties remain committed to the project goals. One of the owner explained the training challenge related to team-participant turnover in the best-value project:

“...the challenge of keeping people from reverting back to their old traditional behaviors of, of silo and blame casting. And so there’s a, a constant need to educate and, and re-inform people of the commonality of the goals, regardless of the selection process. It’s, it’s the nature of the, of the construction process. So there’s new people constantly coming onto the team and others leaving, so there needs to be a constant educational process, so that all new participants understand the goals and the, and the methodology for the, for the delivery mentality.”

Some interviewees mentioned that one of the factors that enhances the chance of success in a project is to take users on tours and get their feedback. While this action has low cost, it increases integration of various parties in a project. These interviewees said the users and owner should not be considered on opposite sides of a war, and all affected stakeholders should be brought to consultation to achieve success throughout the project. Some other interviewees also suggested that it is a good idea to use best-value approach to choose subcontractors too.

In design-build projects, it is necessary to develop detailed documents after the procurement, but the detailed requirements and information should be provided with requests for proposals to clarify the owner’s expectations. Most of the interviewees emphasized that the best-value request for proposal (RFP) should be in a higher level of detail than what requesters normally provide. Such information would offer tremendous benefits. The combined detailed RFP, contract, and assurance lead to less control but more transparency in relationships. However, there is a challenge about balancing the amount of detail required while leaving enough room and authority for the design/builder to come in:

“...I would certainly have some dialogue with the new owner about, you know, what the right level is, and... trying to, to find that sweet spot if you will, between, not enough information which is going to lead to a longer design process, and too much information which is going to lead to... a designer that is constrained and therefore lacks full ownership of those design elements.”

In total, the themes, implementation challenges, and best practices found here resonate with findings of other studies. Previous studies found that the following factors significantly impact the degree of success achieved through the implementation of best-value (Anderson and Russell 2001): training, appropriateness of method for projects, communication, initial agreement, post-award agreement, integration of design, upper management support, a clear definition of the best-value criteria (both objective and subjective), a sound selection method for “trade-off” between cost and non-cost criteria, and an appropriate award algorithm to align selection method with best-value objectives. Our findings are consistent with the outcomes in other literature, thereby validating the concurrence between our qualitative investigation and the existing understanding of best-value procurement.

4 CONCLUSION

One of the owner’s early decisions that has a significant impact on project performance is selecting the procurement method. Traditionally, the public sector prefers low-bid selection; however, projects initiated based on the lowest price may not meet quality requirements or—more importantly—may lead to
adversarial relationships between stakeholders. Thus, some owners use procurement methods such as best-value selection. Several quantitative studies have been conducted to investigate the impact of best-value selection on project performance; however, the number of studies that explore the role of this selection process on team behavior during the project is limited. To address this knowledge gap, we studied best-value process using qualitative research technique. We purposefully selected three healthcare projects that used best-value as a procurement method and interviewed different stakeholders involved in the project. A rigorous content analysis was conducted on transcripts using two coders. The extracted three themes illustrated how best-value selection impacts on team behavior and performance.

The first theme showed that early involvement, considering the proper selection criteria, and maintaining flexibility—all of which are inherent in the best-value approach—enhanced innovation and creativity in projects. Since construction participants seem reluctant to innovate on their own, providing a collaborative environment helps develop trust among parties and facilitate innovation (Ozorhon 2013). The second theme focused on the impact of best-value selection on facilitating partnering. This finding is supported by previous literature, which noted that changing a challenging partnering relationship to an effective one requires building trust among team members, a process that is facilitated by best-value selection (Wong et al. 2005). The third theme is concerned with the impacts of the best-value on the problem solving process. Both the literature (Jergeas and Put 2001, and Arditi et al. 2002) and the interviews performed in this study indicate that the best-value approach due to early contractor involvement helps teams respond to problems quickly and avoid conflict escalation. The other group of codes landed on the challenges of implementing best-value selection—particularly in terms of time and role/responsibility definition—and last group of codes documented experts’ opinions about the best practices that inspire behavior improvements and the most benefits from the project procured using best-value. To summarize, this study provided evidence that best-value selection can indirectly enhance the performance of a project by bringing all parties together early and by facilitating collaborative problem solving. The unique contribution of this study is to help practitioners to understand how best-value selection helps project stakeholders to form high-performance teams based on the trust.

There are some limitations of this research that are worth noting. First, the researchers’ reflexivity might lead to bias in coding processes. To solve this issue, an unbiased coder can analyze the interviews and compare findings. Second, the projects were selected from successful cases and all of these cases involved early contractor involvement through design-build and integrated project delivery. No instances of design-bid-build projects that used best-value and performed poorly were studied; although the certainly exist. To address these limitations, further case studies should be conducted on projects with poor performance and later builder involvement. In spite of these limitations, the study provides a clear advancement in the body of knowledge.

For future phases of this study, the research team aims to conduct several semi-structured interviews on other project types to obtain a holistic view of the best-value selection impact on team behavior. The results will be used to develop a grounded theory to explain how high performance teams can be formed. It is also suggested to implement mixed methods analysis for comparing various procurement methods and provide a comprehensive guideline to establish an integrated team in a project.

Acknowledgements

The authors would like to offer their hearty appreciation to Dr. John Creswell for his valuable insight and guidance for this study. We also like to thank those people who participated in our interviews.

³ House Building Standards, National House Building Council, UK

Abstract: The UK house building sector is facing dual pressures to expand supply, along with delivering against tougher Building Regulations’ requirements, predominantly in the areas of sustainability. A review of current literature has highlighted that the pressures the UK house building industry is currently under may be having a negative impact on build quality, causing an increase in defects. A review and synthesis of the current defect literature with respect to new-build housing and the wider construction sector has found that the prevailing emphasis is limited to the classification, causes, pathology and statistical analysis of defects. There is thus a need to better understand the overall impact of individual defects on key stakeholders within the new-build housing defect detection and remediation process. As part of ongoing research to develop and verify a defect impact assessment rating system, this paper seeks to contribute to our understanding of the impact of individual defects from a key stakeholder perspective by undertaking the literature review and synthesis phase. The literature review identifies the three distinct, but interrelated, dominant impact factors: cost, disruption, and health and safety. By pulling the strands of defect literature together the theoretical lens and key stakeholder sampling strategy is formed as the basis for the subsequent impact weighting development phase.

1 INTRODUCTION

In the United Kingdom (UK) there is a substantial shortfall in the number of dwellings available (Wilcox & Perry 2013) amid claims that the UK requires an additional 240,000 homes per year to meet demand (e.g. Holmans 2013). In order to satisfy the demand the UK government has introduced a number of new-build focussed policies and incentives to increase the housing supply (HM Government 2011). For example, the Get Britain Building investment fund is designed to enable house builders to progress sites that have stalled, not started or are on hold (DCLG 2014a). The UK house building industry has responded to the increased demand and government incentives by significantly up-scaling supply, with a 23% increase in new housing starts for 2013 compared to 2012 volumes (DCLG 2014b). In addition to the pressure to increase housing supply, the UK house building industry is under a further pressure via the introduction of a target for all new houses to be 'zero carbon standard' (Zero Carbon Hub 2014) from 2016 (UK Government 2012). The zero carbon homes agenda has resulted in the introduction of tougher Building Regulations, for example, changes to part L 'Conservation of Fuel and Power' (DCLG 2013), which has resulted in the house building sector incorporating new technical solutions into new-build houses to achieve compliance (e.g. NHBC Foundation 2012).
A review of current literature has highlighted that the pressures the UK house building industry is currently under may be having a negative impact on build quality, causing an increase in defects (e.g. Hopkin et al. 2014). There is increasing evidence that the inclusion of new technologies can and does adversely impact new-home quality; both in the material sense of the home itself and in the well-being of occupants (e.g. Yao & Yu 2012, Gill et al. 2010). In much the same way, it has long been advocated that an increase in housing supply can reduce build quality. For example, tightened delivery dates cause materials and workforce capacity to become stretched, and site management becomes less stringent due to workload (e.g. Sommerville et al. 2004). This situation is worsening as the UK house building sector is currently reporting materials, skills and workforce shortages (e.g. HBS 2013, UKES 2012). Further evidence of the increase in the number of new housing defects is in the Home Builders Federation (HBF) survey results (HBF 2014), which show that in 2014, 92% of home owners reported defects within their new-build house, the first time there has been an increase since 2011.

This paper offers an insight to the impact of individual defects from a key stakeholder perspective by undertaking the literature review and synthesis phase from a wider project to develop and verify a defect impact assessment rating system.

2 DEFINITIONAL DEBATE ON DEFECTS

A synthesis of construction defect literature has highlighted a wealth of research into defects, ostensibly utilising a multitude of separate terms and categories to define defects, for example, defects (e.g. Atkinson 2002), snags (e.g. Craig 2007), faults (e.g. BRE 1990), failures (e.g. Porteous 1992) and non-compliance (e.g. Baiche et al. 2006).

A 'defect' is defined as a shortfall in performance occurring within the life of the product, element or dwelling (BRE 1988). More specifically, Watt (1999) defines a 'building defect' as a failure or inadequacy in the function, performance, legal or user requirements of a building, and can become apparent within the structure, fabric, services or other facilities of the building.

A 'failure' is defined as an unacceptable difference between expected and observed performance (Ahzahar et al. 2011). Porteous (1992) further defines a 'building failure' as a shortfall in the technical performance, to an extent that the user and impartial expert evaluator define the building as defective. Josephson and Hammarlund (1999) conclude a defect to be the failure to achieve intended usage requirements.

A 'fault' is described as an unacceptable departure from good practice set out in Building Regulations and other authoritative publications (BRE 1990). Ilozor et al. (2004) argue that a defect and a fault are one in the same.

A 'non-compliance', also known as 'non-conformance' (Abdul-Rahman 1995), is described to be a deviation from the design specification (Assaf et al. 1995). Baiche et al. (2006) infer a non-compliance to be simply a 'failure' to adhere to Building Regulations, or approved standards; a term Sommerville and McCosh (2006) define as 'regulatory defects'.

A 'snag' is argued by Sommerville and McCosh (2006) to be the same as 'errors' and 'defects' within a new house, whereas Atkinson (2002) argues 'errors' as a cause of 'defects'.

These terms appear to be used interchangeably to describe the same phenomenon, i.e. imperfections in buildings (defects), causing minimal difference in the approach or outcome, as discussed in section 3 below.

3 OUTPUT THEMES IN CURRENT CONSTRUCTION DEFECT RESEARCH

The extant literature, regardless of the chosen designation for defects, tends to adopt a similar position where it limits itself to the classification (e.g. Macarulla et al. 2013), causes (e.g. Josephson & Hammarlund 1999), pathology (e.g. Atkinson 2002), and statistical analysis (e.g. Sommerville & McCosh
defects. The construction defect literature can generally be grouped into three different defect-related output themes: those that produce general findings; those that differentiate between individual types of defects; and, those that introduce a level of importance to individual defects. Each theme is discussed below.

3.1 General findings

The defect scholarship tends to produce general findings in respect to the causes, pathology, and statistical factors of defects. For example, Sommerville and McCosh (2006) analyse the overall numbers of defects within new homes in the UK. Love et al. (1999) review the total remediation cost of defects as a percentage of the production cost of construction projects. Atkinson (2002) examines the responsibility for defects taking place on construction sites, in general. Josephson and Hammarlund (1999) explore the typical causes of defects in construction projects. Whilst the general findings can produce a useful insight into the current status of defects within the construction industry, it can be prone to assuming all defects have the same characteristics, causes and level of importance. The literature can also be susceptible to providing generic recommendations in respect to defect reduction, including: training for trades and better management on site (e.g. Sommerville & McCosh 2006). By differentiating between individual defects, the literature could provide more relevant tailored guidance to reduce individual defect types.

3.2 Individual types of defects

There is literature available that identifies and classifies individual types of defects. However, this identification tends to be through the frequency in which different defects are encountered over particular stages of a construction project. For example, Baiche et al. (2006) identify the most common Building Regulations contraventions taking place during construction, including radon protection, misplaced damp proof membranes and damp proof courses, and inadequate thermal insulation; Craig (2007) presents a list of prevalent 'snags' in UK new homes during the first two years post completion, including making good, paint, cleaning, plastering, mastic, fitting, doors, sealant, and grout; and, Mills et al. (2009) stress the most prominent sources of warranty claims in Australia including, slab foundations, strip foundations, roof leaks, shower base leaks, external water penetration, plumbing, shower cubicle leaks, drainage, pier and beam foundations, leaking windows. The defect classification literature provides valuable detail as to the most prevalent type of defects occurring within the construction industry. However, it does not identify a level of priority with regards to approaching targeted defect reduction. Bringing a level of priority to defects will help to guide this decision (e.g. Sommerville 2007).

3.3 Priority of individual defects

A small subset of the defect classification literature has started to introduce a level of priority to defects, albeit in respect of the process for remediating defects identified on a building survey. This level of priority tends to be based upon the current physical condition of the individual building element. de Oliveira Pedro et al. (2008) proffer a condition survey to identify the severity of the defects identified within a number of building elements, giving individual building elements a weighting coefficient based upon their perceived level of importance. Che-Ani et al. (2011), influenced by the RICS HomeBuyer survey, extend this logic to establish a priority for repairing individual defects, based on two contrasting input parameters: condition and repair priority (ranging from (1) cosmetic to (5) health and safety risk). The survey develops an overall score based upon the product of the contrasting input parameters, with the repair priority being displayed in a traffic light format. Whilst the building condition survey has brought a level of priority to the defect remediation process, it appears to be based around the individual surveyor's perception of importance and urgency. Sommerville (2007) argues that an approach of being able to establish the impact of individual defects will further develop the ability to determine whether individual defects are significant or not, and guide what should be focussed upon. There is, however, a dearth of literature seeking to understand the overall impact of individual defects.
4 THE IMPACT OF DEFECTS

A review of existing construction defect literature has identified a number of common aspects which have the potential to impact on a variety of stakeholders involved with construction projects, including: cost (e.g. Georgiou et al. 1999, Mills et al. 2009, Josephson & Hammarlund 1999, Love & Li 2000, Rosenfeld 2009), potential health and safety/regulatory non-compliance (e.g. Georgiou et al. 1999, Baiche et al. 2006, Ilozor et al. 2004, Love & Edwards 2004, Macarulla et al. 2013, Smith et al. 2013), and disruption (e.g. Davey et al. 2006, BEC 1991, Rosenfeld 2009, Sommerville et al. 2004). Each aspect is discussed below.

4.1 Cost implications

Existing research argues that defects in general have cost implications for the builder and warranty provider. For the builder defects are argued to reduce the amount of profit available from projects (e.g. Sommerville & McCosh 2006, Davey et al. 2006) while for the warranty provider defects are argued to cost vast sums of money to remedy (e.g. Mills et al. 2009). It is claimed that remediation of defects occurring during the construction stage and the defects liability period (first two years post completion) cost the builder on average between 2.3% and 9.4% of the production cost (e.g. Josephson & Hammarlund 1999, Love et al. 1999, Love & Li 2000). Outside of the construction and defects liability period, construction projects tend to be subject to warranty cover (e.g. Sommerville & McCosh 2006). The cost of defect remediation during the post completion warranty period in Australia (seven years post occupation) is argued to be circa 4% of the contract value (e.g. Mills et al. 2009). The generalised cost argument offers valuable insights and headline figures with regards to the overall cost of defects to both builders and warranty providers; however it can be disposed to assuming that all defects have the same cost characteristics. There are notable exceptions that acknowledge the diverse financial nature of defects. For example, Davey et al. (2006) point out that it costs a minimum of £50 for an operative to attend to a single defect. Mills et al. (2009) further identify that different defects cost varying sums to remedy; for instance, remediation of external water penetration is more costly than plumbing, on average. Rosenfeld (2009) drills down deeper to identify a number of specific costs associated with identifying and resolving individual defects. The costs identified include the cost of investigating the cause of the defect (either by internal staff or external specialists, or both), the cost of the repair (including materials, labour, and equipment), the costs of staff time in handling customer complaints (along with any legal fees and/or compensation paid during the complaint process), and the cost of warranty repairs. Along the same line of associated costs, Davey et al. (2006) argue that post completion defects also incur travelling costs during both the investigation and remediation processes. Finally, Georgiou et al. (1999) propose that individual defects with high associated costs should be seen as “major” defects.

4.2 Potential health & safety (H&S)/regulatory implications

It is argued that defects can have a negative impact on project safety (e.g. Love & Edwards 2004). The implication is that reducing defects has the potential to improve construction health and safety (H&S) in general (e.g. Macarulla et al. 2013). There is also a more specific H&S concern proffered within the literature, regulatory non-compliance. Sommerville and McCosh (2006) comment that the majority of construction defect research concentrates on defects that do not comply with the Building Regulations. Smith et al. (2013) further explain that this is because the Building Regulations are the minimum set of standards that a construction project is required to meet. Building Regulations compliance is to certify that reasonable standards of H&S are ensured for building users (e.g. Baiche et al. 2006). Regulatory defects have the potentiality to jeopardise the H&S of the occupants, with Smith et al. (2013) arguing the need to consider human safety once the building is occupied. During construction, a building inspector must take all reasonable steps to satisfy themselves that the requirements of the Building Regulations have been met; however the primary responsibility for achieving compliance remains with those who commission and undertake the work (e.g. LGO 2014). Under the Building Act (1984) if a person carrying out building work contravenes the Building Regulations, they may be taken to the magistrates’ court and ordered to pay a fine for the contravention, and a further fee for each day the contravention continues post-conviction. In specific circumstances, under a new build warranty the warranty provider will provide cover for defects (that contravene Building Regulations) where they present a danger to the H&S of the
occupants (e.g. NHBC 2012). This generalised approach provides a clear indication of the H&S implications associated with non-achievement of regulatory compliance, along with those affected. However it neglects to discuss in detail the varying H&S implications of individual defects. There is a small pool of literature that acknowledges the heterogeneous nature of defects and the accompanying H&S concerns they pose. Georgiou et al. (1999), for example, argue that individual defects with the potential to damage H&S should be deemed a “major” defect. It is also recommended that focus should be placed upon reducing individual defects in areas deemed detrimental to the H&S of the home occupants (e.g. Baiche et al. 2006). Ilozor et al. (2004) further argue that there is still a need to concentrate on defects that are low in number, if only to ensure safety. NHBC (2012) drill down deeper by highlighting ‘chimney and flue defects’ as types with the potential to present an imminent danger to the H&S of the home occupants.

4.3 Disruption implications

It has been argued that defects generally cause disruption to both home occupants and house builders (e.g. Davey et al. 2006). Rosenfeld (2009) identifies that defects occurring during the construction process can cause disruption to the builder through resource usage, for example, site management investigating their causes, and the deployment of labour and equipment to remedy the defects; instead of undertaking new work. Remediation of defects has the potential to cause delays in handover, and put builders at risk of complaints from the home occupants (e.g. Sommerville et al. 2004). Post completion defects are also argued to cause disruption by way of operatives having to return to, and be granted access to a previous job (by the home occupant) (e.g. Davey et al. 2006). The BEC (1991) suggests that home occupants are unlikely to welcome disruption that occurs due to work being carried out incorrectly. Rosenfeld (2009) identifies that handling post completion defects has the potential to cause disruption to a builder’s staff. Disruption to staff can include time spent travelling to investigate and remediate defects, and the process of having to arrange for trades to return to properties to undertake repairs (e.g. Davey et al. 2006). It is further argued that invaluable time of managers within a construction company is consumed dealing with issues of the past, when it could be better spent concentrating on the company’s current and future projects (Rosenfeld, 2009). Over prioritisation of current and future projects in place of resolving defects during the defects liability period (first two years post completion) often results in poor quality service, and breakdowns in communication between construction companies and clients (e.g. Davey et al. 2006). Existing research provides valuable evidence by identifying a number of defect related consequences with the potential to cause disruption. It however can be susceptible to discussing defects only in a universal context. Individual defects have differing potential disruption impacts on both house builders and home occupants, such as divergent levels of inspection, varying repair durations, fluctuating demand on labour and equipment, and the unstable levels of communication and service the combination of these aspects will invariably cause.

What has become apparent from the prevailing literature relating to the impact of defects in construction is how a number of the identified factors are closely interrelated and can involve a number of stakeholders. For example, a post completion defect that is a non-compliance with the Building Regulations has a number of related implications: first, cost implications for undertaking the repair, and/or any potential fines for the contravention; second, potential H&S implications due to Building Regulations compliance being to ensure that reasonable standards of health and safety for building users are achieved; and, finally, disruption implications by the way of operatives having to return to the property, and be granted access by the customer to rectify the situation. Sommerville (2007) has made a useful contribution to the debate by identifying that there are a lack of models available to quantify the overall impact of individual defects. Further, the same defect would likely include a number of stakeholders, including: the home buyer/occupier, builder and building inspector. The following section further examines the defect detection and remediation process, and the key stakeholders involved.
5 THE IDENTIFICATION OF KEY STAKEHOLDERS INVOLVED IN THE NEW HOUSING DEFECT DETECTION AND REMEDIATION PROCESS

Despite the limited research or models to identify the overall impact of individual defects on key stakeholders, the literature has established the defect detection and remediation process in house building along with the key stakeholders involved in the process. Figure 1 provides a simple overview of the process. Four key stakeholders are identified: the home buyer/occupier, house builder, warranty provider, and building inspector. These stakeholders and their involvement within the process are discussed below.

![Diagram of the defect detection and remediation process](image)

Figure 1: Typical defect detection and remediation process in the UK new house building

During the construction of a new home, an inspection procedure involving examination of work on site takes place to assess whether compliance with Building Regulations is achieved (e.g. Smith et al. 2013). The inspection procedure can be undertaken by either a building inspector from the local authority or an independent approved inspector (e.g. CIC 2014a). As shown in Figure 1 building inspectors frequently observe non-compliance (identify defects) during the construction process and produce checklists of faults that require correction (e.g. Baiche et al. 2006). The house builder typically accepts the inspector’s decision and rectifies the defect (e.g. Smith et al. 2013). As work progresses on site employees of the house builder, typically either site or project management, will also undertake quality inspections of the building area. If defects are identified a tradesperson will then be required to rectify the defect for the builder to approve (e.g. Sommerville et al. 2004).

During the builder’s liability period (first two years post completion), the UK house building industry utilises a snagging process which is heavily reliant on the home buyer/occupier (e.g. Sommerville et al. 2004). The home buyer/occupier is responsible for identifying and reporting any problems back to the builder’s customer care department so that they can deploy trades to rectify them.

Outside of the first two years, most new homes are subject to warranty cover. Warranties are typically ten years in length. After the builder’s liability period of two years, the warranty is used to cover building defects in years 3-10 (e.g. Premier Guarantee 2013). According to Construction Industry Council (CIC, 2014b), there are seven key players in the new home warranty market in the UK, each offering new home warranty products; they are Building LifePlans, Local Authority Building Control, Build Zone, Castle 10, CRL, Premier Guarantee, and National House Building Council (NHBC). If the home occupier notices a defect that requires attention, they are required to contact the warranty provider and notify them of the identified defect, and afford the warranty provider the opportunity to inspect the home. Upon acceptance of a valid claim, the warranty provider will make the necessary arrangements to have the defect remedied (e.g. NHBC 2012). Warranty providers will keep a record of claims history as part of their risk assessment procedures and for calculating the builder’s renewal fees (e.g. Auchterlounie 2009). Mills et al. (2009) argue that the warranty provider spends large sums of money rectifying defects. However it is acknowledged that repairs are also undertaken directly by the original builder to protect their renewal fee from increase (e.g. NHBC 2011).
6 DISCUSSION

What has become clear from the review of literature relating to the impact of defects is that there is scant rigorous empirical evidence to identify the overall impact of individual defects on key stakeholders. There is only a small pool of literature that discusses, in isolation, some of the individual facets that contain the potential to impact on a variety of stakeholders, i.e. cost, disruption and health and safety/regulatory (e.g. Georgiou et al. 1999, Baiche et al. 2006, Ilozor et al. 2004). Furthermore, the scholarship has identified that the three aspects with impact potential are closely linked. This close link suggests that it would be difficult to consider one impact criterion without considering the others. Despite this close relationship the review has identified a lack of models available to quantify the overall impact of individual defects (e.g. Sommerville 2007). Such a model would develop the ability to establish the impact of individual defects and will further develop the ability to determine whether individual defects are significant or not, and guide what defects should be focussed upon for targeted defect reduction.

7 RESEARCH AIM AND OBJECTIVES

The aim of this research is to better understand the impact of defects on key stakeholders within the new-build housing defect detection and remediation process.

In order to achieve the above aim, the following objectives will need to be satisfied:

• Determine which of the identified aspects are more important to the relative stakeholders, and why.
• Develop and verify a defect impact assessment system for the purposes of defect analysis.

8 RESEARCH METHOD

To successfully achieve the aim and objectives set out in section 7, further research will be undertaken in three phases (see Figure 2): the development of impact weighting, testing of impact criteria, and validation of impact criteria.

8.1 Development of impact weighting

The literature review and synthesis undertaken in this paper has helped to form the initial defect weighting criteria and identify the key stakeholders in the new-build housing defect detection and remediation process. Questionnaires will be employed to establish the weighting coefficient for the identified aspects of defects with potential to impact upon stakeholders within construction projects. The questionnaire will establish which aspect is deemed to be the most important to the respective stakeholders, and why. As the defect scholarship takes a normative position of the identified aspects, the why question within the survey will seek to explore the stakeholders’ perceptions of these terms and the underlying factors behind their selection. The questionnaire survey will be distributed to the four key stakeholders identified in
section 5, home buyer/occupier, house builder, warranty provider, and building inspector. First, a list of home owners who have had a defect rectified under their warranty within the last year will be sourced from the UK’s largest new home warranty provider. Second, members of the same warranty provider’s staff will be identified. Third, building inspectors from the UK’s largest independent building inspection service will be located. Fourth, active house builders held within the UK’s leading warranty provider and independent building inspector’s register will be identified. (Note: the UK’s largest independent building inspection service is responsible for over 50% of the building control market, and the UK’s largest warranty provider provides cover on circa 80% of new build houses, therefore making them a representative sample).

Developing a weighting coefficient for each of the individual components (e.g. de Oliveira Pedro et al. 2008) and multiplying them together (e.g. Che-Ani et al. 2011) will allow for the overall impact of the combined criteria of individual defects to be calculated. Primary data drawn from the questionnaire survey results will generate the capability to empirically develop a weighting for each of the predefined aspects, which will allow us to identify which of the elements should have the largest influence to the overall impact rating.

8.2 Testing of impact criteria

Upon completion of criteria development, the developed impact model will be tested through its application to defects extracted from the defect records of the UK’s largest new home warranty provider’s claims database. Claim files provide objective information with regards to the magnitude, cost and cause of defects, therefore making them an ideal source of data for research in to defects (e.g. Georgiou et al. 1999). Testing new systems on secondary data is a method frequently employed. For example, Georgiou et al. (1999) tested the suitability of their defects classification system by analysing defect records for Australian homes. The UK’s largest warranty provider provides cover on circa 80% of new build houses, therefore making them a representative sample.

8.3 Validation of impact criteria

The impact criteria will finally be validated through exposing it to expert focus groups to establish whether the system is clear, relevant and produces findings in line with expert expectations, along with identifying any improvement opportunities. Georgiou (2013) argues that expert validation and achieving a level of consensus is necessary to prove that the author’s objectivity is sufficient. The expert focus groups will consist of two comparative focus groups to validate findings (e.g. Adams & Cox 2008). The focus groups will consist of participants, including; Chartered Surveyors, Chartered Engineers and Chartered Building Engineers. Focus groups have been chosen as they offer rich amounts of data and different perspectives on a given topic, and serve as a useful tool for gaining insight in to different views and dynamics within a group context, for example, consensus and disagreement (e.g. Litosseliti 2003).

9 CONCLUSION

This paper set out to contribute to our understanding of the impact of individual defects from a key stakeholder perspective by undertaking the literature review and synthesis phase from a wider project to develop and verify a defect impact assessment rating system. The synthesis of the current construction defect literature established a number of aspects with the potential to impact on stakeholders involved with the construction process. The literature review also identified a number of key stakeholder groups within the defect detection and remediation process in the new house building. This paper is concluded by offering the theoretical lens and key stakeholder sampling strategy as the basis for the subsequent impact weighting development phase, the findings of which to be presented at the upcoming conference.

Abstract: Adequate lighting is a necessity on construction sites not just for work completion, but also for the work quality, worker safety, and project productivity. This paper discusses the problems associated with traditional temporary lighting on construction sites and presents a case study on using LED temporary construction lighting as a potential solution. Various studies have shown that the traditional methods of providing temporary lighting are inadequate due to their non-compliance with OSHA requirements; visual discomfort; constant maintenance; and impacts to productivity, safety and health. On the other hand, studies have shown that using LED as a source of temporary construction lighting provides benefits over the traditional lighting system, even though such uses are still rare within the industry. Using LED for temporary construction lighting, however, is subject to the high initial materials cost and other drawbacks. To this end, the objective of the research is to provide a deeper understanding of LED temporary construction lighting and ascertain its benefits and limitations through a case study. The study involves the University of Washington’s Bothell Science and Academic Building Project. The study involves interviews with both the lighting system vendor and onsite project personnel; survey questionnaire distributed to the field workers; and cost analysis of the LED temporary lighting system. The case study concluded that the benefits of using LED temporary construction lighting outweighed its limitations, but the individual cost savings may belong to different parties and may not necessarily be passed on to the owner depending on the contractual arrangements.

1 BACKGROUND

Adequate lighting is important on the construction site not just for work completion, but also for the work quality, worker safety and productivity of the workers. Whilst construction sites can be lit by natural lighting, temporary lighting is usually required to supplement the natural lighting especially for enclosed work areas, during early/late work hours, and around evacuation egress. Often, a general contractor would place the duty of providing and maintaining temporary general lighting (and temporary power) under its electrical contractor’s scope of works and include it as part of the electrical bid package. Whilst task lighting has always been the responsibility of individual subcontractors, the scope of temporary general lighting has always been ambiguous with the level of illumination required not being clearly defined in the contract provisions.

Various studies have shown that the traditional methods of providing temporary lighting are inadequate. Non-compliance with the regulatory illumination standards during daylight hours was found (Smith and
Azhar, 2007) and only very high wattage light sources (e.g. 400 W metal halides) spaced at an appropriate distance could achieve the illumination standards (Smith, 2008). However, high wattage light sources are very bright, creating glares, shadows, and visual discomfort. The traditional method of temporary lighting also creates safety concerns. It is not uncommon that the lamps would burn out from overloaded source of energy, expose workers to high voltage wires, or become tripping hazards because of the extension cords and wires attached. Based on field observations and experiences, workers’ productivity tends to be negatively impacted with the use of traditional methods of temporary lighting. The traditional method requires constant moving of the lamps, resulting in the lamps being dropped, broken, or smashed easily. Oftentimes workers are required to replace the damaged lamps, or to locate, move and set-up task lighting due to the insufficient illumination of the general temporary lighting. The last area of concern is worker health. When light bulbs break, workers cleaning up the broken bulbs might be exposed to the escaping Mercury vapor or UV rays commonly seen in compact fluorescent lights.

Due to the problems associated with the traditional method of providing temporary lighting, the Capital Project Office at the University of Washington (UW) deployed the use of low voltage temporary LED lighting system to replace traditional temporary lighting on the UW Bothell Phase 3 (“UWB P3”) – Bothell Science and Academic Building project. This is the first west coast installation of low-voltage LED temporary construction lighting system in the U.S. Construction for the 74,000 square foot UWB P3 building consists of four levels and one basement and was delivered using the GC/CM (General Contractor / Construction Manager) and EC/CM (Electrical Contractor / Construction Manager) approach to have the general contractor and electrical contractor on board early. While studies have shown that there are benefits of using low voltage LED lighting system over the traditional methods to provide temporary lighting, there are limitations as well with the most significant one being the high initial system cost. To this end, this paper: (1) introduces the case study background, (2) describes how the LED lighting system was deployed in the studied project UWB P3, (3) discusses data collected through interviews, survey questionnaires, and cost estimates, and (4) presents findings and concluding remarks. It should be noted that as most of the data collected are of qualitative nature, the case study discussion and results although were produced following a scientific procedure are still subject to human bias.

2 DEPLOYMENT OF THE LOW VOLTAGE TEMPORARY LED LIGHTING SYSTEM AT UWB P3

The FLEX SLS lighting system by Clear-Vu Lighting was deployed at UWB P3 to provide temporary construction lighting to all corridors and stairwells, as well as individual rooms where necessary. A typical setup comprises of 450-watt power systems, LED modules with 10’ whips, a T connector and low voltage (24V) cables. As this system made use of low voltage, the temporary lighting power cables and drivers could be designed to be embedded within the concrete slab, with only the whips and LED light fixtures dropped and exposed below the ceiling deck. Installation of the temporary LED construction lighting system at UWB P3 was undertaken in a three-stage process, including pre-construction estimate, planning for the lighting and controller setups, and the physical installation.

During the pre-construction estimate, the electrical contractor estimated that 285 LED light fixtures would be needed based on the site conditions and layout, considering that each LED module’s coverage is roughly 17 ft by 17 ft. During lighting and controller setup planning, layout of the MEP was examined to determine possible locations that did not run across known MEP services. Locations of the walls that reached all the way to the bottom of the concrete deck were also taken into consideration, as they would block any light source once the walls were erected. Due to the capacity of the drivers, the number of LED fixtures connected to each driver was limited and therefore impacted routing of the cables, the number of drivers required to be installed per floor, and the number of circuits required to be run per floor. Upon confirmation of the locations of the fixtures and drivers, approximate measurements of their distances from gridlines were taken to aid the physical installation. During the physical installation, based on the approximate dimensions from the gridlines, the forms had to be drilled through so that the inserts could be placed within the concrete deck for both the fixtures and the whip. Coordination with ironworkers was necessary as the cables were installed concurrently with the reinforcement bars. During concrete pour, the electrical contractor would station a “pour watch” to ensure that the cables do not get damaged or pulled back into the slab during the pour. After the concrete has cured, upon stripping of the formwork,
the LED fixtures were installed on the floor slab and energized immediately to provide temporary lighting for that floor. Figure 1 illustrates how a LED fixture was deployed below a ceiling deck at UWB P3.

![Temporary LED lighting fixture dropped and exposed below ceiling deck](image)

**Figure 1:** Temporary LED lighting fixture dropped and exposed below ceiling deck (courtesy of Nelson Electric)

## 3 DATA COLLECTION

To verify the benefits and limitations of using the LED fixtures as construction temporary lighting at UWB P3, data were collected via various approaches to triangulate common themes. Site interviews providing qualitative data were conducted with the project management staff from the UW CPO, general contractor, and electrical contractor. The interview data can be summarized into six themes as described in Table 1.

<table>
<thead>
<tr>
<th>Theme</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Immediate use of temporary lighting</td>
<td>The temporary lighting system could be energized immediately upon the stripping of the formwork, way before MEP rough-ins</td>
</tr>
<tr>
<td>Light reflection off drywall</td>
<td>Drywalls would reflect the LED light and brighten up surrounding spaces as the internal partitions being erected</td>
</tr>
<tr>
<td>Workers drilling into embedded cables</td>
<td>Workers drilling through the slab for their works would accidentally drilled through the embedded cables</td>
</tr>
<tr>
<td>Upward lighting requirement</td>
<td>The LED lights were generally hung faced downwards but upward lighting is required for HVAC works</td>
</tr>
<tr>
<td>Duration of use of temporary lighting</td>
<td>Due to the ease of light fixture removal, the temporary lighting could be used until permanent lighting was turned on</td>
</tr>
<tr>
<td>Contractual requirement</td>
<td>Temporary lighting as “means and methods”, up to the general contractor’s discretion</td>
</tr>
</tbody>
</table>
A survey was administered to solicit worker input on the lighting requirements specific to their tasks and on how the LED lighting fixtures compared to the traditional methods. Based on the 19 responses received, in overall, the workers appeared to have had a more positive experience with LED lighting as compared to the traditional lighting, consistent with the interview results. Based on the ratings of both systems (on a scale of 1 to 5), the average rating of LED lighting’s attributes (e.g. visual comfort) ranged from 3.5 to 4.0 as compared to an average rating of 2.4 to 3.2 for traditional lighting’s attributes. Particularly, plumbers were in more agreement in their ratings than other trades. The electricians, on the other hand, had mixed reviews as to whether working in LED lighting was a more positive experience than traditional lighting.

Estimated cost data were obtained (see Table 2) to compare the costs of providing a temporary metal halides lighting system and a temporary LED lighting system to meet the OSHA 5 foot candle requirements for UWB P3. As the electrical contractor had never tracked these cost categories for temporary metal halides lighting systems used in the past, estimates from a different electrical contractor, Clear-Vu, and NECA Manual of Labor Units were also consulted to provide a basis of comparison and to establish a range of possible costs.

</tbody>
</table>

4 STUDY FINDINGS AND CONCLUSION

Use of the temporary LED lighting system does provide better illumination and minimizes the other identified problems of safety (less hazards), productivity (less maintenance required), and health (less risk of mercury and UV exposure). In addition, the case study revealed that use of the temporary LED lighting system allowed immediate use of temporary lighting on site as it could be energized upon the stripping of the formwork, allowing the building to be fully lit up at least one to two months earlier than it would have been in a traditional temporary lighting setting. However, it was also revealed that the temporary LED lighting system required additional pre-construction planning; more time and labor was required for installation, including additional works such as coordination with iron workers. These resulted in higher installation costs. Whilst the cost comparison showed that the temporary LED lighting system had lower overall costs, it is pertinent to note that the individual cost savings may belong to different parties and may not necessarily be passed on to the owner depending on the contractual arrangements. Verticality of a trade’s work space and the trade’s type of tasks also seemed to potentially influence the workers’ experience with LED lighting system.

ROLE OF FORMWORK SYSTEMS IN HIGH-RISE CONSTRUCTION

Hisham A. Abou Ibrahim1,2 and Farook R. Hamzeh1
1 Department of Civil and Environmental Engineering, American University of Beirut, Lebanon.
2 haa131@mail.aub.edu

Abstract: The selection of formwork systems in high-rise buildings is often governed by their competence in optimizing concrete activities in an isolated manner, without relating this choice to the entire construction workflow. This paper studies the role of advanced formwork systems in high-rise construction and analyzes this role in shaping not only the progress of concrete activities, but the entire construction sequence. In this context, known research efforts do not address this important aspect in analyzing high-rise formwork technologies, and formwork selection is usually left to constructors’ experience, and corresponding organizational knowledge. Employing process models, the paper investigates advanced high-rise formwork technologies versus regular ones to better advice scholars and practitioners. Results highlight the importance of advanced high-rise formwork systems in streamlining the workflow of concrete and other downstream activities, allowing for better resource allocation, more waste reduction, smaller work batches, less inventory, and safer working environment.

1 INTRODUCTION

1.1 Background of High-Rise Building Construction

High-rise building projects encounter several challenges that affect the progress of their execution. Some of these challenges are related to project location where most skyscrapers are built in tight land lots in cities’ business centers with serious limitations on space. This fact imposes high pressures on the supply chain management where on-time and smooth material delivery is of great importance. Other difficulties could be related to building design complexity, the technology used on site, labor availability and skills, the adequacy of the methods followed, and the capacity of planning professionals to foresee the dynamics of their site and proactively shape its progress. While multiple efforts targeted activity sequencing methods used in high-rise construction (Ranjbaran, 2007; Arditi et al., 2002; Thabet and Beliveau, 1994; Reda, 1990; Suhail and Neale, 1994), other researchers investigated the use of 4D modeling to graphically examine schedule progress on a 3D model where space clashes are detected and proactively solved to ensure smooth tasks handoff (Staub-French and Khanzode, 2007). However, none of the efforts linked the use of formwork systems to the workflow of activities. The choice of formwork systems is governed by several parameters (Gnida, 2010; Ciribini and Tramajoni, 2010), and cost considerations highly affect the final formwork selection especially that contractors try to minimize the cost of concrete activities in an isolated fashion without considering the indirect costs of the resulting schedule and related workflows affected by this choice.

To respond to the limitations of formwork selection procedures that focus solely on concrete construction sequence, this paper presents a comprehensive understanding of the effects of formwork selection that go beyond the execution of concrete elements and introduces to the industry a broader view of the
leading role formwork systems play in high-rise projects. In this regard, the paper: (1) compares advanced
and regular high-rise formwork technologies, (2) highlights corresponding workflow changes, and (3)
examines major enhancements on activities flow, production rates, inventory dynamics, and labor and
material delivery to work areas.

1.2 Repetitive Construction in High Rise Buildings

High-Rise building construction is characterized by the repetition of multiple activities at different
locations. Planners benefit from these repetitive tasks to maintain workflow continuity, decrease labor and
equipment idle times, reduce hire and fire actions, and take advantage of the learning curve effects
(Ranjbaran, 2007). However, these repetitive activities advance simultaneously in vertical and horizontal
directions and may create spatial constraints that hinder the execution of work (Thabet and Beliveau,
1994). To account for these constraints, practitioners and researchers sought scheduling solutions to
navigate the execution of tasks under these restrictions. Since the drawbacks of applying the CPM
method to schedule repetitive tasks were investigated in several studies (Reda, 1990; Hegazy and
Wassef, 2001), efforts targeted other scheduling techniques using the Line of Balance (LOB) method.
LOB allows operations on site to continuously flow from one activity to another by balancing different
tasks, resources, and space concurrently (Hegazy, 2002). While some researchers worked on combining
both the CPM and LOB methods to enhance work scheduling in repetitive construction (Suhail and Neale,
1994), other researchers used 4D modeling techniques provided by BIM technologies to simulate the
construction sequence and proactively account for possible on-site clashes (Staub-French and
Khanzode, 2007).

1.3 Formwork Choice and Construction Workflows

The logic of work execution followed to satisfy building safety and integrity shapes the scheduling of
involved activities. Structural works are the skeleton of every construction project and they set the pace to
other downstream architectural and MEP activities. Hence, ensuring a continuous and on-time execution
of structural framing is essential to keep the project on schedule. Assuming adequate availability of labor
and material, the choice of formwork systems (e.g., the climbing technique) directly affects the progress of
concrete works, and greatly influences the interlocking workflows of walls, shafts, and slabs where
several tasks from different trades are involved. For instance, crane-lifted formwork used for core wall
errection can congest the crane schedule and consequently delay the delivery of materials to other site
zones. Whereas, self-climbing formwork release the crane schedule and can be reused for other critical
activities. Another important factor that affects the progress of work is the resulting quality of cured
concrete. Concrete repair consumes a significant amount of time and affects the speed and quality of
finishing works that follow. In this regard, the quality of formwork system and the tolerance range it can
provide is essential to ensure a smooth progress of work from one phase to another, and from one trade
to another. Nonetheless, smaller tolerance ranges allow the incorporation of prefabrication and remote
assembly that can boost construction speed.

1.4 Formwork Selection Parameters

Construction of high-rise buildings requires innovative formwork system technologies to overcome the
limitations of space, budget, and time. However, many parameters affect the choice of formwork systems
and are mainly divided into internal and external parameters as shown in Table 1 (Gnida, 2010). While
internal parameters fall under designers and contractors control, external ones are affected by owner
requirements, project milestones, project location, and corresponding local rules and regulations.

To account for these parameters, many contributions were made to improve the efficiency of formwork systems resulting in several types. Choosing the appropriate type of formwork depends on many factors including cost, time, quality, and safety. An overview of these types is summarized in Table 2. Other studies linked the selection of the formwork system to building height and weather conditions (Ciribini and Tramajoni, 2010). Figure 1 presents appropriate formwork options according to three height ranges in the case of good or bad weather conditions.

1.5 Formwork Safety and Work Environment

Safety is a major challenge in every construction project especially in high-rise construction. Labor falls from heights are considered to be the major cause of accidents encountered and the most serious ones (Hinze and Russel, 1995; Huang and Hinze, 2003). Different studies targeted the work environment and investigated different safety procedures (Mohamed, 2002; Cecen and Sertyesilisik, 2013), and researchers as well as industry leaders are continuously developing tools and methods to enhance safety standards. Work environment is also affected by other factors that contribute to labor productivity and construction progress. Noise, for instance, is a major contributor to work stress and fatigue. Noise is created by the use of machines, equipment, and space congestion and can cause hearing problems for workers on site (Barkokébas et al., 2012). Methods to reduce noise were suggested by Barkokébas et al., and techniques can be inspired by their study in order to control noise production and transmission. Height is also considered as an additional risk in high-rise construction. Height changes affect workers’ perception of danger and could disturb their response in hazardous situations (Hsu et al., 2008). In this regard, safety measures were incorporated into the design of formwork systems in order to enhance the safety on site.

To respond to the limitations of formwork selection procedures that consider the optimization of concrete works in isolation, this paper presents a comprehensive analysis of advanced and regular formwork technologies and highlights their role in shaping the progress of concrete and non-concrete activities. Addressing the role of formwork systems in leading construction workflows in high-rise projects is a novel approach that allows researchers and practitioners to link the choice of formwork system to construction workflows on one hand, and to logistics planning, inventory dynamics, crane schedule, labor and material delivery and safety procedures on the other. The following sections examine advanced and regular formwork technologies, link the formwork choice to activities sequence, and investigate major related differences.
2 METHODOLOGY

The paper compares advanced and regular formwork systems to underline major differences, and employs a process model to describe construction activities and their interdependent relations in both cases. It also examines the resulting differences in construction sequence and flow from a scheduling perspective, to finally highlight the major enhancement the advanced systems present on inventory size and dynamics, crane availability for non-concrete activities and labor and material delivery to work zones.

![Diagram](image)

Figure 2: Research methodology

3 FRAMEWORK DEVELOPMENT

3.1 Advanced and Regular Formwork Comparison

3.1.1 Core wall Formwork

Advanced as most regular core wall formwork technologies used are self-climbing systems, lifted using hydraulic jacking mechanisms independent of any external crane or lifting equipment, and are available as single or double jump formwork assemblies (Figure 3). As the name implies, the double jump system jumps two floors at a time leading to significant reduction of cycle time; the work to be done is halved. For instance, steel fixing activities have to be done only once every two floors, and the same concept applies to concrete pouring as two consecutive floors are poured together. Other time-consuming activities such as surveying operations, formwork alignment, and reinforcement inspections are also optimized to boost core wall construction speed. Therefore, as the number of cycles is largely decreased, the construction time undergoes substantial drops. Moreover, the single jump system has also been proven to reduce the cycle time to three or four days per floor (Naylor, 2006) considering that the formwork is totally isolated from external weather conditions by cladded screens and a top deck free from mass constraints. This provides workers with a safe and adequate working environment.

![Image](image)

Figure 3: Advanced core wall formwork (Double-Jump System, n.d.)

In addition to time savings, the advanced core wall system also impacts cost savings. By merging two floors into one cycle, or one concrete pour, steel reinforcement splicing (or coupling) will only be done on every second floor. Thus, the number of splices (or couplers) is reduced which implies key cost savings on material. Furthermore, the advanced system ensures that building service elevators are made operational as early as possible. In this regard, lifts of the building are used to transfer material and labor
early on during the execution phase, thus decreasing demand on external hoists and tower cranes and boosting production (Glasby, 2009).

3.1.2 Floor Formwork

The selection of horizontal formwork is governed by several parameters as mentioned in Table 1. Yet, practitioners try to benefit from the repetitive nature of slab construction by standardizing formwork size and material and maximizing the number of formwork reuse. In this context, table forms are widely used on high-rise projects to decrease formwork setup time and slab cycle time to match that of core walls. However, regular table forms are crane dependent and obstruct the crane schedule every time they are moved from one floor to another.

Advanced formwork technologies provide innovative perimeter systems which combine construction and safety screens requirements. A self-climbing system is used to form vertical elements such as columns and walls independent of floor slab construction. The system jacking points are above floor slab giving clear access for slab formwork, reinforcement, and pouring below the system. The key advantage of the perimeter system is the accelerated construction of columns and slabs that progress independently. The system can also provide lifting services to move slab table forms internally without any use of tower cranes which are consequently released for other critical activities resulting in a faster overall construction process. Figure 4 shows the perimeter system where the columns are two floors ahead of slab construction, and pouring activities are taking place below the system's platform.

3.2 Construction Process Mapping

To examine the role of formwork in shaping construction workflows, two process maps, depicted in Figures 6 and 7, were developed to trace the differences in construction sequence between advanced and regular formwork systems. The trailing platform hanging from the advanced core wall formwork (Figure 5) allows internal lift specialists to start fixing lift rails and necessary accessories early on in the project, thus undergoing the same cycle as the core wall cycle. Whereas, elevator related tasks would not start until finishing core wall construction in the case of regular forms. Accordingly, service elevators can be made functional before final core wall erection and can be used to hoist labor and material for finishing crews.

Figure 4: Advanced self-climbing perimeter system (Double-Jump System, n.d.)

Figure 5: Schematic Representation of the Attached Trailing Platform
Figure 6: Construction Process Map Using Advanced Formwork Systems

On the other hand, the advanced perimeter system allows columns and slabs to progress independently, with defined Start to Start and Finish to Finish lag times to allow for the system to be assembled and disassembled as presented in Figure 6. Using regular formwork, floor construction follows successive cycles of columns erection and slab construction with a Finish to Start relation as shown in Figure 7.

Figure 7: Construction Process Map Using Regular Formwork Systems
3.3 Schedule Optimization and Workflow Improvements

Advanced formwork systems allow project managers to optimize the project schedule. The trailing platform plays a major role in opening downstream work early in the project and benefitting from the available core wall shaft areas which are usually wasted work spaces in regular formwork technologies as conveyed through Figure 9. The early engagement of elevator crews reduces corresponding material batches where required accessories can be delivered to site on demand without storing large inventories. On the other hand, the independent progress of columns and slabs helps streamline both activities together and reduce the risk of one process delaying the other as is the case of using regular formwork. It also boosts production of both activities due to learning curve effects. Higher availability of tower crane for none concrete activities when using advanced systems, along with making building service elevators functional at core mid-height, can increase material and labor delivery rates to work zones, thus increasing production rates of non-concrete activities as presented Figure 8. Nonetheless, core wall labors could be relocated to other activities once the core wall is erected, therefore decreasing total labor costs and allowing for more flexibility in resource allocation.

Figure 8: Schematic LOB Schedule Using Advanced Formwork

Figure 9: Schematic LOB Schedule Using Regular Formwork
4 DISCUSSION AND CONCLUSION

Formwork systems play a vital role in leading high-rise construction, and technological advancements are pushing the limits of formwork industry to new perspectives allowing it to surpass traditional constructability constraints. The role of formwork systems in high-rise projects goes beyond erecting concrete elements to set the pace of construction processes at different fronts. Innovative features provided by advanced formwork technologies play a major role in streamlining concrete and non-concrete activities where downstream tasks are more sensitive to formwork pace. For example, this applies to the case of elevator related activities that undergo the same core wall cycle and to column and slab-related activities that follow the advanced perimeter pace. Advanced systems also impact logistics planning as faster labor and material delivery rates are achievable due to crane schedule release and the use of building service elevators early on in the project. Faster material delivery is an important step towards decreasing material batch sizes, where required material can be smoothly delivered to work areas based on site demand instead of having large inventories in laydown areas which may not always be available.

Advanced formwork systems provide innovative solutions for today’s complex high-rise developments, and open the doors for greater improvements in construction methods. Future studies can link the use of advanced systems to the implementation of lean ideals on high-rise projects, such as waste reduction, Takt time calculation, and the use of pull systems and Kanban cards.

Abstract: Effective tracking and timely progress reporting are essential for successful delivery of construction projects. In this respect, several research attempts have been made to identify and track the locations of material, equipment and labor on construction jobsites using wireless sensing technologies. Such developed methods utilize radio signal propagation models to estimate location based on measured received signal strength (RSSI). However, radio signal propagation models are highly dependent on the surrounding environment. As well, these methods are susceptible to interferences caused by metallic structures and obstacles, which are continually changing location on highly dynamic construction jobsites. This paper presents fundamental research work, designed to study the beneficial effect of self-calibrated wireless sensor network (SC-WSN) for higher accuracy of indoor localization. The developed SC-WSN hardware consists of fixed gateway unites mounted at predefined locations and mobile unites mounted on tracked objects. The designed network estimates a tagged object location based on its measured signal strength, which is then converted to corresponding distance using a dynamic signal propagation model. The developed dynamic model calibrates its parameters periodically to minimize errors in its estimated locations using particle swarm optimization algorithm. Experimental results are presented to illustrate the relative effectiveness of the developed system in comparison to commonly used fixed propagation systems.

1 INTRODUCTION

Considerable research work was conducted in recent years embracing the utilization of wireless technologies in construction with a focus on automated project tracking and control. Such application requires frequent location identification of material, equipment and personnel. Despite of the Global positioning system (GPS) success in outdoor localization, it cannot be used indoors due to the lack of satellite’s signal coverage inside buildings. A wide range of wireless technologies were utilized for indoor localization on construction jobsites. The fundamental key for reliable and accurate indoor location estimation is signal propagation model, which is used to convert measured received signal strength (RSSI) into corresponding distances. The dynamic nature of construction jobsites severely impacts the accuracy of location estimation. In the presence of moving resources, metallic objects and structural barriers, the signal propagation model produces poor distance estimates. In order to alleviate such impact, smart and adaptive path loss models are required to cope with the fast-changing environment. This paper was motivated with such need for an enhanced localization method incorporating a dynamic signal propagation model, which would increase the accuracy of location estimation.
2 LITERATURE REVIEW

In the construction management domain, several researchers have investigated indoor localization using three main categories of technologies: wave propagation based; image based; and motion based. Several wave propagation based technologies had been utilized by researchers, such as radio frequency identification (RFID), ultra wideband (UWB), wireless local area network (WLAN) and Zigbee. Each technology has its own inherited advantage and disadvantage with relative to accuracy, cost, coverage range, deployment requirements and scalability (Mahalik 2007). RFID had been used for object tracking without localization (Goodrum et al. 2006; Jaselskis et al. 1995) and for tracking with localization (Ergen et al. 2007; Razavi and Moselhi 2012; Montaser and Moselhi 2014). Researches utilizing ultra wideband (UWB) had reported higher localization accuracy of approximately < 1m (Teizer et al. 2007; Rueppel and Stuebbe 2008; Khoury and Kamat 2009; Shahi et al. 2012; Shahi et al. 2013; Vahdatikhaki and Hammad 2014), however the measurement accuracy is highly dependent upon the line of sight of the point to be located (Aryan 2011). WLAN had been seen as an attractive solution for indoor localization due to its existing universal infrastructure availability (Mazuelas et al. 2009). However, several researchers have reported its low accuracy to be approximately 4–7 m with 97% confidence (Khoury and Kamat 2009; Woo et al. 2011).

3 DEVELOPED SYSTEM

The developed system consists of hardware and software implementations. These implementations are designed to meet three main design objectives: accuracy, scalability and cost. The accuracy of the developed system is the main performance measure in comparing it to others. The higher the accuracy, the better the system; however, there is often a trade-off between accuracy and other characteristics such as cost. The accuracy is measured as the average error in location estimation. The scalability of the developed system is required to be applied to any project size without any need for further adjustment or development. Finally the cost of the developed system must be cost effective with respect to others.

4 DEVELOPED SC-WSN HARDWARE

The developed self-calibrating wireless sensor network configuration is a mesh topology with reference tags. The added reference tags, which are fixed at predefined locations, enable self-calibration of the developed system. This self-calibration feature is expected to enhance the performance of the typical mesh topology and provide the intelligence to dynamically adapt the network propagation models to provide optimal localization accuracy. The developed hardware prototype consists of three components: a Waspomote with ATmega1281 microcontroller; a Synapse RF300 radio frequency module and a BMP180 digital barometric pressure sensor. The microcontroller provides a flexibility to custom develop firmware programs for the purpose of indoor localization. The Synapse RF300 radio frequency module has a high indoor coverage range of 250 meters due to its high transmitter power which provides additional 10 dBm of link margin. The BMP180 digital barometric pressure sensor is distinguished by its relatively high accuracy of ±0.12 hPa (±1m), which provides reliable measurements for precise indoor-navigation applications.

Three types of prototypes were developed: tags (mobile tags which are attached to tracked objects and reference tags which are installed at predefined locations); readers; and gateway (where data processing takes place for location estimation and system calibration). Each tag is equipped with a Synapse RF module and barometric pressure sensor as shown in Figure 1a. The RF module is used to estimate the tag’s location in 2D space, while the barometric pressure sensor is used to estimate the tag’s altitude. The reader node consists of a Synapse RF module, which is programmed to continually scan for nearby tags and report their RSSI value and altitude to the gateway as shown in Figure 1b. The gateway node consists of a microcontroller, Synapse RF module and WLAN module as shown in Figure 1c. It collects data from readers; process the data to estimate tags’ locations; calibrates the system and submits the final location data to the database server.
In order to increase accuracy without placing more readers, the system employs the idea of having extra fixed location reference tags to help location calibration. These reference tags serve as reference points in the system.

5 DEVELOPED LOCALIZATION METHOD

The developed method is composed of two stages, prediction stage and calibration stage as shown in Figure 2. Each reader measures the signal strength (RSSI) from nearby tags and filter it to remove uncorrelated noise. Then filtered RSSI data is forwarded to the gateway node for processing. The prediction stage is initiated by converting the filtered RSSI to its corresponding distance using the dynamic signal propagation model. The initial settings for the signal propagation model parameters are calculated using indoor experimentations as explained by Ibrahim and Moselhi (2014). Once three distances from three readers for a given tag are available its location is estimated using the LSE trilateration algorithm. The localization accuracy is continually monitored by measuring the errors in location estimation generated based on a number of reference tags. These reference tags are deployed on site at pre-defined locations. When the system accuracy is degraded due to on-site interferences, a system calibration request is initialized. The user can define the accuracy limits to initiate the calibration requests. The calibration stage utilizes a particle swarm optimization (PSO) to find the best values for the signal propagation model parameters which maximize the system localization accuracy. Finally, at the end of the calibration stage, the dynamic signal propagation model is updated with the new set of optimized parameters.

Figure 1: Developed Prototypes: (a) Tag (b) Reader (c) Gateway.

Figure 2: Developed Localization Method Overview
5.1 Signal Propagation Model

A propagation model is a set of mathematical expressions used to represent the radio characteristics of a given environment (Neskovic et al. 2000). The signal propagation model used in this research is Log-distance Path Loss Model. The path loss PL (d) for a transmitter and a receiver with distance d is:

\[ P(d) \propto \left( \frac{d}{d_0} \right)^n \]

\[ PL(dB) = PL(d_0) + 10 \cdot n \cdot \ln \left( \frac{d}{d_0} \right) + \sigma^2 \]

Where \( n \) is the path loss exponent which indicates the rate at which path loss increases with distance \( d \). The reference distance \( (d_0) \) is determined from measurements at 1 meter distance from the transmitter. \( \sigma^2 \) is the shadowing variance in mDB. The value of \( n \) depends on the specific propagation environment, i.e., type of construction material, architecture, location within building. Table 1 lists typical path loss exponents obtained in various radio environments (Rappaport 1996).

<table>
<thead>
<tr>
<th>Environment</th>
<th>Path Loss Exponent, n</th>
</tr>
</thead>
<tbody>
<tr>
<td>Free Space</td>
<td>2</td>
</tr>
<tr>
<td>Urban area cellular radio</td>
<td>2.7 to 3.5</td>
</tr>
<tr>
<td>Shadowed urban cellular radio</td>
<td>3 to 5</td>
</tr>
<tr>
<td>In building line-of-sight</td>
<td>1.6 to 1.8</td>
</tr>
<tr>
<td>Obstructed in buildings</td>
<td>4 to 6</td>
</tr>
<tr>
<td>Obstructed in factories</td>
<td>2 to 3</td>
</tr>
</tbody>
</table>

Given that \( d_0 = 1 \) m, equation 2 can be simplified as:

\[ PL(dB) = A + B \cdot \ln(d) \]

Where \( A \) & \( B \) are the parameters for the signal propagation model. The signal propagation model parameters \((A&B)\) are estimated using lab experiments, then automatically adjusted on-site using the PSO.

5.2 Location Estimation Algorithm

Based on RSSI measurement and signal propagation model described above, the multilateration (Karl and Willig 2007) algorithm is used to calculate tag’s location based on its estimated distance from a set of fixed readers (Stüber and Caffrey 1999). When three readers are used, it is called trilateration, as shown in Figure 3a. The intersection of the three circles gives an exact solution for the tag’s location under ideal free space signal propagation (no fading or shadowing effect). However, in real environment, the three circles might not even intersect due to errors in distance estimates by RSSI propagation model. Stuber and Caffrey 1999 presented an optimal localization using least square estimation (LSE) as shown in Figure 3b.

Given the readers coordinates as following: \( A(x_1, y_1) \), \( B(x_2, y_2) \), and \( C(x_3, y_3) \); and their corresponding distances to the tag are \( d_1 \), \( d_2 \), and \( d_3 \); the three circles equations can be formatted as follows:

\[ (x_1 - x)^2 + (y_1 - y)^2 = d_1^2 \]
\[ (x_2 - x)^2 + (y_2 - y)^2 = d_2^2 \]
\[ (x_3 - x)^2 + (y_3 - y)^2 = d_3^2 \]

Where \( x \) and \( y \) are the coordinates for the tag location.
Figure 3. Localization using Trilateration

Using the LSE method the tag coordinates can be calculated using the following equation:

\[
\begin{bmatrix}
2 \times (x_3 - x_1) & (x_3 - x_2) \\
2 \times (y_3 - y_1) & (y_3 - y_2)
\end{bmatrix} \begin{bmatrix}
x \\
y
\end{bmatrix} = \begin{bmatrix}
(d_1^2 - d_3^2) - (x_1^2 - x_3^2) - (y_1^2 - y_3^2) \\
(d_2^2 - d_3^2) - (x_2^2 - x_3^2) - (y_2^2 - y_3^2)
\end{bmatrix}
\]

5.3 System Accuracy Estimation

Localization system’s accuracy depends mainly on the accuracy of the estimated tag’s distances from the fixed readers. It can be measured in terms of Euclidian distance error between the estimated location and the actual location. The location’s error is calculated as the distance in meters between the estimated and actual locations using Eq. 8.

\[
Distance_{error} = \sqrt{(X - a)^2 + (Y - b)^2}
\]

Where: \((X, Y)\) is the actual tag location, and \((a, b)\) is the estimated tag location.

The optimization algorithm described later is designed to find a near optimum solution for propagation model parameters in order to maximize its localization accuracy. However, using the Euclidian distance error as an objective function for the optimization algorithm increases required computational overheads by the microcontroller. Therefore, the error in the distance estimation (between a reader and a reference tag) is used to measure the system accuracy. Hence it was important to study and understand the sensitivity of the estimated distance on the location calculation using the LSE trilateration algorithm described above.

Monte-Carlo simulation is used to study the LSE trilateration algorithm sensitivity to the estimated distances. This simulation is used to quantify the effect of estimated distance errors on the estimated tag’s location. The identified sensitivity thresholds (limits) will be used to flag requests for localization system calibrations. To perform this sensitivity analysis; three fixed readers were placed at locations \((0, 0)\), \((0, 3)\) and \((5, 3)\). A tag was placed at the location \((2.5, 1.5)\), and its estimated distances were ranged to show four levels of error \((\pm 5\%, \pm 10\%, \pm 15\%, \pm 20\%)\). Figure 4 shows the tag’s estimated location against the tag’s actual location.
The empirical CDF of the estimated location errors was calculated to derive the thresholds for the system accuracy with 95-percentile confidence level as shown in Figure 5 and Table 2.

![Figure 4. Tag's Estimated Locations vs Actual Location](image)

![Figure 5. The CDF of Tag's Estimated Location Errors](image)

**Table 2: Location Estimation Error Thresholds vs Errors in Distance Estimation**

<table>
<thead>
<tr>
<th>Error in Distance Estimation</th>
<th>Location Estimation Error (m)</th>
</tr>
</thead>
<tbody>
<tr>
<td>±5%</td>
<td>0.220</td>
</tr>
<tr>
<td>±10%</td>
<td>0.533</td>
</tr>
<tr>
<td>±15%</td>
<td>0.673</td>
</tr>
<tr>
<td>±20%</td>
<td>0.893</td>
</tr>
</tbody>
</table>
The developed system was designed to trigger system calibration when the error in distance estimation becomes higher than ±15% in order to keep the location error within 0.65 meters (however these settings are changeable by the user).

### 5.4 Propagation Model Self-Calibration

The developed calibration process is intended to automatically derive propagation parameters without any prior knowledge on propagation conditions. It relies on periodic calculation of reference tags locations and computation of system accuracy, and then auto calibrate the model parameters when experienced low accuracy conditions.

From equation 3, the measured distance $d_{\text{measured}}$ can be calculated as:

$$d_{\text{measured}} = e^{\frac{(PL(db)-A)}{B}}$$  \hspace{1cm} [9]

The absolute error $d_{\text{error}}$ in the measured distance can be calculated as:

$$|d_{\text{error}}| = |d_{\text{actual}} - d_{\text{measured}}| = |d_{\text{actual}} - e^{\frac{(PL(db)-A)}{B}}|$$  \hspace{1cm} [10]

Where is the actual distance $d_{\text{actual}}$.

The Average Absolute distance error for $m$ readings collected from readers:

$$\left|d_{\text{error}}\right|_m = \frac{1}{m} \sum_{i=1}^{m} \left|d_{\text{actual}i} - e^{\frac{(PL(db)_{i}-A)}{B}}\right|$$  \hspace{1cm} [11]

The calibration algorithm will determine the value of $A$ and $B$ to minimize the mean absolute error for each reader. The objective function of the algorithm is:

$$Z = \min \left(\frac{1}{m} \sum_{i=1}^{m} \left|d_{\text{actual}i} - e^{\frac{(PL(db)_{i}-A)}{B}}\right|\right)$$  \hspace{1cm} [12]

This objective function is non-linear which does not allow for an exact solution. Evolutionary optimization methods such as Genetic Algorithm (GA) or Particle Swarm Optimization (PSO) can be used to solve these kind of problems. PSO has the same effectiveness (finding the true global optimal solution) as the GA but with significantly better computational efficiency (Hassan et al. 2005). The computational efficiency of the selected optimization algorithm is very important for the developed method due to the limited computational resources of the microcontroller (memory and speed).

### 6 EXPERIMENTAL VALIDATION

For validating the proposed method, experiments were conducted using a grid formation test bed, where readers are installed at the corners of the area, then tags were placed one meter apart in grid formation as shown in Figure 6a. This test setup is repeated after adding physical obstacles in the surrounding environment (as shown in Figure 6b) to simulate the change in the environment and test how the proposed method self-calibrates its model to account for interferences caused by the surrounding environment. Experiments were conducted in a laboratory environment at Concordia University Construction Automation Lab. A total of 1062 data sets were collected covering 15 m$^2$ of surface area. The test bed had 17 mobile tags, 4 reference tags and 3 fixed readers, with an average density of one reader per 5 m$^2$ and one reference tag per 3.75 m$^2$. In the first experimental step the setup in Figure 6a was used and the dynamic signal propagation model (Eq. 3) has been initialized with initial values based on experimental measurements ($A = -38.909$ and $B = -8.989$) and tags' distances from the fixed readers were estimated accordingly. The system localization accuracy was measured at 87%.
After adding physical obstacles as shown in Figure 6b, the system location accuracy fell below 80% and the distance error was increased. Figure 7 shows a graphical display of the actual locations versus the estimated tag’s locations after adding the obstacles, the orange triangles represent the actual tag’s locations, and the black crosses represent the calculated tag’s location.

The calibration stage was initiated based on encountering low system accuracy. Each reader signal propagation model is optimized using PSO algorithm and the RSSI from reference tags, the enhancement in the location estimation is clearly identified in Figure 8, which shows a graphical display of actual tag’s locations versus the estimated tag’s location after calibration.
Figure 9 shows the CDF of estimated distance errors for reader 1 before and after the calibration stage, where the mean error in the distance shows a decreasing trend. The mean absolute percentage error before calibration was 37.69%, while it was 14.96% after calibration. The SC-WSN method decreased the mean absolute percentage error by 60%.

It is important to mention that from a practical deployment point of view, an in-depth analysis about the relationship between the density of reference tags and their geometrical distribution needs further investigation. Also, it is important to investigate the processing time for the proposed method with respect to its real time applications. These issues are part of this ongoing research.

7 CONCLUSION

This paper presented a newly developed method for indoor localization on dynamic construction jobsites utilizing a self-calibrated wireless sensor network (SC-WSN). The developed SC-WSN hardware consists of fixed gateway units mounted at predefined locations, reference tags and mobile tags mounted on tracked objects. The developed method consists of a prediction stage and calibration stage. The prediction stage estimates the tag’s location based on its measured signal strength (RSSI), which in turn is converted to the corresponding distance from fixed readers by a dynamic signal propagation model. The calibration stage is executed whenever the system accuracy falls below 80%, where the dynamic propagation model parameters are optimized to minimize the distance estimation errors of the reference tags. A particle swarm optimization (PSO) algorithm is used to find a near optimum solution for this non-linear problem. The PSO is not only able to find a solution effectively, but also has significantly better computational efficiency. Experimental results illustrated the significant accuracy improvement in estimating locations on construction jobsites, where the mean absolute percentage error before calibration was 37.69% while it was 14.96% after calibration. The SC-WSN method decreased the mean absolute percentage error by 60%.

³ raimar.scherer@tu-dresden.de

Abstract: The application of simulation technique for construction project planning is a very promising but also a challenging field of research. Creating reliable and reusable simulation models is very complex, combined with high costs. This paper presents the development of Construction Simulation Toolkit “CST” and a collaborative simulation portal “ProSIM”, which supports the planning of construction project using discrete-event simulation method. The objective of this research is promoting a wider adoption of simulation in construction industry and support planning of real project using simulation technique through providing a construction-specific simulation toolkit allowing the rapid development of simulation models and an online collaborative platform in order to facilitate the integration of complex construction projects data. CST aims to support planning of production and logistic operations of construction projects in one unified simulation models and running “what if” scenarios in order to support decision making and improve planning quality, while ProSIM aims at enabling the collaboration among the simulation experts and other project design and planning teams. The paper presents the latest research work and the prototype implementation through study cases.

1 INTRODUCTION

Construction planning is a fundamental and challenging activity in the management and execution of construction projects. It involves the choice of technology, the definition of work tasks, the estimation of the required resources and durations for individual tasks, and the identification of any interactions among the different work tasks (Chris 2000). There are many planning methods and techniques to help with project and resource planning; one of the advanced techniques is using simulation technique. It can help to optimize project schedules and run “what if” scenarios or test different construction strategies or different resource profiles to proof and compare different plans against different goals e.g. total duration of the project, total cost, and resource utilization aspects. However using simulation for construction projects is still limited compared to other branches of industries. Adoption by construction industry has lagged, for three potential reasons: (1) simulation is not accessible, (2) it cannot handle the complexity of modern construction projects, and (3) the benefits are not immediately obvious (AbouRizk 2011). Therefore, providing a convenient simulation tools and collaborative platforms to support and integrate the huge and complex projects data with low-cost entry for construction industry is crucial to promote a wider adoption of simulation in construction industry. With convenient we mean here tools which are designed especially to take in account the unique aspects and commonly used data models in construction industry. Consequently, having such tools will improve the planning quality and reduce costs, waste and construction conflicts.
The Construction Simulation Toolkit CST and the web-based collaborative portal for managing simulation models “ProSIM” have been developed within the national German leading research project Mefisto (www.mefisot-bau.de 2009-2012) which is a part of the IKT 2020 research for innovation intuitive. The development of CST aims to accelerate the process of creating reliable simulation models for production and logistic operations during the planning and operation phases of construction projects. ProSIM portal aims to enable communication and collaboration between involved planning and simulation experts.

In general, simulation models based on CST aim to support the planning process in order to reduce the total duration and cost of construction projects and to avoid any conflicts during the construction phase by improving the planning quality and utilization rates of resources. The simulation model should support the project manager to verify the feasibility of a given project schedule with a combination of different resource constraints or different building design alternatives or construction methods. The toolkit provides a set of reusable simulation components with a simple user interface for rapid building of process-based simulation models for planning projects with resource and activity calendar constraints. It has a modular structure and consists of a set of simulation reusable input and output components. Sections 2 and 3 describe briefly the concept of using formal reference process models of construction operations and the multi-model data exchange approach. Section 4 presents the simulation platform architecture and provides more details about CST and ProSIM implementation, finally in section 5 a two study cases are discussed.

2 REFERENCE PROCESS MODELLING OF CONSTRUCTION OPERATIONS

Reference models are generic conceptual models that formalise recommended practices for a certain domain (Rosemann 2002). As the knowledge in every domain keeps evolving, the reference models change continuously and goes through a "discover, model, evaluate, and optimize" modelling cycle. So new reference models will be added or existing models will be improved and detailed with time. Therefore, a continuous collaboration between planning, construction management and simulation teams is very important to capture the best practice of delivering construction and logistic activities as well as to validate and integrate the feedbacks during the construction phase of real projects. The reference process modelling method allows identifying, capturing, documenting, improving and sharing the knowledge about the best practice of construction processes and their related information. In our approach, there is a clear separation between the core simulation components and the process models for the application domains. Business Process Modelling and Notation (BPMN) models are used to capture and describe the logic of production and logistic operations and to transform them automatically in one step into simulation models.

Special BPMN Extension elements are developed in order to define resource requirements and durations of tasks inside the reference models in a flexible way. Each activity or task inside the project schedule is linked with a reference process model during simulation. In this way, the process models define the logic and level of details of simulation models. One needs to examine every detail of the construction process carefully and identify the major events and processes that will be presented in the simulation model in order to create a reliable simulation model (Aouad et al. 2006). The graphical representation of BPMN models makes models easy to understand between all involved teams and the formal specifications in XML allows transforming process models into simulation models automatically. The BPMN reference process models will be transformed and imported into a ready to use process templates repository in the simulation toolkit. The process repository includes reference process models which are reusable across different construction projects and their data definitions of resources and productivity factors.

In our approach, aforementioned BPMN modelling technique is used to create semantic and graphic process models for various construction operations. BPMN models consist of simple diagrams constructed from a limited set of graphical elements.

Flow Objects are the main elements to define and control the behaviour of a business process. The scope of BPMN elements which can be used inside the simulation process templates are:
• Start/End events
• Task and sub-process
• Sequence flow
• Gateways: Parallel Fork/Join, Data-Based XOR
• Conditional and default flow.

Process models will be imported into a process catalogue as ‘ready to use’ Reference Process Models (RPM) inside the simulation model. The process catalogue includes reference process models for the best practices of various construction processes that are reusable across different construction projects. In addition, RPMs are extended to include resource requirements and productivity factors. The knowledge accumulation enables a continuous improvement of the process catalogue.

A process template can be as simple as having one single activity or a set of serial activities which run sequentially without any kind of control flow or very complex ones including loops and conditional gateways which may result in skipping/ repeating some activities. In order to create reliable simulation model, one needs to carefully examine every detail of the construction process and identify the major events and processes that will be presented in the simulation model (Akhavian and Behzadan 2011).

In CST, the user has the freedom to move the logic and the dependencies between different tasks to be a part of the input data for each simulation model or to be included inside process templates. However this may lead to one of the following extreme situations:

1. Very detailed project schedule and a lot of tasks dependencies as a part of simulation input with a set of simple process templates for each task.
2. Very simple project schedule consisting of few tasks with a high level of abstraction combined with very complex process templates.

Both cases must be avoided to get the most out of the simulation model in the sense of ease of use and the flexibility of answering as many as “what if” scenarios. It is mainly the responsibility of the user to maintain balance between these options according to the simulation goal and the availability of data. Figure 1 shows as an example of a good balanced process template for erecting a wall for three construction methods: Precast, In-situ concrete and as bricks walls.

By using this template there is no need to use three different templates and link them explicitly to each wall as part of the simulation input, which reduce the time and efforts to prepare the simulation data. The definition of resources and duration value/formula for each single task can be embedded inside the BPMN process template or maintained in separate database.
3 MULTI-MODEL PROJECT DATA EXCHANGE APPROACH

Multi-model project planning is a paradigm shift from the building-centric approach, which tries to add and link all project data with building models toward an equivalent interlinked data models using special link models. The multi-model method offers solutions to structural problems of nD modelling in construction information processes (Akhavian and Behzadan 2011). A multi-model container comprises several data files and includes, besides the meta-information about the container content, several application models as well as link models (Schapke and Scherer 2010). It allows the combination of heterogeneous application models from different domains and various data formats. Inside multi-model containers link models bind the application models together (Fig. 2).

The link models specify the relationships between items from different data models. Multi-model containers can be used to exchange associated models among the project stakeholders by a common format (Fuchs et al. 2010). In their entirety the multi-models on a construction project open up a multi-dimensional information space of interdependent application models that can be independently processed by the project participants. Each participant has the opportunity to produce new application models on his/her own responsibility and interlink them with existing models. Depending on the situation these newly created multi-models can be maintained locally or published project-wide as a basis for further planning and controlling tasks. In comparison to the often pursued integration of project information in central project databases or product model servers, this approach distributed model-based collaboration represents a paradigm shift (Schapke and PfIug 2012). Multi-model approach is integrated with CST through providing import/export interfaces.
4 SIMULATION PLATFORM

The simulation platform consists of 5 main modules (Fig. 4): (1) Simulation engine and CST toolkit based on the event-discrete simulation software “Plant Simulation”, (2) ProSIM portal as Ruby on Rails web application, (3) Simulation database, (4) BIM data server based on IfcWebServer.org and (5) Apache web server.
4.1 Construction Simulation Toolkit CST

The CST toolkit is implemented on top of the simulation software “Tecnomatix Plant Simulation” © from Siemens PLM. Simulation components of CST can be added to the simulation models in a modular way as they are needed. Most of the core components are generic and are not related directly to the construction industry domain; therefore the toolkit can be used to solve planning and scheduling problems in different domains. Construction domain specific components are responsible of processing the input information coming from various data models of construction project data and to represent and evaluate simulation results and making them accessible and understandable for engineers without deep experiences in simulation techniques.

Both of production and logistic operations can be simulated using CST toolkit. They affect each other interactively i.e. production tasks starts after the material delivery, or logistic operations can block the key resources like tower crane and prevent production tasks to use them. Figure 5 shows the main simulation components on CST, which are described in details in this list:
- **Multi-Model-Container**: It is the import/export interface between a multi-model container and the internal data in simulation model.

- **BIM Data**: This component contains all the information from the BIM model that is relevant for the simulation and extracted from IFC models using special scripts based on the IFCWebServer.org data model server, or created inside the simulation model directly using the Floor-Editor component.

- **Task List**: This component is an important core element for simulation input. It contains all the information about the logistic and construction operations that they have to be simulated.

- **Resource-Pool**: This component is a manager and container for all available resources and the definition of their capacities during the simulation. It includes standard resources used in construction domain like labours, equipment, and building materials or any kind of resources, which can be added in a generic way. The availability of resources is defined as delivery tables (time, amount, attributes) so level of resources can vary over time in a planned manner.

- **Construction Site**: With the help of this simulation component the information of the construction site layout and equipment i.e. transportation routes, tower cranes, storage space, loading zone, arrivals and departures are managed. The changes to the construction site layout during the project progress are considered.

- **Process Repository**: This component manages the global Reference Process Models RPMs of typical construction process.

- **Process-Pool**: Process Pools are virtual hierarchical containers of process instances; each process pool can contain other process pool objects or process instances. In this way it is possible to put a set of related tasks inside one process pool object and define the “end to start” relationships between different groups of tasks using an alphabetic hierarchical string in a very flexible and powerful way. The status of any process pool object will change from “started” to “completed” when all process instances and sub-process pools inside it are complete. The hierarchy structure of the process pool is not restricted in any way, however it is recommended to use a similar hierarchy structure of the real project and to create sub-process-pools for each summary task in the project schedule, for example:

- **Construction site**: With the help of this component the information about construction site layout and equipment are managed. At moment CST supports the following elements:

- **Gantt Charts**: It represents the simulation results (planning schedules) as Gantt charts. It allows combining the individual sub-tasks to summary tasks, compare different simulation scenarios and export the results in various level of details to MS Project.

- **Draw-Panel**: With help of this component 2D graphical representation and animations of the progress of construction processes can be created during the simulation. Each task inside the process model can be provided with a special code to draw on a different layer with predefined colours regarding the kind and location of the construction activities.

- **Project Monitor**: This component displays the resource utilization and material consumption graphically during the simulation run, for example, the utilization rates of workers, tower cranes, concrete pumps and material consumption.

- **4D Visualizer**: This component provides the ability to visualize and animate (3D&4D) the construction progress and state of construction site elements at any time point. 3D models are exported using the standard format COLLADA and the export function can be configured to run based on fixed time intervals, (hourly, daily, weekly, etc.) or after the finish of certain construction processes. 4D visualization can be generated automatically using the 3D models and special scripts written for Trimble SketchUP®.

- **Floor-Editor**: With the help of this component the user can quickly create a simplified building model.

- **Project Template**: The input and output simulation components are combined together as the default simulation project template. This makes it possible to create simulation models very quickly and to simulate and compare different scenarios of the same construction project in parallel.

### 4.2 Collaborative Portal ProSIM

The ProSIM platform is designed as an online web-based portal to support the communication and collaboration among all project planning members and to publish simulation model results and all related input data (Ismail et al., 2014). It facilitates the verification of all input parameters and simulation results effectively.
Besides publishing simulation models, their scenarios and results, it offers the following functions:

- Online management of productivity factors of various construction operations (http://bci52.cib.bau.tu-dresden.de:3000/aws)
- Online management of resource requirements and task duration definitions (http://bci52.cib.bau.tu-dresden.de:3000/aws)
- Online repository of reference process models of construction activities as BPMN models (http://bci52.cib.bau.tu-dresden.de:3000/rpms)
- Multi-Model Navigator to explore and transform the content of interlinked project data (http://bci52.cib.bau.tu-dresden.de:3000/mmc)
- Online viewers of various input and output data (Gantt charts, resource utilization charts, 2D animations, Calendar view, etc.)

ProSIM is implemented using the modern web development framework “Ruby on Rails”. This web development framework was chosen because it is suitable for rapid development. It also emphasizes the use of well-known software engineering patterns and principles, such as active record pattern, and Model–View–Controller MVC. The Web application is deployed via Apache web server and MySQL database.

5 STUDY CASES:

5.1 Mefisto Office Project

The first demonstration and validation simulation project “Mefisto office” is a multi-storey office building. The structural work activities have been simulated based on a rough master project schedule. In this project all simulation input data was created or imported manually and the logistic (construction site layout, material delivery, etc.) and cost information were excluded. For this project 2 simulation models and various scenarios were implemented and analysed in order to: (1) Automatic generation of detailed project schedules for the whole building taking in account different construction strategies and maximal resource capacities, (2) Simulate and optimize the structural work for short term planning of construction phase taking in account the formwork and reinforcement work details. More details and simulation scenarios are this demonstration project are described in (Ismail and Scherer 2014).

![Image of simulation results]

Figure 6: The effect of changing number of workers on the of structural work duration
Fig. 6 shows the effect of changing the number of workers between 10-40 workers on the expected duration of structural work, workers utilization and the consumption of concrete for 2 floors.

All results of simulation scenarios for this project are available under: http://bci52.cib.bau.tu-dresden.de:3001/simweb/

5.2 Mefisto Airport Terminal Project

For the second demonstration project “Mefisto Airport” two simulation models based on CST toolkit were implemented and different scenarios were prepared and carried out.

The first test case was to generate automatically a detailed project schedule of construction work of the whole building based on the concept of “top-down simulation method” described in details in (Ismail 2011). The main inputs of this case are: (1) master project schedule, (2) high level reference process model which describe the logic of structure work in each floor, and (3) a set of detailed reference process models which describe the logic of structural work for different kind of building elements (slab, beam, column, etc.).

The multi-model project delivery approach and multi-model-container data exchange method have been used in order to extract all related project information and transform them to the internal data structure of the simulation model as following:

- The master schedule in the multi-model container (in iTOW XML format) has been transformed into a “Task list” simulation component. Each task represents the structural works within one floor or a work-section has been linked with the high level reference process model of structural work.
- The simulation related data inside the IFC model of the building were processed using MMQL, BIMFit and IFCWebServer data model server and converted to the internal data structure of the simulation database.
- Link model data has been imported into simulation model in one step

After the automatic generation of the detailed project schedule a “minimal project duration” scenario was carried out. In this scenario the capacity of available workers and building material was set to unlimited and only the capacity of tower cranes were considered. The aim of this scenario was to validate and test the feasibility of top-down simulation method and also to analysis the effect of changing the construction strategies and the dates of milestones in the master schedule on the ultimate minimum construction duration. The simulation model and the results of this test case are available through ProSIM under: http://bci52.cib.bau.tu-dresden.de:3000/sim_models/3

The second case study for the Mefisto Airport focused on the simulation of structural work inside one floor. The target was to analyze the effect of changing various factors like resource capacities, the interaction between production and logistic operations and construction methods (in situ concrete, precast) on the expected total duration and the resources utilization ratio. In order to simulate the logistic operations the necessary information about the construction site model was imported from a special IFC model. This model includes the following information: entry and exits gates, transport ways, tower cranes properties and location and yard storage areas. This information was mapped directly into the internal data structure of the “Construction Site” component, which convert them in turn into active and passive material flow simulation objects. With help of “4D Visualizer” component the construction site model can be generated automatically as 4D models including full movement records of crane operations and yard storage areas utilization rates. The simulation model and the results of both scenarios are available through ProSIM under: http://bci52.cib.bau.tu-dresden.de:3000/sim_models/8

6 CONCLUSION AND FUTURE WORK

The target of this research was to promote a wide adoption of simulation methods to support construction project planning. Systems integration and collaboration are believed to be the key enabling technologies that drive the construction industry in improving productivity and efficiency (Shen et al., 2010). This paper
presented the design and development efforts of a process-based simulation toolkit and a collaborative platform and discussed the integration of various project data models into the simulation models using multi-models data exchange approach. It discussed also the concept of using formal process models based on BPMN in order to capture and manage knowledge in construction domain and transfer them directly into simulation models. The results obtained from demonstration projects showed the potential of using CST and ProSIM by the rapid deployment of simulation models and the flexibility of applying various scenarios. The future development will include the integration between the simulation platform and the project real data collected on site and adding more reference process models for other project types or disciplines like bridges and electric and interior work.

A CASE STUDY OF HYBRID LEARNING IMPLEMENTATION IN CONSTRUCTION ENGINEERING

Charles Jahren1,2, Aliye Karabulut-Ilgu1, David Jeong1, Larry Cormicle1
1 Department of Civil, Construction and Environmental Engineering, Iowa State University, USA
2 cjahren@iastate.edu

Abstract: Hybrid learning is an educational approach that combines the elements of online and traditional face-to-face instruction. When planned and implemented well, hybrid learning provide benefits at the student, faculty, and institutional level. The experience of a major Midwestern university in implementing hybrid learning is reported in this paper. Included are six semesters of experience and incremental improvement with a construction equipment course, three semesters of experience with a construction scheduling course, and two semesters of experience with a cost estimating course. The three courses were led by three different faculty members with various expectations, preferences, and approaches. The case study discussion reported here demonstrates the robustness of the hybrid learning approach. Workflow and effort in developing the hybrid classes, online and computer software application tools, best practices and lessons learned are presented.

1 INTRODUCTION

Hybrid learning is an educational approach that combines the elements of online and traditional face-to-face instruction (Garrison & Kanuka, 2004). Because of its blended nature, hybrid learning is commonly referred to as the best of the two worlds as it has the potential to provide the benefits while avoiding the challenges of the two formats (Lamport & Hill, 2012). When planned and implemented well, hybrid learning provide benefits at the student, faculty, and institutional level (Dziuban, Hartman, Moskal, 2004). Online content can be used to address the knowledge, comprehension, and application levels of cognitive activity while the face-to-face learning addresses analysis, synthesis, and evaluation levels while reinforcing learning at the previously mentioned levels. For hybrid learning to be successful, the asynchronous online component needs to be carefully planned and balanced with the face-to-face activities. Well-planned asynchronous online activities can promote student learning with less input of instructor effort and the instructor effort that is diverted can be invested to provide more student engagement during face-to-face activities where students are learning at higher cognitive levels.

The experience of a major Midwestern university in implementing hybrid learning is reported in this paper. Included are six semesters of experience and incremental improvement with a construction equipment course, three semesters of experience with a construction scheduling course, and two semesters of experience with a cost estimating course. The three courses were led by three different faculty members with various expectations, preferences, and approaches. The case study discussion reported here demonstrates the robustness of the hybrid learning approach. Workflow and effort in developing each of the hybrid classes, online and computer software application tools, best practices and lessons learned will be presented next.
2 CASE DESCRIPTIONS

2.1 Case 1: Hybrid Learning in Construction Equipment

*Construction Equipment and Heavy Construction Methods* is a three credit junior level course required for construction engineering students. In the traditional format, the course included two lecture hours and a two-hour calculation lab each week. The overarching goal behind the conversion of the course from traditional to hybrid format was to replace the passive lecture content with the online content and use some of the time released in class time for active learning exercises. Additionally, depending on how much time spent on online activities, the contact hours were reduced to create flexibilities in to both students’ and the instructor’s schedule.

The construction equipment course was the first in the department that was converted to the hybrid format. The instructor worked with an instructional development team consisting of instructional designer, graduate and undergraduate students. Using the screen-recording software Camtasia Studio®, the instructor recorded the content that he would lecture when using a traditional format. Then, the instructional designer worked with undergraduate students to edit the video, slice it into more manageable short segments, enhance it using additional visuals, and create quiz questions. For a more detailed explanation of the workflow for the online component please see Mallen, Jahren, Koehler, & Karabulut (2014). An example video lecture can be seen at [http://www.screencast.com/t/A9MCvuwlyhOG](http://www.screencast.com/t/A9MCvuwlyhOG)

Another unique feature implemented in this course was to replace the example problem sessions that typically follow a lecture presentation with online interactive exercises. These exercises were created using the content development tool Lectora®. The exercises present a problem statement which usually involves multiple steps. Students are required to go through each step to be able to reach a conclusion about the problem statement. Throughout this process, students are supported through additional explanatory videos and demonstration videos for how to solve the problem. A video explanation of how these online modules work can be seen at [http://www.screencast.com/t/MznFBUMh6aF](http://www.screencast.com/t/MznFBUMh6aF)

The face-to-face component of the course involved having students work on more open-ended and real-life problems in teams of 3-4. A teaching team consisting of the instructor, and graduate and undergraduate teaching assistants facilitated the sessions. Rather than spending time lecturing on the content, the teaching team was able to work with individual teams and address any emerging issues, and answer questions. For example, in one of these face-to-face sessions, students were provided with an instructions sheet; plans and blueprints of the jobsite; and a crane chart document. Students were asked to work in groups of three or four to design the whole crane sequencing process using the concepts they learned in the online lectures and modules.

The conversion of the course from traditional to hybrid format provided several benefits at the student and instructor level. First, it created flexibilities both in students’ and instructor’s schedule. The instructor was able to balance out all the administrative and research responsibilities he held as the division leader without sacrificing any teaching load. Likewise, students were able to work on the class activities on their own time. Second, students were able pace their own learning thanks to the recorded content. In their end-of-semester evaluations, they indicated that they liked being able to pause, rewind, and re-watch the portions of the videos as opposed to one-time-shot in traditional lectures. Finally, this format empowered graduate and undergraduate students as they played a major role in facilitating the face-to-face sessions and provided them the experience of teaching a junior-level course.

2.2 Case 2: Hybrid Learning in Construction Scheduling

*Construction Planning, Scheduling, and Control* is a-three-credit senior level course required for construction engineering students. In the traditional format, this course also included two lecture hours and a two-hour calculation lab each week. The overarching goal behind the conversion of this course to the hybrid format was to capture timeless, theoretical content that remains the same regardless of time in the best way possible so that students can watch it on their own time and at their own convenience. The online lecture development process was quite similar to that of the construction equipment course. First,
the instructor carefully analyzed the course syllabus to identify the topics that could effectively be
converted to the online format. Then, he recorded the lectures using the screen recording software,
Camtasia®. The instructional design team then worked on the recorded lectures to edit, animate, and
produce the content. Every semester, feedback was collected from students on these online lectures to
address any issues on a timely manner.

The conversion of this course to the hybrid format also provided two major benefits to the instructor and
students. First, it created a flexible schedule for everyone. The instructor was able to travel to attend
conferences on new construction scheduling technology without having to cancel any classes. In other
words, he moved the topics around based on his travel plans so that students could do the online
activities while the instructor was traveling. Similarly, students could work on the online activities at their
own convenience and balance their workload. The second benefit was the learning gain for students. The
informal feedback from the students and the anecdotal data from the instructor indicated that the students
in the middle range of the grading scale were the ones who benefited the most from this format. Because
they were able to pause, rewind, and re-watch the portions of the video, they were better able to retain
the information.

2.3 Case 3: Hybrid Learning in Construction Estimating

Construction Estimating is a three-credit senior level course required for civil and construction
engineering students. In the traditional format, this course also included two lecture hours and a two-hour
calculation lab. The overarching goal behind the conversion of this course to the hybrid format was similar
to that of the construction equipment. By taking the passive lecture component of the course to the online
format, the instructor was able to create space in face-to-face classroom time for team-based learning
and active learning exercises. The conversion process for this course has been a little more complicated
than the other two courses, and it is still under development.

The process started with recording a regular classroom lecture. The instructor used a regular audio
recorder to capture his traditional lectures. A graduate student transcribed the recordings, and the
instructor cleaned up the transcripts to better fit into a screen capture format (e.g. removing student
interactions, etc.). The instructor for this course is a non-native speaker of English and he wanted the
lectures to be recorded by a native speaker, so transcripts were sent to a native speaker who recorded
the audio for each slide of a lecture presentation. The instructional design team then combined the audio
files with slides, added visuals, and inserted quiz questions, and uploaded the materials to the course
management site.

Another online component in this course was software application tutorials. The instructional design team
worked with a graduate student who had been a teaching assistant for the course before to create
tutorials for the construction estimating software, WinEst. Students were required to use the software for a
few class projects. The tutorials were created using the screen recording software demonstrating the
main features of the application that could be helpful for students in completing their projects. These
tutorial videos were posted on the blackboard and made available for students’ convenience. However,
they were not required as the online lecture videos were. Rather, they were provided as on-demand help
videos. If students felt comfortable with the software, they did not need to watch the videos, or they could
choose which ones to watch.

Finally, the instructor revised the face-to-face activities and lab assignments and converted them to more
open-ended problem cases so that he could use the released class time for teamwork and active
learning. For this conversion, the instructor contacted industry leaders and asked them to provide real
construction projects and data for students to work on. The homework and assignments were re-written
based on the input received from the construction industry leaders. Although similar benefits are expected
in this course, we have not collected any feedback from students yet.
3 LESSONS LEARNED

Based on our experience in hybrid course development in a construction engineering program, we can conclude that hybrid learning improves learning and provides benefits for students and faculty by creating a flexible teaching and learning environment. These kinds of innovative teaching environments enhance life-long learning skills in students, as they have to arrange their own learning and study agendas, keep up with different learning activities, and improve their meta-cognitive strategies to be successful learners. We can make the following practical recommendations for those who are interested in converting their traditional face-to-face classroom to a hybrid format.

- **Required online content**: Students need to be held accountable somehow to ensure they are engaged in the online activities. In our case, we have embedded quiz questions along the videos to gauge students’ understanding of the content and motivate them watch the assigned videos which would be essential to be successful completing the in-class assignments. These quizzes were auto-graded and automatically recorded in the gradebook on course management site, which substantially reduced the instructor load.

- **Online support**: Because students will be learning a new concept on their own without an opportunity to ask for clarification immediately, the online environment should be designed in a way to facilitate student learning. In our case, we provided additional explanatory videos both for the content and how to solve problems.

- **Technical issues**: Technology should not get into way while students are trying to learn a new concept. Therefore, every effort should be made to reduce the number of technical issues to minimum, or they should be addressed in a timely manner.

- **Connection between online and face-to-face activities**: There should be a clear connection between online and face-to-face activities and they need to be meaningfully weaved together. This will help students better understand the rationale behind the hybrid format and how they can improve their learning in this new environment.

- **Preparing students**: Although the students engage in all kinds of online activities in their daily lives, this kind of learning environment can be new to them. Training students for hybrid format so that they know what it is, why it is done, and what is expected of them will help them be more engaged in their learning experience. In our case, we have found out that successful students used some study strategies (i.e. taking notes while watching, working on problems on one screen and watching the video on another screen, etc.) that helped them succeed in the course. We have taken those strategies and used them as recommendations for how to be succeed in hybrid courses in the following semesters.

- **Consistent structure**: A hybrid course may have different requirements for online and face-to-face activities and students may lose track of all the tasks they need to engage. Providing a well-established and consistent course structure will possibly help students keep track of the tasks.

INTEGRATING DECISION SUPPORT SYSTEM (DSS) AND BUILDING INFORMATION MODELING (BIM) TO OPTIMIZE THE SELECTION OF SUSTAINABLE BUILDING COMPONENTS

F. Jalai1, A. Jrade2 and M. Nassiri3

1PhD Student, Department of Civil Engineering, University of Ottawa, Ottawa, ON, Canada
2Assistant Professor, Department of Civil Engineering, University of Ottawa, Ottawa, ON, Canada
3Graduate Student, Department of Civil Engineering, University of Ottawa, Ottawa, ON, Canada

Abstract: One of the challenges in sustainability analysis and its development is the selection of sustainable materials during the design stage, which can meet the owner’s expectations when investing in sustainable building projects. This expectation is achieved only when a strategic approach is adopted by decision makers (DMs) while selecting the construction materials despite of the complexity of this process. Building Information Modeling (BIM) helps designers assess different design alternatives at the conceptual stage of the project. Additionally, BIM aids in assessing the environmental impacts (EIs) of these design alternatives as well as their associated energy savings all over the building life. Thus, applying BIM concept would help designers to select the right type of materials at the early design stage and to make material related decisions that have great impact on the building’s life cycle. The main purpose of this study is to propose a methodology to integrate BIM tools with problem solving methods for decision making (i.e. Entropy-TOPSIS) in order to optimize the selection of sustainable components in an effective way at the conceptual design stage of building projects. Therefore, a Decision Support System (DSS) is developed by using Multiple Criteria Decision Making (MCDM) techniques to help design team decides and selects the ideal type of sustainable building components and hence design families for proposed buildings based on the sustainability main criteria: 1) Environmental, 2) Economical “cost efficiency”, and 3) Social wellbeing, in an attempt to identify the influence of design’s variations on the sustainable performance of the whole facility. The multi-criteria procedure embedded in the DSS relies on numerical models used to simulate alternatives’ situations, as well as ranking the best alternatives based on owners’ strategic preferences and the availability of sustainable materials in the market; and thus provide detailed and accurate results. The set of models included in the DSS describe the relationship between the different sustainability criteria, companies’ sustainable decisions, and interactions that take place when selecting sustainable materials for building projects. An actual case project will be used to validate the workability and capability of the proposed methodology.

1 INTRODUCTION

The variety of projects’ boundaries, decision makers’ preferences, and availability of sustainable building materials make the aspects of decisions more difficult to achieve in terms of sustainable development. Owners who choose to invest in the construction of sustainable buildings want to use materials and products that are fully sustainable, thus deciding on the ideal ones can be questioned especially when suppliers offer diverse ranges of these types of materials. Usually, a typical building’s component/product
is manufactured by using various elements, where each element may consist of several types of materials. In many cases, a chain of suppliers/producers assemble the products by processing and manufacturing their elements, which lead to a final release of the materials to customers (Aumonier, 2013).

The Multiple Criteria Decision Making (MCDM) approach is a well-known branch of the decision making process. It deals with decision problems under the presence of a number of decision criteria. The decision-maker is required to choose from different types of criteria that are either quantifiable or non-quantifiable or multiple. The objectives are usually conflicting due to their dependency on each other and therefore, the solution is highly dependent on the preferences of the decision-maker, which sometimes must be compromised. Generally, two different methods are used to solve the MCDM problems, which are the Multiple Objective Decision Making (MODM) and the Multiple Attribute Decision Making (MADM). MODM deals with many objectives to come up with an optimal solution to achieve the set objectives, which sometimes conflict one with another and accordingly makes the goal to attain an ideal solution more challenging and problematic. Whereas in the MADM method the decision maker transacts with alternatives that have variety of performance attributes and factors, which can be either qualitative or quantitative (Shanian and Savadogo, 2006). The MADM is generally a discrete method, with limited numbers of pre-determined alternatives. It specifies how to process the attribute's information in order to reach an ideal choice. Rao (2007) thinks that this method needs both inter-attributes and intra-attributes comparisons and should involve appropriate explicit trade-offs. To model these attributes, most of the MADM methods are presented through a decision matrix. This matrix consists of alternatives, criteria and relative significance of criteria where all the components should be normalized to a comparable scale. The key method for ranking the alternatives is Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS), which is one of the objective weighting methods in MCDM. It is a method of compensatory aggregation that compares a set of alternatives by identifying weights and normalizing scores for each criterion and then calculating the geometric distance that exists between each alternative and the ideal one, which is the best score for each criterion.

The significant advancement in computers makes the application of MCDM methods simpler for decision makers and users who are dealing with multiple alternatives and complicated mathematical problems. Thus, Decision Support Systems are generated to aid in problem solving procedures by providing solutions that combine quantitative data and qualitative knowledge/perceptions, and process information in order to present, compare, and rank potential alternatives and, ultimately, select the one that meets the established decision criteria (Lu et al., 2007). DSS can help increase the decision maker's efficiency, productivity and effectiveness. It can also facilitate the communication between different parties in an organization and contribute to quick problem solving.

Building Information Modeling (BIM) is a recent concept used in the building industry all over the lifecycle of projects starting from design and documentation passing through construction and ending by operation. BIM Models not only provide graphical presentation of the project but also automatically generate information such as drawings and reports, design analysis, schedule simulations, and ultimately help the design team make better-informed decisions that affect the whole lifecycle of buildings (Byrne, 2009).

This paper proposes a methodology that integrates Building Information Modeling tool with Decision Making techniques in the format of a data-based Decision Support System (DSS) that systematically incorporates the selection procedures of sustainable components and green materials into BIM environment. The DSS is developed within the principles considered while creating an efficient integration between Building Information Modeling (BIM) concepts and environmental and socio-economic indicators for sustainable development. In particular, the DSS evaluates green building materials supplied by different suppliers and afterwards suggests the optimum selection.

2 LITERATURE REVIEW

Commonly, modeling the decision making step is considered as the most fault-finding phase in the whole decision making processes (Simon, 1977). Thus, it is essential to properly define the problem in order to
formulate the model. To solve the decision making problems, there are several approaches. Lu et al. (2007) described different methods and systems that can be used during the decision making process that include: 1) Analytic Hierarchy Process (AHP), which is a decision making method that allows decision makers consider both the qualitative and the quantitative aspects during the decision making process. 2) Paired Comparison Analysis method, which is employed in cases that alternatives are related to each other. The method enables decision makers consider priorities, which are sometimes on the contrary to the project demands. 3) Grid Analysis method, known as matrix or multi attribute theory, is an effective approach in which decision makers cope with many alternatives and criteria. In this method, the criteria and alternatives are first defined, then the importance of relative factors' is identified and after that the weights are employed based on the decision makers' priorities that are also combined with the criteria's importance. 4) Computerized Decision Support Technology System, which is a tool by which the decision maker is able to perform large numbers of complex models in a short period of time. This tool helps decision makers to share, store, and update and transmit the data in a faster and more economical way besides reducing the risks of human errors. Simon (1977), however, describes the Decision Tree Model as a graphical presentation of decisions and their likely results. This predictive model consists of data-sets of observations that are connected to each other through sets of nodes and leaves, where each interior node stands for a variable and each leaf demonstrates the expected values of that variable.

Due to the variety in MADM approaches, there are different methods that may be used during the process of selecting materials, these include: TOPSIS, ELECTRE, VIKOR, ANP, and PROMETHE. Each of these methods has advantages and disadvantages. Therefore, researchers have applied diverse approaches while identifying the proper technique. For example, Jahan and Edwards (2013) applied VIKOR method for the selection of materials for buildings. Peng and Xiao (2013) used ELECTRE decision making technique for the purpose of material's selection problems arising out of various engineering applications. Recently, Liu et.al (2014) utilized the novel hybrid multiple criteria decision making method, which simultaneously considers the qualitative and quantitative factors. That method is a combination of both the ANP and VIKOR approaches.

Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS) is a multi-criteria decision analysis method that was originally developed by Hwang and Yoon (1981). The principal objective in TOPSIS is to select the best alternative with the shortest distance from the ideal one (Yoon, 1981). The developers assumed that if each factor takes a decreasing and increasing variation, it is possible to find the ideal solution. The unique features of TOPSIS explains its popularity and efficiency where the vector normalization eliminates the units of criterion function so any change in one attribute can be presented in a direct or opposite behavior by the other factors. Also, the results can be ranked according to their preferences and their numerical values. This ranking gives a clear comprehension of the differences in the preferential alternatives and their similarities while other MADM methods (e.g., ELECTRE) show only the ranking values of the alternatives regardless of their differences and similarities. The main pitfall of the pair-wise comparisons in AHP methods is highly avoided. While working with vast numbers of alternatives and attributes, TOPSIS is more efficient and faster.

The impact of BIM on the design practice is significant since it raises new ways and processes of delivering design, construction, and facilities management services. Currently, owners not only want buildings to be designed and delivered on time, within budget, and with high quality but they are also interested in their services beyond the design and construction (Clayton et al, 1999). Based on Kubba (2012), Becerik-Gerber and Rice (2010) the development of a schematic model prior to the creation of a detailed building model, helps designers make more accurate assessments of the proposed scheme and identify whether it meets the functional and sustainable requirements set by the owner. This would increase the project performance and its overall quality. An integrated BIM model can facilitate the collaboration and communication processes between project participants during the early design phase to effectively provide a well-performed building during the operation stage (Hungu, 2013). BIM concept allows multidisciplinary information to be superimposed within one model by incorporating structural, mechanical, electrical, plumbing and lighting information into a single model (Tucker and Newton, 2009). It helps owners visualize the spatial organization of the building as well as understand the sequence of the project’s construction activities and their related durations (Eastman et al, 2008). Combining sustainable design strategies with BIM concept has the potential to change the traditional practices of
design and to efficiently produce high-performance designs for proposed buildings. BIM concept can be used to support the design and analysis of a building system at the early design phase. This includes experimental structural analysis, environmental controls, construction methods, selection of new materials and systems and detailed analysis of the whole design processes.

The methodology proposed in this paper can be used to implement an integrated platform to do sustainable design for new buildings at their conceptual stage. The methodology is implemented by designing and developing a Decision Support System (DSS) that simplifies the process of selecting building components and construction materials while designing sustainable buildings. The methodology incorporates an integrated model capable of guiding users when performing sustainable design for new building projects. Although previous studies described several methods and techniques used to help the project team in selecting optimum combination of building components, authors could not find any research that has been implemented with the focus on integrating BIM concept with DSS techniques. Creating and linking DSS with BIM tool helps users design and animate sustainable buildings easily and efficiently at the conceptual stage. Yet, part of the integrated methodology is to develop new plug-ins into BIM tool in order to link it with the DSS. The successful implementation of such a model represents a significant advancement in the ability to do sustainable design for buildings at early stages of their life, to optimize the selection of sustainable building components and materials and to evaluate the Life Cycle Cost (LCC) of every design alternative.

3 METHODOLOGY

![Flowchart of the integration Process](image)

One of the expected contributions of this proposed research is the development of an integrated model that incorporates a Decision Support System (DSS), which will be used by designers when selecting and deciding on the best type of sustainable building components and design families for proposed building projects. Traditionally, designers use to choose the construction materials whose characteristics are known or used in previous projects, which may cause multiple problems related to expectations, standards, and owners’ budget. The shortcoming of the traditional method can be handled by using the
MADM method, which is basically based on a complex comparison between the available alternatives. Since the proposed methodology integrates different applications, as shown in Figure 1, its development is implemented through three sequential phases.

**Phase 1** consists of designing the model’s relational database that stores information related to green materials in the form of predefined design families that can be recognized by BIM tool used by designers while designing sustainable buildings. The reason for developing a separate database is to have it loaded every time BIM tool opens by defining its path, which is linked to the predefined library of that tool (e.g., Autodesk Revit). The data related to green materials is saved as families with either (RFA) or (RVT) files format. Thus, in the external sustainable database, up to 3,000 design families are collected from different sources, such as suppliers’ web pages, USGBC and CaGBC websites as well as published data, and are arranged based on the 16 divisions of the Masterformat Work Breakdown Structure (WBS). The information stored in the external database consist of different types such as details about the materials used, suppliers’ contact data, assigned keynotes, potential LEED points and assembly codes.

**Phase 2** focuses on customizing BIM tool to fit the modularity requirements of the proposed model. The first step is to design and implement a 3D module capable of storing newly created families, in BIM tool, and their associated keynotes for components, commonly used in buildings, by using certified green materials. The module is linked to the database developed in Phase 1. Keynotes can be assigned to elements that are typically used in case the user wants to note an entire assembly, such as a wall assembly. The sixteen Masterformat divisions present the main WBS applied in this research. It is very important to select a unique code for each item that is presented in a separate line in the database to ease and simplify their retrieval and use.

**Phase 3** consists of developing a DSS module that assists in selecting sustainable building components. The DSS uses the conceptual design and decision-making parameters, along with material selection heuristics to generate a list of alternatives from the materials database for each design component. After the list of alternatives is generated for each design component, the weight factor extractor requires the user to enter a weight for the sustainability attributes. Generally, alternatives in the MADM problems are often defined by some attributes that are qualitative (Hwang and Yoon, 1981). For comparison purposes, qualitative attributes need to be converted to the quantitative scales. This conversion usually takes place by utilizing the five Point Likert-type scales (Lu et al., 2007). Although these scales convert the qualitative attributes to numbers, in many cases, the scales are not able to clearly distinguish the differences between scores that are close to each other (e.g., high and very high). To solve this problem, Saaty (1980) comes with nine point scale while more intervals are employed by Lu et al. (2007). The values of the sustainability attributes (the importance factor of every attribute to each other) will be collected from experts in the AEC industry. Then, the user’s weights are integrated with the attribute values for each potential material and sorted by the integrator, resulting in a relative ranking of the potential materials for each building component. The building components (products) with the highest ranking are recommended by the system. The user reviews the DSS’s recommendation for each building component, and selects a component for each design element either based on the user’s professional judgment and/or the system’s recommendation. As the building components are selected by the user, the DSS will execute an internal test by using its knowledge base to detect any potential conflicts between the selected alternatives and their associated components and materials. The list of recommended materials for each element is modified automatically as materials are selected for the design elements.

The database module includes information about the materials’ suppliers and their associated BIM information. This information is stored and organized based on the main suppliers of the different building components including doors, roofs, windows, ceilings, floors and walls. Afterward, Important Sustainability Factors are identified from the literature. After gathering all the required data, the DSS should be designed based on the applied decision making approaches involving TOPSIS and Entropy in order to be able to choose the optimal alternative. Then, by associating this data and the DSS, an integration interface is developed to import the tasks into BIM tool.

The DSS is based on the multi-criteria assessment weighting scale that is combined with Entropy, which enables the comparison and ranking of different potential alternatives and scenarios. This is a criterion for the amount of uncertainty through the structured prioritization of a variety of sustainability objectives and
indicators. The other method employed in this DSS is TOPSIS Logic, which is mixed with a weighted criteria matrix to show the shortest distance from positive ideal solution and the longest distance from the negative ideal solution. The multi-criteria procedure embedded in the DSS relies on numerical models used to simulate the baseline and alternative situations, as well as ranking the best alternatives based on owners’ strategic plans and the availability of sustainable materials in the market. One of the most critical steps for this research is the arrangement and selection of the criteria and attributes that affect the selection process of project’s sustainable materials. Mainly, the attributes’ assessment is made according to the literature review, previous researches and questionnaires completed by experts. The importance of this assessment is its categorization of the essential sustainable development criteria, which are divided into three categories: 1) environmental, 2) economical, and 3) social criteria. Each of those categories consists of sub-criteria that have been listed by the scoring system that is completed by experts. Table 1 shows the sustainability assessment criteria used by the DSS.

4 MODEL IMPLEMENTATION

Interoperability processes will be implemented in order to develop a functional integrated BIM-based DSS. Knowledge, experience, and experts’ validations are required to implement the DSS. A portion of the technical knowledge required for this research is obtained by consulting with experts who are knowledgeable in sustainability and by using decision making approaches besides the literature. The design phase is followed by identifying the Criteria/Attributes and then calculating the Weight Matrix with Entropy method in order to establish the Decision Maker’s Matrix (DMM). Normalizing the decision making Matrix, which is made by the Decision Maker as well as multiplying the DMM by the Weights Matrixes to get the weighted decision making matrix to evaluate the Positive Ideal and Negative Non-Ideal Solution and to calculate the shortest distance from the Positive Ideal Solution (PIS), farthest distance from the Negative Non-Ideal Solution (NIS) and relative closeness to the ideal solution for each alternative is the further step to rank the alternatives according to their relative closeness proportion. To implement this method, programming the DSS algorithm as well as creating plug-ins in BIM tool, which is in this case Autodesk Revit, is needed. The data set required for this research is divided into two categories: (1) Alternatives (vendors of sustainable materials and basic assembly groups e.g., doors, walls, windows, ceilings, roofs and floor) and their correspondent BIM families; (2) green buildings' sustainability controlling criteria.

Due to the numerous numbers of companies that produce products, only leading companies with wider ranges of products have been selected. To ease the process of accessing the required data, the selected companies and their materials’ BIM information are hyperlinked to the list of products in the developed plug-in. In order to obtain the weight criteria’s matrix from the selected criteria as an output, the experts' opinions have been utilized. For this reason a blank weight criteria matrix has been sent to experts for scoring purposes. After distributing the prepared matrix criteria to the experts, the results should be interpreted. To merge all the collected responses into one matrix, a normality behavior test for the responses of each question has been run by using the Statistical Package for the Social Sciences (SPSS©) software’s normality analyzing tools. Based on the obtained results it is found that all the responses had normal distributions. Therefore, for each correlative score, the normal distribution’s average is substituted. To convert the un-weighted matrix to the weighted one, the Entropy weighting approach has been employed. To calculate the entropy values (Ej), the following formula is employed where k=1/ln (m) and (m) presents the number of criteria. Furthermore, pij is the normalized values of the weight matrix’ elements.

\[ [1] \quad E_j = -k \sum_{i=1}^{m} [p_{ij} \ln (p_{ij})] \quad j = 1, 2, \ldots, J; \quad i = 1, 2, \ldots, I \]

One of the benefits of entropy method is the possibility to mix the decision priorities with the sensitivity analysis. Thus, the final weight is the combination of both. If the priorities for the criterion are the same for the decision maker, the set of weights can be calculated with the following formula, where all the criteria have the same priority.

\[ [2] \quad w_j' = \frac{d_j}{\sum_{j=1}^{n} d_j}, \forall j, \quad d_j = 1 - E_j, j = 1, 2, \ldots, J \]

At the first stage, the matrix is normalized; then the entropy of the weights is calculated; after that the dj factor is estimated. Ultimately, the weighted criteria are determined including each dj on the summation of djs as represented in table 2.

As part of the DSS design, a plug-in in Autodesk Revit is created. This plug-in helps designers evaluate the materials in terms of their sustainability features during the conceptual design phase. The plug-in procedure is created by using C#, the object oriented programming language, and afterward it is imported into Autodesk Revit as a shortcut in its tool bar. TOPSIS begins its procedures by employing two matrices: criteria’s matrix and decision maker’s matrix. The criteria’s weighted matrix is assessed from the previous step. While the developed plug-in aids users to import weights into the decision maker’s matrix, which are recognized by user’s comparison results based on the available products in the external database of BIM tool. The criteria matrix has been coded and inserted in the background of the plug-in’s procedure.

## 5 MODEL VALIDATION

To validate the developed model, its performance is examined through the use of an actual five floor office building project that can house around 300 people (occupants), which is currently under design in the city of Ottawa. The proposed construction site has a total area of 46,980 ft² and the building’s gross area is 88,587 ft². Building functions are distributed into three categories: public, semi-public and private. Public function is related to both ordinary people and employees such as conference and exhibition rooms. Semi-public spaces include secretary offices and managers’ rooms, which are used by employees and visitors. Employees’ offices and private gathering rooms are considered as private spaces used by employees and managers. In order to control the sunlight, louver systems are installed to improve indoor daylighting to limit glare and redirect diffuse light. The authors created a 3D conceptual design of the
current project where its associated sustainable components and materials are selected from the developed database. The components used in the design of this case project have their specifications as it is recommended by the DSS plug-in. Every component, such as floor, wall, roof, and window has its associated sustainability information linked to the families inherited into BIM tool, which includes the manufacturers’ web pages and contact information. Figure 2 shows a rendered snapshot of the sustainable office building case project, which is created by using the developed model.

![Figure 2. Snapshot of the sustainable case building model (Office Building)](image)

During the development of that case project, it is needed to make a decision while selecting the type of sustainable materials, which are supplied by different suppliers, and hence selecting from different alternatives of the current design including the materials for doors, roofs, ceilings, walls, windows and floors. To start the DSS, the user needs to click on the TOPSIS plug-in in BIM tool, Autodesk Revit in this case. After that, the user is asked to assess the decision maker’s matrix by providing a score for each of the alternatives based on the defined criteria. Every product has its technical specification linked to the web page of its supplier and producer. The help button, included in the plug-in, provides the user with necessary information and instructions on how to fill the blank spaces in the form based on the 9 points ranking scale. To run the DMM plug-in the user is required to click on the calculate button designed in the DSS. The final results will be presented as a list that ranks the alternatives with their companies’ names, and the (Ei) factor. Figure 3 shows a snapshot of the filled DM’s matrix and the final sorting of alternatives for the door component.

![Figure 3. The snapshot of filled form in the DSS and the results for door component](image)

6 CONCLUSION

This paper described the development of a model that integrates DSS with BIM tool in an attempt to help designers select the type of materials and components that best fit the design of sustainable building
projects. The focus of this research is at the conceptual design stage where decision makers are in need for assistance to make important decisions related to the continuation or dismissal of proposed projects. Therefore, any additional information would be an asset and helpful to support their decisions. The novelty highlighted in this paper describes the development of an integrated model that comprises Decision Support System (DSS), which aids the design team decide and select the optimum type of sustainable building components for proposed projects based on owners’ needs. The developed DSS is integrated with BIM tool through an automated process by creating new plug-ins for designers to use when doing the design of proposed sustainable buildings at the conceptual stage in a timely and cost-effective way. The specifications and requirements of the DSS implemented in this research are first established and afterward the system architecture is developed. Although this is an ongoing research, its potential for more development is proven to be possible. The DSS database is on a small scale, but it can definitely be expanded to Online Analytical Processing (OLAP) design in order to enable relevant green material producers to update their information online periodically.

Abstract: In 2012 and 2013, ten building product categories were eligible for United States ENERGY STAR Federal Tax Credits. High performance windows that meet certain energy efficiency criteria are one of the qualifying products. The ENERGY STAR Tax Credit program sets U-factor and Solar Heat Gain Coefficient (SHGC) standards for these windows according to four climate zones. Research demonstrates that buildings with well-designed and constructed fenestration systems can lower requirements for heating, cooling and lighting during operation. However, previous research and energy modeling also demonstrates that, in addition to energy efficiency characteristics, orientation impacts the energy performance of windows. The ENERGY STAR tax program makes no distinction regarding window orientation or placement when evaluating tax credit eligibility. This research studies the potential impact of orientation on performance for qualifying ENERGY STAR window products. Using TRNSYS energy modeling comparisons, findings suggest that the performance of qualifying windows may vary up to 14 percent for different orientations depending on climate zone.

1 INTRODUCTION

In the United States in 2010, residential and commercial building sectors accounted for approximately 41 percent of nation’s primary energy consumption. In residential buildings, space conditioning (heating and cooling) accounted for 43 percent of energy consumption, followed by water heating and lighting (EERE, 2014a). Building Technologies Office (BTO) is a part of the US Department of Energy (DOE), with the mission “to improve the efficiency of existing and new building in both the residential and commercial sector through the development of high-impact energy efficiency technologies and practices” (EERE, 2014a, p. vii). A 2014 BTO report prepared by Energetics Incorporated identified windows and building envelope technologies as two areas with significant potential to reduce energy consumption in buildings (EERE, 2014a). The 2011 Building Energy Data Book states that 25 to 35 percent of the energy used for the heating, cooling and lighting of buildings is wasted through inefficient windows (BEDB, 2012). The BTO report on Window and Building Envelope Research and Development projects that the use of cost-effective and energy-efficient technologies could result in savings of 23.4 quads in the United States in 2030, 23 percent of which would be the result of improvements in windows and building envelope technologies.

Several tax incentive programs by the United States Federal government currently exist for energy efficient building features (DOE, 2014b). Specifically, 179D Federal tax deduction refers to Section 179D of the Federal Tax Code, which provides tax deductions for energy efficiency improvements (e.g., Building envelope, HVAC and lighting) to qualifying commercial buildings (EERE, 2014b). In 2012 and 2013, United States ENERGY STAR Federal Tax Credits were available for residential buildings for ten
product categories including: Biomass Stoves; Heating, Ventilation, Air Conditioning (HVAC); Insulation; Roofs; Water Heaters; Windows and Doors; Geothermal Heat Pumps; Small Wind Turbines; Solar Energy Systems; and Fuel Cells (EnergyStar, 2014a). A major difference between many of these eligible products and high performance windows, is the potential for orientation of installation to impact performance. Whereas many products, themselves, (e.g., biomass stoves, insulation, roofing, etc.) provide relatively consistent performance irrespective of the building orientation, research has shown that windows’ impact on building performance can vary significantly depending on the orientation (self-shading) of the building, as well as the façade on which they are placed. Specifically, a window’s performance is directly related to solar angles striking its surface and solar angles differ significantly relative to orientation. The goal of this research is to use energy modeling to begin to assess the performance range of ENERGY STAR windows based on orientation across climate zones.

1.1 ENERGY STAR Tax Credit Program

ENERGY STAR products can cost more than traditional alternatives. The goal of the ENERGY STAR program is to provide financial incentives to support technologies that pay back through lower energy bills within a reasonable amount of time. In order for windows to qualify as ENERGY STAR certified, they must meet three main criteria: (1) The product is manufactured by an Energy Star partner, (2) The products are tested and certified independently by National Fenestration Rating Council (NFRC), and (3) The products' NFRC ratings meet the guidelines set by US DOE (EnergyStar, 2014c). In addition, ENERGY STAR sets minimum qualification requirements for the windows’ performance characteristics according to climate zone (see Table 1). ENERGY STAR defines U-factor as the heat transfer per time per area and per degree of temperature difference, and Solar Heat Gain Coefficient (SHGC) as the fraction of incident solar radiation entering the space through the window. The windows must also be installed on your “principal residence” to be eligible for the Tax Credit. ENERGY STAR defines four climate zones (i.e., Northern, North-Central, South-Central and Southern) as relevant to these performance criteria (see Figure 1).

In 2012 and 2013, homeowners could receive a Federal tax credit equal to 10 percent of the product cost up to $200, with a $500 maximum per homeowner for all energy efficiency tax credits (EnergyStar, 2013). The following sections present a simple study to assess the impact of orientation on minimally compliant Energy Star windows in all of the four specified climate zones.

1.2 Background

Research demonstrates that buildings with well-designed glazing and efficient fenestration systems can lower the requirements for heating, cooling and lighting. Several studies suggest that energy usage and total peak demand of buildings can be reduced by up to 15 percent through effective design of fenestration and daylighting systems (Johnson et al., 1984; Tahmasebi at al., 2011). Windows also provide many known psychological benefits resulting from access to daylight and views of the outside (Tahmasebi et al., 2011).

Several studies have used a variety of energy modeling or building performance simulation programs to investigate the influence of glazing characteristics in combination with various parameters such as window size, orientation, frame type, insulation, ventilation, internal loads, external shading devices and climate. Eskin and Türkmen (2008) used EnergyPlus to simulate the interactions between different building conditions and control strategies in office buildings across climate types in Turkey. The findings of the study suggest that low emissivity, double glazed windows can decrease the maximum energy requirement of the building as much as 15.9 percent (Eskin & Türkmen, 2008). Poirazis et al. (2008) used IDA ICE 3.0 to study the impacts of glazing type, window size, building orientation, shading devices and control set points on highly glazed office buildings in Sweden. The findings suggest that low SHGC values for windows greatly influence the cooling demand, however, increased window to wall ratio and window orientation appeared less impactful (Poirazis et al., 2008). Gasparella et al. (2011) utilized TRNSYS to investigate the impacts of double and triple glazed systems, window sizes, and orientation of the main windowed façade on energy usage and peak demand for well-insulated residential building across four climate types in south and central Europe in both winter and summer. The study suggests that placing the windows on south orientation improves the energy performance of the building, especially during winter, and recommended the use of shading systems to improve the summer performance without sacrificing winter performance (Gasparella et al., 2011).

Morrissey et al. (2011) investigate the implications of building orientation on residential houses in Australia in an attempt to maximize passive solar benefits (Morrissey et al., 2011). Another study by Persson et al. (2006) used DEROB-LTH to examine the performance of windows for low energy houses in Gothenburg, Sweden. Results suggested the size of the glazed surface does not have significant
impacts on the winter heating demand, but can contribute to reducing the summer cooling demands (Persson et al., 2006). Similarly, Wall (2006) used the same dynamic simulation tool to study the impacts of several building variables on passive houses in Sweden. Results suggest that energy efficient windows are essential in reducing thermal losses in buildings while providing thermal comfort for the occupants (Wall, 2006). Hassouneh et al. (2010) investigated the effects of different glazing types, window orientation and windows size using self-developed simulation software on residential buildings for the climate of Amman City. Results suggest that certain glazing types are more efficient in certain orientations. For example, clear glass is effective for south, west and east orientations, but increases energy losses when installed on the north facade (Hassouneh et al., 2010).

Although considerable research exists that suggests a range of factors can influence overall window performance, few, if any studies exist which assess the impact of orientation on ENERGY STAR qualified windows for the four ENERGY STAR climate zones specified by the program.

2 METHOD

For this research, the authors created a simple, square, one story 25 m² (269 SF) building model with facades oriented North, South, East and West. In all cases, a total of 15 m² (161 SF) of glazing was placed on the model façade(s). For the baseline model, the glazing was equally distributed on all facades. Four alternative models were also developed with all glazing placed exclusively on North, South, East or West facades respectively. Each of these five models was simulated using weather files from four cities, representative of the four ENERGY STAR climate zones: Denver, CO (Northern Zone); Albuquerque, NM (North-Central Zone); Atlanta, GA (South-Central Zone) and Miami, FL (Southern Zone) resulting a total of twenty simulations. Window specifications (U-factor and Solar Heat Gain Coefficient (SHGC) standards) were set to meet ENERGY STAR criteria in each climate (see Table 1).

2.1 Energy Model

The authors developed a simple energy model of a small, square building using TRNSYS software (TRNSYS, 2013). Modeling assumptions were based on similar, existing energy modeling research including (Clevenger et al., 2014; Saeli et al., 2010) as well as building codes and standards (ASHRAE, 2010). Simulation set time was one year, with data simulated every hour. Simulations were performed using climate data from four representative cities. In each of these climate zones, a market-available window which met the program’s criteria was selected and assigned a window type: A, B, C, D. The performance criteria of these products are shown in Table 2.

Table 2: Selected (ENERGY STAR eligible) window performance criteria per climate zone

To model these windows, the authors used TRNSYS Type 56 window library. The window library is created using software developed by Lawrence Berkeley National Labs and references ASHRAE 90.1.99 Table A17, ASHRAE Standard 140 and the Building Energy Simulation TEST (BESTEST) Standard. These windows were placed in a baseline model with glazing equally distributed on all facades, plus four alternative models with glazing placed exclusively on North, South, East or West facades respectively. Subsequently, each of these five models was simulated using weather files from the four representative cities for a total of 20 simulations.
3 RESULTS

Table 3 shows the total estimated energy usage and the percentage difference between the baseline and each alternative by climate zone. A positive number indicates that the performance of the alternative has improved (uses less energy) compared to the baseline. A negative number indicates that the performance of the alternative has declined (uses more energy) compared to the baseline.

*2012 Average Annual Residential Electricity Bill by State (Data from forms EIA-861- schedules 4A-D, EIA-861S and EIA-861U). Costs account for electricity average price differences per State. However, no other fuel type (i.e.; natural gas or propane) is included.

4 DISCUSSION

This study presents preliminary energy modeling results to estimate the potential range of energy performance (use and cost) impacts of installing ENERGY STAR windows on various orientations. While the examples (all glazing on one orientation) are extreme, they, nevertheless, provide valuable insight about how design decisions on window product installation can have significant impact on energy and cost savings. Currently, the ENERGY STAR program for windows, doors and skylights does not include any provision for orientation.

One of the reasons that the ENERGY STAR tax credit program may not consider window orientation is that building science principles are complex and interactive. For example, a window’s impact on buildings’ energy performance is not a direct function of available solar resource. Table 5 demonstrates
the average annual incident solar irradiance on a vertical surface in all four orientations by representative city (Greenstream, 2014; NREL, 2014). Solar irradiance is the amount of solar energy that arrives at a specific area at a specific time, which varies throughout the year. However, the benefits of available solar resource is greatly influenced by other climate factors (i.e.; temperature) and building characteristics (i.e.; thermal mass, insulation etc.).

</tbody>
</table>

Comparing results from Tables 4 and Tables 5, it is clear that calculating performance using available solar resource alone, could over-estimates the impact of window orientation on energy performance. Therefore, more detailed and custom energy modeling is necessary for accurate assessment. Such modeling can quickly prove cost and time prohibitive and is likely a main deterrent to the ENERGY STAR program considering window orientation in the tax credit calculation. Nevertheless, results suggest (Table 4) that design decision related to the orientation of the installed window can have significant impact on pay back periods and the value of the tax credit investment.

The following additional observations and recommendations are based on the study's findings:

- Results suggest that placing the entire glazed surface on the south façade tends to improve building energy performance relative to baseline (evenly distributed glazing) in all climate zones. Improved performance over baseline ranges from approximately one percent in the Southern climate zone to seven percent in the North-Central climate zone.

- Results suggest that placing the entire glazed surface on any one façade on any orientation other than the south, tends to worsen building energy performance relative to baseline in the majority of climate zones, except in the Southern climate (i.e., Miami, FL). The magnitude of the negative impact ranges from one to seven percent. Interestingly, in Miami, FL concentrating windows on any one façade appears beneficial presumably because it limits the number of hours of solar exposure.

- Cumulatively, the annual energy consumption of the buildings could vary up to 14 percent between different climate zones based on the orientation of the glazed façade. This large variance could be seen in the North-Central area, where placing the window on the south façade improves the energy performance by 7 percent, while having the windows on the west side, reduces the building performance by 7 percent.

- Cumulatively, the annual cost impact for an individual residence of ENERGY STAR windows may vary on the order of magnitude of $15 (Southern) to $132 (South-Central) annually. Such a range can significantly change the economics and, specifically the payback of such an energy efficiency feature.

- In general, whether a climate is heating or cooling load dominated significantly impacts the role of ENERGY STAR windows (and their orientation) on overall building performance.
Available solar resource (i.e.; average annual solar irradiance on vertical surfaces, Table 5) is not an accurate basis for estimating the impact of ENERGY STAR windows (and their orientation) on building energy performance. Therefore, more detailed and complex energy modeling is recommended.

5 CONCLUSION AND POLICY IMPLICATIONS

This study provides preliminary results based on twenty energy simulations for a simple, representative building model used to illustrate the range of the potential impact of ENERGY STAR qualified windows by orientation across climate types. Results suggest that the cost effectiveness of the incentive programs such as the ENERGY STAR Tax Credit program will vary not only based on the performance characteristics of products, but also based on design decisions related to orientation of installation. Currently, the ENERGY STAR Tax Credit Program only specifies U-values and SHGC minimums according to climate zone. As a result, findings suggest that the Tax Credit's effectiveness could vary by as much as 14 percent depending on installation.

Buildings are complicated systems, and multiple internal and external factors influence performance. For example, heating, cooling and lighting requirements in a building are affected by space conditioning requirements as well as external factors like ambient temperature, solar gain and shading devices. Airtightness and the level of insulation used in buildings in addition to occupants’ preferences and behaviors could also have impacts on building energy performance. Such complexities present challenges for energy efficiency incentive programs. This research highlights the potential impact of orientation on qualifying ENERGY STAR window product performance and concludes that while performance can vary as much as 14 percent, accurate assessment is challenging since it requires detailed, custom energy modeling to account for such variation. Potential policy implications may be to tie incentives to installed performance. Additional energy modeling and economic studies related to the ENERGY STAR Tax Credit or other energy efficiency incentive programs are recommended to further analyze and illuminate the impact and effectiveness of such programs.

Abstract: Supply chain management (SCM) concepts suggest that high fragmentation of roles on projects causes significant negative impacts such as lower processes integration and higher transaction volumes. Within the scope of construction SCM, relationship management (RM) is regarded as one of the most important aspects for achieving efficient SCM. The use of RM in construction projects administration worldwide is manifest on alternative procurement methods, drifting away from traditional systems to ones that are relationship-based. Despite the significance of relationships for project delivery, there were no previous studies that investigated the influence of supply chain RM on construction projects utilizing different project delivery methods (PDMs). The aim of this paper is thus, to determine how RM among parties may be influenced by the PDM utilized. This is achieved through conducting case studies to compare RM in multi-prime design-bid-build versus design-build projects. The researchers adopted the core values developed by Meng’s 2011 RM maturity model to assess RM on projects utilizing different PDMs. Based on the two case studies, the total project RM score was seen to be lower in DBB projects compared to DB projects suggesting that the PDM employed influences RM on construction projects. Such findings can serve as a preliminary evidence of PDM choice effect on project RM and can help project parties gain a better understanding of PDM association to effective supply chain RM implementation. This study could be further extended to encompass more projects to provide statistical evidence of the influence of PDM on RM.

1 INTRODUCTION

The construction industry is characterized by high fragmentation with significant negative impacts such as perceived low productivity, cost and time overruns, conflicts and disputes, and resulting claims and time-consuming litigation (Cain 2003). The application of Supply Chain Management (SCM) is a means of developing vertical integration in the design and production process and operation to link the process into a chain, focusing on maximizing opportunities to add value while minimizing total cost. As this application requires a significant shift in the mind-set of the participants toward collaboration, teamwork, and mutual benefits, it is surprising that only few sophisticated applications have been reported in the construction industry (Kadefos 2005). Within the scope of construction specific supply chain literature, supplier relationship management (RM) is regarded as one of the most important aspects for achieving efficient SCM (Maqsood & Akintoye, 2002; Bemelmans et al. 2012). Despite the significance of relationships for the delivery of projects, there is a dearth of research in this area (Bemelmans et al. 2012).

Over the past decade, there has been an increasing emphasis on the use of RM in the construction projects administration worldwide. This emphasis is manifest on alternative procurement methods, drifting
away from traditional procurement systems to ones that are relationship-based (Walker & Hampson, 2003). Though the dynamic nature (Teece & Pisano 1994) of the construction industry allowed for the continuous implementation of relationship-based systems through different project delivery methods (PDM), there yet remains a lot of room for improvement and development in this area. The aim of this paper is thus, to determine how RM among parties within the construction SCM may be influenced by the project delivery method (PDM) utilized in a construction project.

2 BACKGROUND

Reliance on the traditional project management approach which focused on scientific/mechanistic tools and techniques led to dramatic project failures in addressing cooperative, complex inter-relationships among project parties, especially in mega-projects with high uncertainties. The inadequacy of traditional project management to deal with uncertainty had driven the focus towards relational contracting, partnering, joint ventures, and other collaborative patterns, which target softer skills and show how crucial good relationships are to the successful management of projects. A relationship approach, based on relationship building and management, is emerging as a new construction management paradigm of the future (Pryke & Smyth, 2006). Whilst broader than relational contracting and RM, the relationship approach embraces social capital generally and the role of relationships in core competency development and adding value. It shows how to create and maintain effective relationships between the client and the project team, as well as intra-coalition relationships.

RM does not only play a key role in procurement and transactional relationships (Gadde & Snehota, 2000) but determines the realization of many other facets of business activities (Chen & Paulraj 2004). For example, Monczka et al. (2011) particularly emphasized the aspects where relationships play a key role such as value-driven interaction; communication; trust and commitment; and establishing close partnership relationships with strategic or key suppliers. Rowlinson & Cheung (2006) explored the use and operation of RM as a means for engaging stakeholders through parallel studies in Australia and Hong Kong. They identified stakeholder typologies and adopted a multi-perspective view of project performance in order to link RM, stakeholders and sustainability in a framework which allows exploration of projects and their success. In their research they pointed out that RM is useful for enhancing project performance and client satisfaction (Rowlinson & Cheung 2008). All of these elements have significant importance in the relationship development process but unfortunately, RM has not received adequate attention to reflect its critical role within construction supply chain management (cSCM).

2.1 Relationship Management in Construction Supply Chain

PDMs in construction define the relationships, roles, and responsibilities of parties and the sequence of activities required to provide a facility while RM is a process to establish and manage these relationships between the parties that aims to remove barriers; encourage maximum contribution; and allow all parties to achieve success. Studies suggest that relational approach, such as partnering, alliances, framework agreements and RM, provide positive contributions to social, environmental and economic sustainability and help satisfy client and stakeholder interests (Blau 1963; MacNeil 1978, 1985; Rousseau & Parks 1993). In other words, relational contracts provide the means to achieve sustainable, on-going relationships in long and complex contracts by an adjustment process of a more thoroughly transaction specific, on-going, administrative kind (Kumaraswamy & Matthews 2000). The essence of RM is also found in collaborative procurement. Collaborative procurement aims at engaging parties at all project stages; competitive bidding is no longer the only selection criterion for contractors and design consultants, as well as suppliers (Hughes et al., 2006). Also, some reliance is placed on the deliberate development of long-term working relationships which requires trust building.

Benefits of collaboration and relational approaches in construction projects include time and cost savings, trust, motivation, open communication, and joint risk management (Bennett & Jayes 1998; Bresnen & Marshall 2000a; Kumaraswamy & Matthews 2000; Wood & Ellis 2005; Wood et al. 2002). Successful sustainable relationships in the supply chain rely on relational forms of exchange characterized by high levels of trust and commitment between project stakeholders. Close collaboration with a wide variety of
stakeholders from various backgrounds and professions is essential for business to thrive. To truly benefit from RM, the whole supply chain including the project team, project organizations and stakeholders, must understand the principles of RM and be part of the process.

2.2 Core values in RM

A number of authors have given insights into the core values of RM in cSCM whether focusing generally on the core values of RM (Cheung, 2011, Pinto et al., 2009, Gulch & Raisanen 2009, Kadefos 2005) or specifically on partnering and its relation to RM core values (Marrewijk et al. 2008, Maqsod & Akintoye, 2002). Meng (2010) built upon those studies by integrating the main factors of RM included in previous studies to eight core values: procurement, objectives, trust, collaboration/joint working, communication, problem solving, risk allocation and continuous improvement. The next paragraphs will provide some background on these eight core values and their significance on construction projects.

Procurement and contract is the fundamental of the establishment of a supply chain relationship. The sub criteria of “Procurement” include “Selection criteria,” “Procurement route,” and “Form of contract (Meng et al 2011). Mutual objectives encompass the change in traditional relationships to a shared culture; based upon trust, dedication to common goals, and an understanding of each other’s individual expectations and values (Brensen & Marshall, 2000a). Integrative interactions are characterized by cooperative behavior; hence, parties in a business transaction seek ways to achieve mutual objectives while bargaining (Grover et al 1996). Establishing relational goals may reduce the negative influence of formal contractual rules on people’s behavior (Kadefos 2004) and instead align the goals and objectives of different parties (Meng 2010).

As for trust, it is a psychological state comprising the intention to accept vulnerability based upon positive expectations of the intentions or behavior of another (Kadefors 2004). This could imply that trust is a process that begins within an individual and must rely on certain human qualities or characteristics, such as ability, benevolence and integrity (Kadefors 2004). Showing trust communicates to a partner that cooperation is anticipated and tends to be reciprocated with a behavior that validates trust (Kadefors 2004). However, in the construction industry trust has a different meaning for the parties involved in the industry, such as contractors and owners (Pinto et al. 2009). Trust has direct effects on work group process and performance. Successful collaborative relationships rely on relational forms of exchange characterized by high levels of trust.

Communication, on the other side, mainly involves the transfer of information between people in a group or organization (Gluch & Raisanen 2009). One of the major causes of delay in construction projects is communication problems, however, delays can be minimized by discussions that lead to understanding (Assaf & Al-Hejji, 2006). Performance can be improved in the construction industry if the focus was shifted to examining the constraints of organizational cultures (Gluch & Raisanen 2009) such as the lack of the “no-blame” culture, through communication which will encourage individuals within the organization to experiment with new ideas (Dulaimi et al 2002).

According to Meng (2010), joint working is generally reflected by joint decision-making based on clear understanding of mutual objectives, joint effort of problem solving and joint effort for continuous improvement. Bresnen and Marshall (2000a) suggested that project performance, in terms of cost, time, and quality can be dramatically improved if participants adopt more collaborative ways of working, however before collaboration can become a team effort it depends on individual behavior (Bresnen & Marshall 2000a). Although the willingness to share information and knowledge occurs over time (Gale & Luo 2004), construction project teams learn to part and share what they know in a short space of time. Lack of continuity of relationships, due to the short-term nature of most construction projects, undermines attempts to secure full benefits of collaborative working (Bresnen & Marshall 2000a).

As for risks, they cannot be eliminated; however, they can be effectively managed as they are perceived to be the occurrence of unwanted or uncertain events (Zou et al. 2007) that may negatively affect the success of a construction project. A successful project risk management process relies on the risk being thoroughly and properly understood before it is allocated or before the method of allocation is chosen.
(Rahman & Kumaraswamy 2002). Risk should be allocated to the party best able to anticipate and control that risk, however the willingness of that party to take on the risk is an important consideration in the allocation of project risk (Ward et al. 1991). Conditions of contract are themselves alone not sufficient to allocate risk properly (Rahman & Kumaraswamy 2002); an open and cooperative attitude towards risk by all contractual parties must be maintained for the risk management process to be successful (Schmidt et al. 1999). Risks are inherent in all construction projects, none the less due to the temporal and unique nature of construction projects, their precise and natural form is project specific (Rahman & Kumaraswamy 2002). The identification of risks as early as possible in a project’s life is important (Ward et al. 1991) in ensuring that the primary project performance objectives of time, cost, and quality are achieved.

Continuous improvement implies successfully establishing a culture of development and constant learning within an organization or a project team, and facilitating the learning process of the individuals is regarded as important to the continuity of the continuous improvement activities (Alstrup 2000). The construction industry has seen the introduction of various tools, techniques and methods such as partnering, benchmarking and joint ventures (Bresnen & Marshall 2000a), as measures of continuous improvement in the aim of improving the industry’s project performance. Partnering assumes that continuous improvement is a joint effort to eliminate barriers to improvement (Larson, 1997) and that it is a possible solution for reducing the adversarial nature of the construction industry (Love et al. 2002). Continuous improvement has been seen as a way of promoting long-term performance improvement (Bresnen & Marshall, 2000a). However, the short term nature of most construction projects is not a suitable one as it means that most project teams and organizations live from project to project and each time focus on the successful completion of these projects, as a result this may inhibit the learning process and thus the continuous improvement of project teams (Gieskes & Broeke 2000).

Lastly, according to Barron (2000), joint problem solving requires collaboration within peers and a willingness and openness to be influenced by others, which will result in joint understanding within the parties involved in a problem solving process. Construction projects frequently encounter unforeseen and unanticipated challenges which require the project team to be highly efficient and effective in responding to resolving such challenges. A focused project team with a range of skills and experiences to cope with such problems (Walker & Hampson 2003) and a right attitude to joint working can positively affect the performance of a project.

3 METHODOLOGY

The aim of this paper is to determine how RM within the construction SCM may be influenced by the PDM utilized in a construction project. To achieve this aim, the following three tasks needed to be completed: (1) identify relationship indicators to measure the relationship among project participants; (2) identify the parties involved in the processes and their interactions in different PDMs based on a construction supply chain perspective; (3) compare RM of key suppliers based on the relationship indicators in projects with different PDMs. The first task was completed through literature review where the researchers decided to use the core values of RM adopted from Meng (2011) maturity model as RM indicators. Meng (2011) maturity model included eight main RM core values (discussed in Section 2.2) each divided further to 3 sub criteria with each sub criteria having four maturity levels. The main criteria represent the main aspects of a supply chain relationship, whereas the sub criteria describe different detailed areas in each main aspect. For example, ‘procurement’ was broken down to selection criteria, procurement route, and form of contract each having four maturity levels.

The relationships at maturity Level 1 represent an extreme position dominated by self-interest and mistrust, mutual objectives do not exist, and parties only focus on achieving their own objectives and maximizing their own profits, with no regard to the impact of their actions on others. Trust is limited to the formal contract commitment with price competition being common practice. Win-lose business philosophy are prevailing resulting in adversarial relationships. At maturity Level 2, parties are mainly interested in their own objectives and interests. The mutual objectives are not established. However, a win for one party and a partial win for another enables limited degree of cooperation between the parties. Competition
does not focus on price anymore; instead quality competition becomes more common. Although the parties rely on the formal contract, trust is mainly built on the basis of mutual understanding of each other’s capabilities to carry out their tasks. At Maturity Level 3, alignment of objectives is achieved in a single project. Everyone’s interests are best served by concentrating on the overall project success. Partners work collaboratively as an integrated project team and the win-win attitude becomes the fundamental of the project partnering relationship. Finally, the relationship at maturity Level 4 is characterized by highest degree of trust and alignment of objectives over a series of projects, which focuses on long-term relationship. Fair gain sharing ensures that partners collaborate most closely in the whole supply chain. Continuous improvement is made jointly by learning from performance measures feedback and adopting innovative technology and management approaches. In general, this relationship is reflected as strategic partnering or strategic alliance (Meng 2010).

As for the second and third tasks, they were realized through conducting case studies to gain insights on RM in two projects implemented using different PDMs. The case study included analysis of project documentation and semi-structured interviews with project participants from owner’s, designer’s, or contractor/subcontractor perspective. Interviewing different parties involved in the project allowed the researchers gain a holistic view of the RM in the two projects studied. Interview questionnaire was divided into two parts. The first part aimed at gaining a deeper understanding of the project background and identifying contractual and relational issues among the project parties (including the project phase in which the different participants were initially involved). The second part was based on the core values adopted from Meng (2011) maturity model described above. It included close-ended questions about the eight main RM core values, each of which has four maturity levels. Respondents were asked to choose the statements/levels that was best suited for their project in each of the sub criterion for each of the different parties they defined in the first part of the questionnaire. Each response was assigned a score number equivalent to the level under which it falls, i.e., responses were assigned score between 1 and 4 which corresponds to the maturity level it lies at. For example, if the respondent in sub criteria ‘type of trust’ chooses the “contractual trust” - a statement in level 1 – then a score of 1 is assigned. On the other side if “Long-term goodwill trust” - a statement in level 4 – is selected, then a score of 4 is assigned. After obtaining a score for the sub criteria, the core RM score was obtained using the Equation 1:

\[
\text{Core Value RM Score} = \frac{\sum \text{Total for each subcriterion}}{\text{Number of parties} \times 4}
\]

and then the project total RM using Equation 2:

\[
\text{Total Project RM score} = \frac{\sum \text{Score for each RM core value}}{\text{Number of core values (i.e. 8)}}
\]

4 CASE STUDY ANALYSIS

4.1 Case I – DB project

Case I is a project delivered under a Design-Build PDM in which the owner procures both design and construction services in the same contract from a single, legal entity referred to as the design-builder. It is a value based DB project. The project started in 2011 valued at $200.35M. This $200 million project features the construction of 22 bridges (including two fly-over bridges and a one-of-a-kind cap with a cultural wall), 28 retaining walls, two new urban avenues, an additional lane for through traffic, additional lanes on both directions, wider sidewalks and improved lighting on bridges 4,000+ feet of 54” storm sewer micro tunneling, and roadway reconstruction along 29 alignments. There were eight parties that were identified by the respondents, both owner and design-builder, in this project (Figure 1). The project team included the owner, design builder, two owner consultant (one responsible for record keeping and paperwork tracking and the other assisting in quality oversight), subcontractors responsible for specialty work, consultants working for the design builder for quality assurance, design consultant working for the design-builder as well as subcontractors working for the design-builder. All the eight parties were involved in the early design stage of the project. One party was involved in the development of the construction
documents, six parties were involved in the bidding process, all parties were involved in the construction and finally six parties were involved in occupancy. The solid lines in figure 1 shows the contractual relationships while the dotted lines show non contractual relationships.

![Figure 1: Schematic representation of the organization of all the parties involved in the project](image)

As discussed in the methodology, both the owner and design-builder were asked in the interview to report the eight core values of RM model utilizing the four maturity levels for the eight parties involved in the project. In terms of core value 1 'procurement', the owner reported that the design-builder was selected based on multi-criteria from long-term perspective (level 4) which is the prospective for long-term engagement, while project record keeping and quality oversight parties were selected based on cost and quality (level 2). Subcontractor and sub consultants were selected based on multi-criteria from short-term perspective (level 3). Bidding was done based on two stage tendering (level 2) except for owner project record keeping and owner’s assistance for quality oversight parties where they used direct negotiation (level 4). The design-builder had the same responses as the owner but had more information regarding the subcontractors who were selected based on direct negotiation (level 4) that was possible because of previous projects that they had done together.

As for core value 2 'objectives and goals', the parties in this project seem to be differently informed. According to the owner, he intends to work with these parties in the future (level 4) except for the subcontractor for quality assurance that the owner intends to work with in prospect of future work through tendering (level 2). The design-builder intends to work with the subcontractors in future projects while with the design and quality monitoring units, the design-builder will work with them in prospect of future work through tendering (level 2). According to the owner, in terms of core value 3 'trust', there was a contractual trust (level 1) with the contractor and subcontractors while there was competence trust (level 2) with the record keeping and quality oversight parties and long-term goodwill trust (level 4) for final designer and specialty design parties based. As for the design-builder, there was short-term goodwill trust with some confidence within the parties in this project (level 3). In terms of monitoring, checking was 'somewhat reduced' (level 2).

In terms of core value 4 'communication', according to the owner, most information is exchanged openly (level 4) with the record keeping and quality oversight parties, while some information is exchanged openly with the contractor and subcontractors (level 2). With the other parties including subcontractor for quality assurance, final designer, and specialty designer, much information is exchanged openly (level 3). There is continuous sharing learning and innovation (level 4) except for subcontractor where there is sharing learning and innovation (level 3). Open book costing between two parties (level 3) is listed under the subcontractors, final designer, and specialty designer, whereas there is open book costing throughout the whole chain (level 4) for all the other parties. The design-builder response was that most information was shared among the parties (level 4) except for the consultant responsible for record keeping and paperwork tracking where, there was continuous sharing, learning and innovation throughout the whole chain and in terms of cost information (level 4), there was open book costing throughout the whole chain (level 4). As for core value 5 'collaboration', Owner reported close collaboration with the owner project record keeping and quality oversight parties (level 4). With the subcontractors, the owner has limited cooperation (level 2) and with the rest of the parties including the contractor, the owner has a
collaborative working relationship (level 3). The working relationship between the parties in the project was that of close collaboration (level 4) according to the design-builder. The parties abandoned the blame culture and always supported the weak party (level 3).

As for core value 6 ‘risk allocation’, according to the owner, risk sharing was greatly increased (level 3) with subcontractors reported as having limited risk-sharing culture (level 2). Risk is allocated to the party able to manage it in the project (level 3) for the project teams except for the project record keeping and quality oversight parties where risk is allocated to the party best able to manage it in the long-term (level 4). There are always appropriate rewards for the party taking the risk (level 4). The design-builder’s response to this particular core value was that risk-sharing was greatly increased in the project based (level 3) and risk was allocated to the party best able to manage it in the long-term based (level 4). The parties also always appropriated rewards for the party that took the risk (level 4).

As for core value 7 ‘continuous improvement’, continuous effort for better ways of working (level 4) is exhibited in the project according to the owner, with common measures, formal, regular, and continuous feedback. However, for subcontractors, common measures and regular and formal feedback in the project (level 3) was selected. Generally, there are multiple incentives by project parties for improvement (level 4). During the project, there was a joint effort to better ways of working according to the design-builder (level 3). Also, common measures, formal, regular and continuous feedback was given by these parties with multiple incentives (level 4).

As for core value 8 ‘problem solving’, according to the owner, there was early risk warning throughout the whole chain based (level 4) with project record keeping and quality oversight parties having most of their problems timely resolved at the lowest level (level 4). The other parties have many problems timely resolved at the lowest level (level 3). With subcontractors, final designer and specialty design parties, few problems are repeated (level 3) while rare problems are repeated by the other project parties (level 4). The design-builder stated that there was early risk warning throughout the whole chain (level 4). Many problems were timely resolved at the lowest level and rarely were problems repeated (level 4).

The responses in this case shows that the average score of all the eight core values is 3.5 on the designer-builder perspective while the average score is 3.2 based on the owner response. The case average is 3.34 (table 1) meaning that this case lie in level 4 of Meng, 2011 maturity model.

4.2 Case II - Multiprime project

Case II is a multiple prime contract which is a variation of the traditional Design-Bid-Build, in which the owner holds separate contracts with contractors of various work disciplines. In this system, the owner, or its construction manager (CM), manages the overall schedule and budget. Case II is a refinery construction project, a multiprime contract, valued at $2M located in Toledo Ohio. The project started in September 2013 and was completed in October 2014. The owner was represented by the CM who had direct contact with the prime contractors. All prime contractors’ communications to the owner was through the CM. The prime contractors also had several other subcontractors (Figure 2). The prime contractor interviewed has other projects going on with the owner because of their previous working relationships. According to the interviewees, there were nine key parties involved in the project, owner, prime contractors, subcontractors, architect/engineer, material suppliers and local authorities. The contractor was involved in the early stages of the project and gave input during preconstruction and design stages of construction. There were four parties involved in the predesign, three in the design and development of construction documents, four during bid process, all parties in the construction, and two in the occupancy stage. There was a contractual relationship between the prime contractors and the owner representative.

In terms of core 1 ‘procurement’, according to the interviewees both from the owner and contractor perspective, single-stage tendering (level 1) was used in selecting contractors except the architect/engineer who had direct negotiation (level 4) with the owner and also the CM was selected through tendering then negotiation (level 4). For core 2 ‘objectives’, according to the respondent from the contractor’s perspective, some parties in the project were aware of the mutual objectives of the project
and were working towards achieving these project objectives (level 2). Other units focused on the mutual objectives in the long-term while working towards achieving these project objectives (level 4).

Figure 2: Schematic representation of the organization of all the parties involved in the project

In terms of core 3 ‘trust’, there were mixed reactions between the project participants. According to the owner and contractor, some had long-term goodwill trust (level 4), others had competence trust based (level 2) while others only had the contractual trust (level 1). One of the parties that showed contractual trust (level 1) was a new company and this was their first job while the other ran out of business even before the start of the actual construction. One of the interesting parts in this project is that there was transparency on the side of the CM. One of the interviewees representing the contractor said that towards the closure of the project the CM realized an accounting error of $25,000 owed to the contractor of which they were unaware.

As for core 4 ‘communication’, some information was exchanged openly (level 2) in this project while the construction manager and the owner exchanged much information more openly (level 3). It was interesting to note that there was little sharing and learning information (level 2) in this project while on cost information there was either little cost transparency (level 2) or open book costing (level 4) between two parties. All correspondences and change of scope was done through the CM. The CM held weekly meetings with these other units and was in charge of change orders.

As for core 5 ‘collaboration’, there was close collaboration (level 4) between the owner, CM and the primes. Limited collaboration (level 2) was noticed in the relationship between the primes and the subcontractors, who usually sought self-defence as part of their working culture (level 2). The contractor, owner CM relationship was a problem solving focused culture and always had to support a weaker party (level 4). The designer for this project only supported with the issues related to self-interest (level 2) while subcontractors often had support for a weaker party (level 3).

In terms of core 6 ‘risk allocation’, there was limited risk sharing (level 2) between the parties in the project. Basically the interviewees responded by saying that nobody would wish to share risk because they already have enough. Risk was always allocated to the party best able to manage it in the project (level 3). Some rewards for the party taking up the risk were awarded (level 2). As for core 7 ‘continuous improvement’, there was continuous effort for better ways of working between the owner and the CM (level 4). Limited joint effort (level 2) was noticed between these other units within the project as there was no common measure and no formal feedback (level 4). As for core 8 ‘problem solving’, notably missing was the incentives (level 1) for the units except for the owner CM where there were multiple incentives (level 4) for the CM. Few problems (level 3) were repeated throughout the project. Risks were identified and early warning issued throughout the chain (level 4) and most problems were solved timely at the lowest level (level 3).

From the findings, there seems to be a variation in terms of how the RM values are affected in each project. For both cases, subcontractors obtained the lowest level in the RM core values. The consultants or the professionals working for the owner seem to rank highly in the hierarchy in all the indicators of the RM. The average scores for owner and contractor/design-builder responses are summarized in Table 1.
In case I, the DB project, even though all the parties were involved in the early stages of the project especially in the design phase, they don’t seem to be aware of the objectives and hence not working towards achieving them. However, all other indicators especially on problem solving, the design-builder’s response rank the core values at the highest maturity level. In case II, the contractor reported levels 2 and 3, with risk allocation and trust being the lowest while owner also reported trust being the lowest.

5 CONCLUSIONS

RM is different from investigating the contractual relationship on a construction project. The aim of RM is to build upon the partnership by going beyond typical partnership ‘rules’ and draw on co-existing social and cultural norms. RM requires that all parties to the contract agree to align their individual goals, thereby establishing common or aligned goals for the project. The gain share/pain share mechanism is structured so that the parties (client, designer and contractor) will either win or lose together. There can be no blame - success or failure is a joint responsibility. This is a significant departure from traditional project practice. DB PDM is assumed to have better/improved relationships as compared to DBB just by the virtue of early contractor involvement. To investigate that preposition, an assessment to compare between a traditional and an alternative PDM is needed. This paper presents a comparative analysis which compares two project delivery methods. It also goes further to look at the interaction structure of the project parties in the different phases of construction and investigates whether core values of RM are affected by the project delivery used on the project using two case studies. It was established based on the documentation and responses from the owner and prime contractor that in a multiprime design-bid-build project the average total project RM score during the assessment lie in Level 3 where the parties are engaged in partnering relationship while in design-build project, it lies in level 4 where the parties are engaged in strategic partnering/strategic alliance. Therefore, the results of the study can serve as preliminary evidence to that alternative PDMs have better RM compared to traditional project delivery methods. It also shows the benefits of cSCM implementation not only in assessing RM but also a tool that could be inherently used in the construction project operations. The research can be further extended to incorporate more projects to provide a statistical evidence of the influence of PDM on RM and compare RM in different types of construction projects such as commercial, residential and expand it to include other alternative project delivery methods.

Abstract: Falls are a leading cause of fatal and nonfatal injuries in construction. One of the most important steps in analytical research to prevent falls is to identify and measure the factors that can affect the construction workers’ fall risk. While several intrinsic and extrinsic factors can affect workers’ fall risk—such as the effects of aging, jobsite environments, posture and movement characteristics, workers’ experience, and workers’ equipment type and use— one unanticipated factor that can increase fall risk is the incorrect use of personal protective equipment—including full body safety harnesses and heavy tool belts—when safety harnesses and tool belts are not worn properly or body loading balanced they can cause unstable posture, changes in walking gait, and center of gravity problems. The objective of this study was to analyze the effects of the wearing full body safety harnesses and heavy tool belt loading symmetry on construction worker fall risk. Using the time-series quantitative kinematic measures obtained from Inertial Measurement Units (IMUs) connected to the workers’ waistline, the postural stability of a group of subjects was measured by calculating the velocity of Center of Pressure (COPv) and the resultant Accelerometer (rAcc)—lower rAcc and COPv values mean lower fall risk for construction workers. The postural stability for each worker was calculated for two different postures (standing and squatting) and for three different configurations of the tools (without attaching tools to the full-body harness, symmetrical attachment configuration, and asymmetrical attachment configuration). T-test results for mean values of the calculated rAcc and COPv showed significant differences in the postural stability of subjects with different placement and loading balance configurations of tool belts connected to the fall protection harness. When tools were not placed in the tool belt connected to the fall protection harness, test subjects had the lowest rAcc and COPv values; asymmetrical tool loading configurations rAcc and COPv had higher values than symmetrical loading configurations. The higher risk values associated with asymmetrically connected tools to a full body safety harness suggests the importance of safety harness tool attachment to construction worker fall risk safety.
Keywords: Construction workers, safety harness, tool belts, quantitative kinematic measure, postural stability, IMU, fall risk

1 INTRODUCTION

Construction is one of the largest industries by economic impact in the U.S., employing 7% of the total U.S. workforce or more than 9 million workers. Construction is in the top 3 most dangerous industries along with mining and agriculture based on annual number of workplace fatalities. Occupational injuries and fatalities in the construction industry lead to high direct and indirect accident costs, such as income loss, reduced workforce productivity, reduced quality of life, increased total project time and cost, cost of medical treatment and follow-up, short term and long term disability, medical services burden, etc. (Horwitz and McCall, 2004; Lipscomb et al., 2003; Meerdng et al., 2006). Falling from height is the leading cause of injuries and fatalities in the U.S. and international construction industries (Bentley et al., 2006; Bobick, 2004; Chan et al., 2008; Chi and Wu, 1997; Huang and Hinze, 2003; Meerdng et al., 2006; Yung, 2009).

Many construction incidents could be prevented if the causal factors leading to workplace falls were identified and mitigated correctly. There are several identified factors that are associated with falls in construction sites, such as aging workforce effects, jobsite environmental factors, walking and movement characteristics, worker training and experience, and tooling and equipment. One of the overlooked factors that can increase fall risk is the incorrect use of personal protective equipment—including safety harnesses and tool belts—since construction workers and their supervisors often do not pay attention to the loading symmetry of heavily loaded tool belts attached to full body fall protection harnesses (Cory Lyons, personal communications, 2014). One of the reasons this problem exists may be due to the limited explicit knowledge and training related to the effects of improper tool belt loading as part of a full body harness. Proper loading and symmetrical tool placement in a tool belt and full body fall protection harness could help reduce construction worker fall risk. The objective of this study was to assess the effects of tool belt and full body harness loading symmetry on postural stability by measuring and analyzing whole body stability using a wearable inertial measurement unit (IMU) data collection system.

The ability to maintain a position of the body—or more specifically, the body’s center of mass—is defined as postural stability (Lord et al., 2007). There are several methods and metrics that have been suggested in clinical and healthcare settings to assess the fall risk of human body subjects by measuring their body postural stability, such as Hurst rescaled range analysis (HR/s), average velocity of center of pressure (COPv), and resultant acceleration (rAcc). Hurst rescaled range analysis examines fractal properties after integrating a time series and can be used to characterize a time series of motion data when studying a body’s stability (Delignlères et al., 2003). The average velocity of center of pressure (COPv) illustrate the total distance between each consecutive points of the body’s center of pressure in the total data collection time (Hufschmidt et al. 1980). COPv is considered to be the most reliable measure used in the biomechanical domain to measure the stability of human bodies in stationary motions (Lafond et al., 2004). Resultant acceleration (rAcc) is another metric used in the clinical domain to measure the human body’s stability in a stationary posture (Bruumagne et al., 2008; Liu et al., 2012; Soangra and E Lockhart, 2013). rAcc measures the total human body motion in a certain period of time using the accelerometer vector components from inertial measurement units (IMU). In this research, the COPv and rAcc parameters were selected as the metrics for measuring and analyzing construction worker postural stability based on body movement and center of pressure demonstrated by subjects in the standing and squatting postures in the experimental setup.

2 EXPERIMENTAL DESIGN AND METHODOLOGY

2.1 Instrument, Procedure and Test Subjects

This research project used IMU data to calculate the COPv and rAcc even though most previous research into COPv used a force plate (Bruumagne et al., 2008; Chaudhry, Hans et al., 2004; Clair and Riach, 1996; Karlsson and Frykberg, 2000; Önell, 2000; Soangra and E Lockhart, 2013) to measure human subject
postural stability. This decision reflects the fact that using a force plate in real world job sites would be cumbersome and difficult since such plates are expensive, heavy, not easily carried, and require a flat stable surface to maintain calibration, accuracy, and repeatability.

To provide a stable surface for the test subjects to use while performing different steps of the test, a flat, stable steel plate was provided. Test subjects were asked to do both standing and squatting postures on the steel plate since the plate could provide the same standing surface condition through all of the stages of the test (See Figure 1-g). For all test trials test subjects body motions were recorded using a tri-axial accelerometer (Shimmer 9DOF) (See Figure 1-h). Sensors collected 52 data points per second for anterior-poster (AP), medio-lateral (ML), and vertical (VT) directions, each of which were oriented with X, Y, and Z axes, respectively. IMU sensors were attached to the dorsal surface of each test subject's back at a height of 57% of subject's total standing height (stature). According to Mayagoitia et al. (2002), this location is the appropriate human body location that can be selected as the body center of mass point for tracking and analyzing total human body motion.

Ten healthy able bodied human subjects participated in this research. (Mean age: 30.8 years; mean height: 6 ft.; mean weight: 192 lbs.). The subject sample had no reported history of clinical conditions or disabilities that would disqualify them from participation in the research project. All subjects verified that they were not taking any medications, drugs or consuming substances like alcohol that could cause drowsiness or adversely affect their body posture or movement stability. Test subjects with corrected vision wore their eye glasses or contact lenses during the experiments. All test subjects were college graduate student volunteers with no construction work experience.

Test subjects were asked to perform two different postures (standing and squatting) for three different tasks. For Task 1, test subjects stood on the steel plate for 30 second while they wore a full body harness without any connected tools; the subjects then repeated the test for another 30 seconds in a squatting position (See Figure 1-a&d). For Task 2, subjects repeated the standing and squatting motions—same as Task 1—while their full body harness was loaded with tools in a symmetrical configurations (See Figure 1-b&e). Task 3 repeated the same test as the first two tasks but with tools attached to the full body harness in an asymmetrical configuration (See Figure 1-c&f). The tools used in these tasks were selected from common sets of ironworkers tools for tool belts (See Figure 1-i). The total weight of the tools, tool belt, and full body fall protection harness was 30.0 lbs. The total weight of just the tools was 9 lbs. For the symmetrical tool belt configuration, tools were loaded with an equal weight on the right and left side of the tool belt. For the asymmetrical configuration, all the tools were loaded into the left side of the tool belt and fall protection harness.

Visual inputs—such as high and low-contrast visual acuity, contrast sensitivity, depth perception, stereopsis, and lower visual field size— are considered one of the extrinsic factors that could affect human body stability as a destructive factor (Jeka et al. 2004; Lord and Menz 2000); Visual inputs can disturb the human subjects and affect their stability by moving their bodies upright posture. To provide the same conditions for the different subjects while they performed different tasks, a white screen was installed in front of the subjects that covered the subjects’ vision completely. Subjects were asked to look forward and not to move their heads. The testing location was in a human factors and safety test lab in almost an imperturbable place protected from noise, disturbance, or distraction sources. The test lab environment helped to eliminate test procedure interference and avoid test subjects distractions.

Factors that could have increased data collection error were: (1) assigned test task ordering effects and (2) confounding effects due to test subject physical fatigue. In order to prevent or reduce the task orders effects physical fatigue confounding, 5 minutes rest was provided between different test tasks for each subject, and test tasks were randomly assigned for each subject. Before starting the experiment subjects were informed about the experimental procedure and any questions about the procedure were addressed. Figure 1 summarizes the different experimental tests (Tasks 1, 2, and 3) in this study.
Figure 1: Illustration of the experiment: (a) Standing while wearing full body harness without any connected tools; (b) Standing while wearing full body harness laden with some tools in the symmetrical configuration; (c) Standing while wearing full body harness laden with tools in asymmetrical configuration (d) Squatting while wearing full body harness without any connected tools; (e) Squatting while wearing full body harness laden with some tools in the symmetrical configuration; (f) Squatting while wearing full body harness laden with tools in asymmetrical configuration; (g) Steel plate with a flat surface; (h) Inertial Measurement Units; (I) Selected connected tools (right to left: full body fall protection harness and tool belt bag, 5 lb. sledge hammer, finish construction wrench, erection wrenches, pry bar, and pinch bars)

2.2 Measuring the Postural Stability

In this paper, resultant accelerometer (rAcc) and the average velocity of the center of pressure (COPv) were selected as two measures to calculate postural stability of construction workers. Resultant acceleration (rAcc) is a metric that was introduced in the clinical domain to measure the human body stability in a stationary posture (Brumagme et al., 2008; Liu et al., 2012; Soangra and E. Lockhart, 2013). The rAcc measures the total human body motion in a certain period of time using the accelerometer vector components from inertial measurement units (IMU). Higher rAcc means higher instability for human subjects.

The average velocity of center of pressure (COPv) was introduced as the most reliable measure for assessing the stability of human bodies in stationary positions within the biomechanical domain (Lafond et al., 2004). COPv is calculated by summing the distance between each consecutive point of the body’s center of pressure and dividing this over the total data-collection time (Hufschmidt et al., 1980). In a stable situation, the location of the center of pressure is constant or has a minimum displacement. Increasing the displacement of the center of body location will increase the COPv, and higher COPv means higher instability.

Resultant acceleration (rAcc) was calculated using Equation 1.

\[ rAcc = \sqrt{\sum (a_{x}^2 + a_{y}^2 + a_{z}^2)} \]
Where \( a_x, a_y, a_z \) are the acceleration measurements from the IMU.

This paper used Mayagoitia et al. (2002) method to calculate the COPv. The main idea of this method is to measure the sway path of the accelerometer and to assume that this sway path is same as the sway path of the body's center of pressure. The magnitude of the resultant acceleration \( (A) \) for each point can be calculated using Equation 2 where \( a_x, a_y, \) and \( a_z \) are the acceleration measurements from the IMU across each axis (See Figure 2-A).

\[
[A] = \sqrt{\left(\frac{a_x^2}{A_x}\right) + \left(\frac{a_y^2}{A_y}\right) + \left(\frac{a_z^2}{A_z}\right)}
\]

After calculating the \( A \), the angle between the different directions of the accelerometer vectors and the magnitude of the resultant acceleration can be calculated using the group of Equations 3-6.

\[
\cos \alpha = \frac{a_x}{A} \quad \cos \beta = \frac{a_y}{A} \quad \cos \gamma = \frac{a_z}{A}
\]

\[
x = D \cdot \cos \alpha \\
y = D \cdot \cos \beta \\
z = D \cdot \cos \gamma
\]

Where \( \cos \alpha, \cos \beta, \cos \gamma \) are the directional cosine and \( \alpha, \beta, \gamma \) are the angles between the components of the acceleration and the resultant acceleration. \( D \) is the magnitude of the accelerometer vector.

In the above mentioned equations, \( D \) has an unknown value. \( D \) can easily be calculated from equation 6 since it can be assumed that \( z_i \) has a constant value equal to the height of the IMU. Finding the value of \( D \) and replacing \( D \) in equations 4 and 5 will lead to one finding the value of \( x_i \) and \( y_i \) (See Figure 2-b). Next, the average velocity of the center of pressure (COPv) was calculated by summing the distance between each consecutive point of the COP and dividing this over the total data collection time \( (T) \) using the equation 7 (Hufschmidt et al., 1980).

\[
[COPv] = \frac{\sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2}}{T}
\]

Where \( T \) is the total data collection time and \( x_i \) and \( y_i \) are the center of body's coordinates. All of the calculations were performed using custom-made software written in MATLAB (ver 8.1.0.604, The Math Works Inc., USA). The commercially available SPSS was used for statistical analyses.

Figure 2: Representative stabilograms obtained from a subject. (A) The time-series data captured by IMU in three directions (Vertical accelerometer, ML accelerometer, AP accelerometer). (B) Stabilogram of center of pressure.
3 STATISTICAL ANALYSIS

T-test Analysis

T-test analyses for small equal sample sizes were conducted for rAcc and COPv values between Task 1 (standing and squatting while wearing full body harness without a load) and Task 2 (standing and squatting while wearing full body harness laden with tools in a symmetrical configuration), and between Task 2 and Task 3 (standing and squatting while wearing full body harness loaded with some tools in an asymmetrical configuration). The alpha level for the t-test was set at $\alpha=0.05$.

Two-way ANOVA

Two two-way analysis of variance (ANOVA) were performed for rAcc and COPv values to compare the effects of the loaded-tools’ configuration on rAcc and COPv values. The alpha level for ANOVA test was set at $\alpha=0.05$.

4 RESULTS

The mean and standard deviation (SD) values of rAcc and COPv values are shown in the Figure 3. For both standing and squatting postures, rAcc and COPv had their highest value in Task 3. The highest overall COPv was found in the squatting posture of Task 3 as 41.05, while the minimum value was found in the standing posture of Task 1 as 5.379. Higher rAcc and COPv values specify the low postural stability of the subject, which can be interpreted as having a higher fall risk. Similar to the COPv results, the highest rAcc value was found in the squatting posture of Task 3 as 41.05, and the lowest rAcc was found in the standing posture of Task 1 as 1.848.

Table 1 summarizes the results of the t-test between different loaded tools configurations in the standing and squatting postures. The results show a significant difference in the comparison between Task 1 and Task 3 in both the standing and squatting postures, Task 2 and Task 3 in both postures, and Task 1 and Task 2 in the standing posture. The t-test only failed to confirm a significant difference in the comparison between Task 1 and Task 2 in the squatting posture. While the t-test did not show significant difference in comparing the Task 1 and Task 2 in the squatting posture, however, there was a significant difference in the mean value of both rAcc and COPv in these two cases. The lowest t-test p-value appeared in comparing Task 1 and Task 2 which implies that there is a significant effect of improperly loaded-tools’ configuration on construction worker stability.

Table 2 summarizes the results of the ANOVA test in the comparison between the different tasks in their respective standing and squatting postures. The ANOVA test results also indicate a significant difference in both rAcc and COPv among the three tasks in both the standing and squatting postures. The p-value of COPv in both standing and squatting postures was lower than the p value of rAcc, which again shows that COPv demonstrates more significant differences in the comparisons between the different tasks.

Although both rAcc and COPv metrics have the same trend in comparing different loaded-tools’ configuration in standing and squatting postures, there was a higher sensitivity in COPv values rather than rAcc values when changing the tasks, according to Figure 3. Another result of this paper is the higher value for rAcc and COPv for the different tasks in the squatting posture rather than the standing posture, which shows that construction workers have a higher instability in the squatting posture than the standing posture. Also, the difference of in the calculated COPv between different tasks is higher in the squatting posture rather than the standing posture. This implies that the load configuration may have a higher adverse effect in more instable postures—such as squatting—than in stable postures—such as standing.
Figure 3: rAcc and COPv values for different full body harness tool configurations in standing and squatting postures.

Table 1: T-tests p values between different loaded-tools’ configuration and measures in standing and squatting postures.

5 CONCLUSIONS AND DISCUSSION

The goal of this research was to demonstrate the effects of tool belt loading symmetry on posture stability of construction workers wearing a tool belt connected to a full body fall protection harness. Sometimes, young construction workers do not fully understand the importance of symmetrical tool belt loading and its relationship to working postural stability and lower fall risk. This research reinforces the importance of proper tool belt loading for young or less experienced construction workers.

The results of this research revealed that asymmetrical tool belt loading was associated with lower posture stability in the standing squatting postures when compared with symmetrical tool belt loading. In addition, it was found that even a symmetrical tool belt loading condition will result in some instability for construction workers when compared to a situation in which there are no tools loaded in the tool belt fall protection harness system. Another key finding was the confirmation of the usefulness of the suggested postural stability metrics in distinguishing the fall risk of construction workers while performing tasks with different fall risk profiles. These results also highlight the value of using IMU wearable sensors as a possible monitoring device to assess construction workers’ fall risk. IMU sensors can attach to
construction workers to measure the stability of construction workers’ while they perform different tasks in different postures on a construction site and can foreseeably be used as a method to prevent fall accidents.

Future research should examine the effects of other intrinsic and extrinsic factors—such as walking speed, construction site walking surface friction characteristics, worker age, worker training and experience—on the construction workers’ postural and work movement stability since these factors may adversely affect worker safety. Other future studies could study the sensitivity of different stability metrics in order to find the most sensitive metrics to compare the effects of different intrinsic and extrinsic factors on work posture and movement stability.

Abstract: Digital models incorporating 3D geometry and information attributes are becoming a standard for industrial facility and commercial building design. Despite the advancements in technologies to develop design models there is an opportunity to better leverage models within facility construction processes. The current work aims to identify the breadth of construction needs for using information models, and develop an approach to improve information accessibility to support construction. With a thorough literature review, the current work identifies the state-of-art workflows in using design content to support construction tasks. The existing gaps of using models for construction uses have also been captured, indicating the opportunities of better leveraging model content throughout construction process. Discussion of how a planning approach and implementation guidelines will be developed to advance model uses in construction will help conclude the paper.

1 INTRODUCTION

Digital models incorporating 3D geometry and information attributes are becoming a standard for industrial facility and commercial building design. Depending on the technology, a variety of model uses have been developed to serve particular purposes for project stakeholders, such as designers and contractors, across project phases. Practitioners have acknowledged the benefits of adopting the data-enriched models in integrating design and construction (Eastman et al., 2011). Regardless, challenges remain in better leveraging models within facility construction processes. Current practices frequently require significant design content remodeling or revision for construction, such as the creation of detailed fabrication models and coordination models adding details required for construction. Moreover, there is a need for a comprehensive understanding of construction information requirements that are not presently available, but could be delivered via a model. This presents an opportunity to create coordinated industry guidelines and a process for leveraging model content through the construction phase.

As an initial step, this paper focuses beyond the implementation of models for commercial building projects, and aims to identify the breadth of construction needs for using information models. A thorough review of recent academic publications has been conducted to capture the state-of-the-art construction modeling. The existing gaps of using models for construction uses have been revealed, indicating the opportunities of better leveraging model content throughout construction process. The need of developing a planning approach and implementation guidelines to advance model uses in construction is discussed as well.
2 BACKGROUND

Information modeling has been adopted in the architectural, engineering, and construction (A/E/C) industry since late 1980’s. Focusing on commercial building projects, Kreider and Messner (2013) defined a building information model use as “a method of applying Building Information Modeling (BIM) during a facility’s lifecycle to achieve one or more specific objectives.” There have been many efforts on listing BIM uses, documented in publications (Eastman et al., 2011), industry guides (Department of Veterans Affairs, 2010), and other industry efforts (Computer Integrated Construction Research Program, 2010). None of them are completely comprehensive or generated by a consistent methodology. Regardless, according to the BIM Project Execution Planning Guide (Computer Integrated Construction Research Program, 2010), which is the most widely adopted for BIM uses, there are 9 of 25 defined uses that can be adopted to support the construction. Among them, 3D coordination was reported in an online survey as the most frequently used BIM use and perceived as the highest beneficial use; while the others, digital fabrication, in particular, was considered as very beneficial, yet not used frequently (Kreider et al., 2010).

One of the main reasons to explain the challenges during adoption is managerial (AGC, 2005). There is a need to standardize the process and to define the guidelines for using the models along with the embedded information to facilitate construction process (Azhar et al., 2011). Driven by the managerial challenges, Kreider (2013) applied a methodology and generated a model use taxonomy for BIM implementation, which has also been approved for adoption in the National BIM Standard – US, Version 3 (still awaiting publication). The primary components of a BIM Use are shown in Figure 1, with five different purposes identified as “Gather,” “Generate,” “Analyze,” “Communicate,” and “Realize.” The ontology that applied in this study provides an effective methodology to categorize BIM Uses and also allows for future expansion of BIM Uses.

Therefore, this paper employs the ontology to capture the state-of-the-art model use and identifies the gaps and areas to potentially expand modeling implementation in the future. To avoid the challenges related to the perception of BIM’s application to be specific to a category of facilities, more broad language is used here by John Messner to define the “Model Use” as: “a method or strategy of applying digital modeling during a project lifecycle to achieve one or more specific objectives.”

3 METHODOLOGY

A review of recent academic research on the development and implementation of construction modeling has been applied to capture the leading model use and identify potential construction needs for future modeling implementation. Seven journals and five conferences were targeted as sources (Table 1). “Virtual model” and “construction” were used as key words to search the targeted journal publications and conference proceedings for relevant papers. With a total number of 53, Figure 2 shows the number of relevant papers in each 5-year period of the past two decades.

Through the literature review, matrices are used to capture the current model uses and to reveal the opportunities of future model uses to support construction tasks. In the current work, three types of matrices have been plotted:

- Model Use Technology verses Construction Task: to capture the construction tasks that can be supported by model uses leveraging emerging emerging technologies.
Model Use Technology versus Model Use Purpose: to capture the purposes of existing model uses in construction.

Construction Task versus Model Use Purpose: to capture the construction tasks that have modeling supported in different purposes.

In addition to capture the existing model use, the three matrices are expected to reveal the gap of model uses in construction, indicating opportunities of leveraging technologies and model information to facilitate construction operations. The next two sections will discuss the review results, starting with the description of the matrix components.

### 4 DIMENSIONS OF MODEL USE MATRIX

Three dimensions are used to develop the model use matrix and to capture construction modeling uses: model use technology, construction task, and model use purpose.

#### 4.1 Model Use Technology

The first dimension of model use matrix is “model use technology,” to capture the emerging technologies being leveraged for model use in the construction industry. Anderson and Schaan (2001) categorized the advanced technologies into five high-level groups: communications, on-site plant and equipment, materials and systems, systems, and design. Fenn (2010) mapped out a number of potentially transformative technologies, from augmentation to tablets, depending on the time to and the impacts on the mainstream adoption of each. In the current study, seven different types of models use technologies are categorized and summarized:

- **Simulating technology:** it described as the technology to create a model that behaves or operates like a given system with a set of controlled input (Anderson and Schaan, 2001).
- **Business management tools:** it includes all the systems and applications used by organizations to cope with the planning and management of expenses, process, resources, documents, field administration, and communication (Neelamkavil, 2009). Example tools can be Enterprise Resource Planning (ERP), and document management systems.
- **Geographic information system (GIS):** GIS is defined as a computer system “capable of storing, editing, processing, and presenting geographical data and information as maps” (Campbell and Shin,
2011). GIS applications allow users to query and analyze spatial information, edit geographical data in maps, and present the results of all these operations.

- Positioning systems (or tracking systems): it describes the usage of technology to determine or track the location of an object during construction (Grau et al., 2009). Related technology includes Global Positioning System (GPS), Radio-frequency (RF) Technology, and Ultra-wideband (UWB).
- Imaging technology: it indicates the application of technology that is used to capture, process, and preserve images to support construction operations, such as 3D video rage imaging, photogrammetry, laser scanning, and augmented reality (Turkan et al., 2013).
- Mobile technology: this technology provides support for small, handheld computing devices with a display screen, such as mobile phones and tablets, to be used by mobile workers to view, input, and transmit information (Kondratova, 2004).
- Robotics: it indicates the application of robots to support and even automate construction operations (Neelamkavil, 2009).

4.2 Construction Task

The second dimension of the matrix is “construction tasks,” to capture the construction activities that can be supported by model uses. Preliminary investigation of construction tasks was based on the schedule-based control structure approach (Halpin et al., 1987), also named as work breakdown structure (WBS).

As the first level of breakdown structure, those following categories can be subdivided into the level of detail as needed. The planning and management tasks throughout the construction process are considered as a separate category listed as follows:

- Construction planning & management: it describes the activities related to planning and management before and throughout construction, including construction scheduling and planning, progress monitoring, resource tracking and management, safety, and coordination activities.
- Procurement: it describes the acquisition of resources needed to transform a design to a physical facility, from purchasing to manufacturing/fabrication, and delivery to the construction site.
- Civil engineering activities: here it is considered as site development tasks based on hydraulic, environmental and geotechnical engineering, like surveying, drilling, boring, pavement, etc.
- Excavation & Foundation: it describes the construction tasks for excavation and foundation construction.
- Frame Erection: the erection of structural frame/components is the focus of this category.
- Assembly & Installation: it describes the construction assembly and installation tasks at site.
- Engineering Systems: it refers to the construction activities related to mechanical, electrical, and plumbing (MEP) systems.
- Enclosure & Finishes: it indicates the construction of building envelope and finishing work.
- Quality Assurance/Quality Control (QA/QC): activities that help to inspect and control the quality of construction belong to this category.

4.3 Model Use Purpose

Another dimension that used to plot the matrix is model uses purposes. According to Kreider (2013), there are five categories and eighteen subcategories of model uses purposes in the industry (Figure 3):

- Gather: to collect or organize facility information, covering the sub-purposes such as “Qualify,” “Monitor,” “Capture,” and “Quantify.”
- Generate: to create or author information about the facility, covering the sub-purposes such as “Prescribe,” “Size,” and “Arrange.”
- Analyze: to examine elements of the facility to gain a better understanding of the elements, covering the sub-purposes such as “Coordinate,” “Forecast,” and “Validate.”
- Communicate: to present information about a facility in a method in which it can be shared or exchanged, covering the sub-purposes such as “Visualize,” “Draw,” “Transform,” and “Document.”
- Realize: to make or control a physical element using facility information, covering the sub-purposes such as “Fabricate,” “Assemble,” “Control,” and “Regulate.”
5 RESULTS

Plotted between the three dimensions, three matrices are developed and explained in the following.

5.1 Model Use Technologies Supporting Different Construction Tasks

Figure 4 illustrates the matrix of model use technologies broken down by construction tasks. The data indicates the number of publications that employed the particular model use and technology to support construction operations. It should be noted that one case may use multiple technologies; and on the other hand, one type of technology use can be applied for multiple construction tasks. For the modeling effort that supports construction planning and management, it is also interested to capture the phases, from procurement to quality inspection, when the application emphasized and occurred.

![Model Use Technologies for Construction Tasks](image)

As illustrated, construction planning and management is considered as the primary task that needs the support from construction modeling with advanced technologies. More specifically, progress monitoring and resource management become the focus, considering the technological impacts on the improvement of craft productivity (Grau et al., 2009). They are widely tested in the procurement, erection, assembly, and installation of structural components such as beams and columns (Figure 4). Simulation technology, imaging technology, and positioning systems are mostly applied to support the activities. Compared with structural components, monitoring and tracking the work of engineering systems is found to be challenging. However, leveraging model uses and technologies for construction tasks regarding engineering systems is largely needed (Figure 4), since they constitute a large portion of construction costs and asset value (Bosché et al., 2013).

Robots have also been studied in order to support various construction operations, such as excavation and foundation work (Ha et al., 2002), frame erection (Kang and Miranda 2006), assembly and installation (Chu et al., 2013), finishes (Bai, 2007), and QA/QC (Shen, Lu, and Chen, 2010) (Figure 4). Regardless,
they are not implemented on a wide scale for many reasons, such as dynamic nature of construction sites, culture, human skills, and cost of applying robotics technology (Caldas and Goodrum, 2010).

5.2 Implementing Model Use Technologies with Different Model Use Purposes

Similarly, Figure 5 illustrates the matrix of model use technologies broken down by model use purposes. The numbers indicate the quantity of publications that leveraged the particular technology for certain model use purpose(s). One case may have multiple technologies applied together to serve a primary model use purpose. Thus, for each case, only the primary model use purposes of the study was plotted into the matrix. For example, Hammad et al. (2007) employed simulation technology and GIS to perform an equipment workspace analysis for infrastructure projects. The representation of the workspace (i.e., “Communicate”) through capturing the existing site information (i.e., “Gather”) can be two model use purposes. But considering that the goal of the study is to detect and resolve the potential equipment workspace conflicts, the primary model use purpose was identified as “Analyze” instead.

![Figure 5: Categorizing model uses and technologies by model use purposes](image)

As shown, “Gather” is the most popular model use purpose, majorly by implementing technologies such as positioning systems and imaging technology to track materials and monitor construction progress (Figure 5). This result is consistent with the high demand of technology uses for construction planning and management indicated in Figure 4. On the contrary, the least amount of studies on construction modeling are found to be driven by “Generate” and “Communicate” purposes. The reason could be that the benefits of implementing 3D modeling and mobile technology to generate, access, and transfer facility information has been widely demonstrated in practice. With the increasing experience of model use, the needs of model use gradually progress beyond the initial intent of visualization and coordination, and to sophisticated analysis (Taylor and Bernstein, 2009). Those analysis employed simulation technology (“Analyze” in Figure 5), to simulate and optimize construction planning, such as planning for site layout (Astour and Franz, 2014), logistics (Said and El-Rayes, 2014), and equipment workspace (Hammad et al., 2007). Moving beyond “Analyze,” the ultimate model use of robots, combined with other technologies, to automate the realization process of a facility product also attracted fair amount of attention in academia (“Realize” in Figure 5).

5.3 Construction Tasks Supported with Different Model Use Purposes

The third matrix (Figure 6) illustrates the construction tasks that can be supported by model uses on different purposes. Consistent with previous results, Figure 6 captures the primary need of implementing modeling for planning and management. The majority of model uses were applied to collect information about a facility at various phase, from procurement to quality inspection, for progress tracking and
resource management ("Gather" in Figure 6). Figure 6 also indicates the construction needs of more sophisticated model use, as the number of studies increases from category of "Generate" to "Realize." Even with "Generate" purpose, the modeling application shifted from creating or authoring information about the facility product to generating the plan of temporary structure such as scaffolding for frame erection (Kim and Teizer, 2014). The considerable number of studies with "Realize" model use purpose (Figure 6) reflects the interests of automated construction tasks such as fabrication. Regardless, in overall, there is still lacking model support for construction tasks such as excavation, engineering systems, and envelope and finishes (Figure 6).

![Construction Tasks Supported by Model Use Purposes](image)

Figure 6: Supporting construction tasks with different model use purposes

6 DISCUSSION AND CONCLUSION

To summarize, this paper captures the state-of-the-art model uses for construction tasks. These efforts have been mostly applied in progress monitoring, as well as resource tracking and management. Driven by the "Gather" purpose, technologies such as positioning systems and imaging technology have been used to support these activities. Moreover, this paper identifies the breadth of construction needs of model use, and indicates that the current model uses need to be broadened with sophisticated analysis to support construction operations, such as excavation and engineering systems. The lag of current adoption also calls for developing implementation guidelines, which are expected to address the model use purposes, process, and technology and information requirements, to better support construction needs. It is also important to note that multiple model uses can be combined to achieve an overall goal on a project. Examples of goals which require the integration of multiple model uses include a series of model uses to develop, visualize and analyze a site logistics plan, or the development, visualization and analysis of the material management information for a project. These overall goals require a defined series of activities which build the model content through a progression of model uses, and model information. This paper provides the ground of building such a model progression based on the breadth of construction needs and the paradigm of model use purposes.

Thus, future work will focus on defining an approach to organize the model uses that can be applied together to achieve an overall project goal. The information needs will be identified, along with the interactions between the model uses. Potential near-term future model uses will be explored and defined.

Abstract: Maintenance of highway bridges built during the high economic growth period is performed based on their design drawings and as-built drawings. For these elevated highway bridges, however, drawings were produced on paper media at the times of design and completion; therefore, in many cases they have already been disposed, making it difficult to perform maintenance. In such a case, regenerating the detail design of the current status is required, but it takes huge cost. For this problem, a large number of researches have been made on automatic generation of three-dimensional models for maintenance of highway bridges from point cloud data obtained through MMS (Mobile Mapping System). However, it is hard to use the models generated in these researches because engineers do not consider the original geometric information of highways. Thus in this research, we aim to regenerate the CAD drawings of the superstructure of an elevated highway bridge, and propose a method for extracting alignment information of the elevated highway bridge from point cloud data of MMS. We verify the usability of our method and system by comparing the experimental data with surveyed drawings in our experiments.

1 INTRODUCTION

In Japan, many elevated highway bridges built in the high economic growth period have been worn out. Particularly for elevated highway bridges, it is urgently required to propose effective and feasible maintenance plans to extend their lifetime. Further, to ensure the appropriateness of inspection, repair plans and construction methods, the construction drawings (e.g. design drawings and as-built drawings) need to be provided to correctly understand the current status. However, drawings of many elevated highway bridges constructed during the high economic growth period around the 1970s were produced on paper media. After the lapse of 30 years document retention period (MLT 2010, MLT 2001), many of them have been disposed. In such a case, it is necessary to regenerate the detail drawings of current status. However, the field surveying will be necessary involving road closure, which will result in huge costs. To avoid this, many researches were done to obtain the data of current status without disturbing the traffic flow by using Mobile Mapping System (MMS). These researches, however, were made on automatic generation of 3D models from point cloud data, which were only tailored for visual data processing of the superstructure of an elevated highway bridge, without considering the original alignment information of the elevated highway bridge. Therefore, it is too hard to rely on as the drawing of current status to use for maintenance. Thus in this research, we aim to regenerate two-dimensional (2D) CAD drawings in SXF format (CAD Data Exchange Standards Subcommittee 2005) of the superstructure of an elevated highway bridge, and propose a method for extracting alignment information of the elevated highway bridge from the 3D data, in order to solve the problem of current status.
2 SYSTEM OVERVIEW

This research aims to regenerate the CAD drawings of the superstructure of an elevated highway bridge by performing a proposed method to extract alignment vector information of the superstructure from point cloud data of MMS measuring the elevated highway bridge. System flow is shown in Figure 1.

![Figure 1: System flow](image)

This system consists of two parts of functions: Generation of 3D data and analysis of alignment information. Firstly, in the generation of 3D data, we analyzed the point cloud data obtained through MMS to get the point range of plan, cross-section and longitudinal-section of elevated highway bridges, which generated the 3D data. Secondly, we extracted the joint of elevated highway bridge to segment superstructure and generate the 3D data which can keep the information in each span of them. Then in the analysis of alignment information, we used the 3D data obtained through the generation part of 3D data to calculate the alignment information through analyzing the point range of plan, cross-section and longitudinal-section, thereby obtaining the required alignment information. On this basis, we considered the association of geometric information of the front and back of the superstructure to correct the alignment information, thereby improving the precision of geometric information. Finally, we calculated the formula parameters of the alignment information in each span of superstructure, with CAD drawings generated.

2.1 Point-Cloud Analysis Function

The high-precision laser scanner carried in MMS can ensure the accuracy of data amount. However, the collected data amount through the laser scanner is too large, making it difficult to analyze via common software. Thus, in this function, we analyzed the feature of point cloud data as shown in Figure 2, to recognize the features of elevated highway bridges, thereby extracting only the useful data for generation of 3D data.

![Figure 2: Point-cloud analysis function](image)

2.2 3D-Data Generation Function

As such, we extracted the useful point cloud data through the point-cloud analysis function, and automatically generated 3D data which can be processed by common software. We also extracted the center line to use for maintenance based on 3D current status drawings. In this function, we used the point range and feature points of each cross-section obtained through the point-cloud analysis function as
input data, and output the point range representing the road alignment of the elevated highway bridge and the feature points of the cross-section point range at regular spacing, as shown in Figure 3.

Figure 3: 3D-data generation function

2.3 Function of Segmenting Elevated Highway Bridge

In drafting the construction plan, a design proposal is supposed to be made for each span of the superstructure. In this regard, we segment the 3D data from span to span of the elevated highway bridge, in order to fulfil the design requirement of the construction plan. In this function, we extracted out the joint parts between the spans of superstructure by using colour information. Then we segmented the structural points of 3D data based on the joints, as shown in Figure 4.

Figure 4: Function of segmenting elevated highway bridge

2.4 Line-Type Determination Function

To extract out the alignment information, it is essential to figure out the line type. In the alignment of road plan, we applied straight lines, arcs and clothoid curves. In addition, we used straight lines and quadratic curves in the vertical alignment. In this function, we chose the joints which were output through the 3D data generation part as the candidate locations of the start and end points of the alignments, and determined the line types of all alignments by performing the method of least squares as shown in Figure 5.

Figure 5: Line-type determination function

2.5 Line-Type Correction Function

When the curvature radius of an arc or a clothoid curve is too long or there are too many abnormal feature points, the line type may be misjudged. In this function, we harnessed the feature of a clothoid curve to link a straight line with an arc for improving the extraction precision of alignment information by correcting the possibly misjudged line type, as shown in Figure 6.
2.6 Function of Generation of CAD Drawings

In this function, we calculated the CAD alignment parameters based on the formula of various CAD alignments as shown in Figure 7, and generated CAD drawings. However, we used a cubic Bezier curve to represent a quadratic curve.

3 CONCLUSION

In this research, we tried to generate CAD drawings by using the features of 3D data obtained through MMS measurement of elevated highway bridges, as shown in Figure 8. In the future, we will verify the applicability of our method to practical business and aim to improve the precision of alignments so that municipalities in Japan can use CAD drawings generated by applying this method.

CONDITION DIAGNOSTICS OF STEEL WATER TANKS USING CORRELATED VISUAL PATTERNS

Vamsi Sai kalasapudi1, 2, Pingbo Tang1
1 School of Sustainable Engineering and the Built Environment, Arizona State University, 651 E. University Drive, Tempe, AZ ,U.S.A
2 vkalasap@asu.edu

Abstract: Insufficient, unreliable, and delayed condition assessment of steel water tanks is causing poor maintenance planning, wastes of maintenance resources, and unexpected structure failures. Visual inspection of water tanks heavily relies on engineers’ experiences for achieving comprehensive and reliable condition assessments. Recent studies reveal the potential of using imaging technology for improving the efficiency and comprehensiveness of capturing visual conditions of large civil infrastructures, but manual interpretation of imagery data still impedes engineers from reliable awareness of structural conditions. On the other hand, some studies show that deteriorations of structures result in correlated visual patterns that can assist engineers in structural diagnosis. The objective of the research presented in this paper is to examine correlated deformation patterns of a steel tank based on analyzing 3D laser-scanned point clouds collected in the field. Specifically, the authors aim at identifying correlated shape change patterns of a water tank through various 3D data analysis algorithms, and synthesize these 3D data patterns as knowledge for guiding data-driven condition assessment of the water tank. The authors examined two 3D data analysis approaches for revealing the deformation patterns of the studied tank. The first approach calculates the deviations of the 3D data points from as-designed shapes of the water tank for identifying structural deformation and defects. The second approach visualized anomalous variations in local shape descriptors, such as curvature, for identifying defects of structures. Correlations between the patterns could then reveal systematic changes of the tank for helping engineers conduct more reliable condition assessments.

1 INTRODUCTION

Many civil engineering structures are prone to damages and deformations. Structural damage evaluation has become very important part of maintenance. Statistics estimate that to eliminate the deficit bridges by 2028, the nation has to spend minimum of $20.5 billion per year by, however only $12.8 billion is being spent for design, construction, replacement, and rehabilitation of bridge structures (Cooper and Munley 1995). To accommodate these funds in a right way there is a need for a systematic approach that can find the root cause and avoid unnecessary repair work behind these structural failures. Detailed geometric assessment of civil infrastructure is essential for reliable maintenance planning and public safety. Non-destructive testing such as visual inspection of a structure only offers a broad view of the structures’ current state, but fails in providing the root cause of the structural damage. Hence, comprehensive geometric data is essential for effective structural rehabilitation. Using imagery sensors to capture meticulous data of a structure precise to 2mm range distance can support detailed structural assessment. Such detailed data could help in eliminating unnecessary repair work of an infrastructure by exactly identifying area that requires structural renovation. However, manual interpretations of such
detailed geometric data require professional experience and are sometimes error prone. Correlated deformation patterns can assist engineers in accurate visual data interpretation and achieving reliable structural assessment. For example, collective growths of cracks and deformations on interconnected components reveal the changes of loading paths across a structure and likely defects. Formalizing these correlated visual patterns as signatures of structural health conditions hold strong potential in reducing the reliance on engineers’ experiences in structural health monitoring.

Building surveyors play a key role in maintaining the structural integrity of the building during and after construction process. Surveyors use high quality optical instruments such as Total Stations for geometric measurements of a structure (Fröhlich and Mettenleiter 2004). These measurements include distance, horizontal and vertical angles and the coordinate information of the measured component. However, the density of the measured data completely relies on surveying time (Erickson, Bauer, and Hayes 2013). Furthermore, the instrument should move several times in order to get the complete structure and have portability limitations. Additionally the instrument requires a licensed professional to operate and record the measurements. Moore et al. (2001) highlights the limitations of visual inspection for surveying highway structures. Currently LIDAR (Light Detection and Ranging) technology has gained popularity over the conventional surveying systems (Jaselskis and Gao 2003). Researchers used 3D laser scanning technologies to analyze the deformations of bridges and identified the advantages of capturing geometric details for achieving more effective Finite Element Modeling (FEM) and analyses of existing facilities (Dai et al. 2013; Park et al. 2007).

However, reliable visualization of the captured data and accurate conditional geometric assessment is still error prone. Goor 2011 stated that registration errors and measurement errors could affect the quality of deformation analysis. He proposed using Iterative Closest Point (ICP) algorithm for accurate surface matching to eliminate registration errors. However, this approach is manual and requires lot of time to process. Many of the existing research indicate the challenge of reliably associating data collected from the laser scanner with the as-designed model of a building structure (Kalasapudi, Turkan, and Tang 2014). This association will aid in deformation detection by identifying changes between as-is condition and as-designed condition. Yet, identifying the root cause of detected deformation of a structure is still unreliable as many factors may cause the structure to undergo such deformations.

This paper focuses on formalizing the data processing procedures to detect deformation patterns for efficient structural health monitoring of water tanks to improve the 3D data interpretation in assessing a water tank. Initially, the authors detected the deviations of 3D as-is laser-scanning data with the as-planned model of water tank structure to analyze its spatial changes (Section 4). This step identifies various defects and deformation of every individual component of the tank. The authors then correlated the detected deformations to identify patterns that lead to systematic changes of the tank during its service period (Section 5). This detailed geometric assessment of the structure can help reduce the incorrect decisions of building maintenance, and reduce unnecessary costs or propagative errors.

2 APPLICATIONS OF 3D IMAGERY TECHNOLOGY IN STRUTURAL INSPECTION

Previous studies in the domain of construction and infrastructure management examine the technical feasibilities of using 3D imaging systems in geometric assessments of various buildings and structures. Park et al. 2007 carried out an experiment for health monitoring of a simply supported steel beam and compared to the results obtained from other diagnostic techniques such as electric strain gauges, long-range fiber optic sensors etc. Lee and Hyo 2013 estimated the maximum stress in a steel beam structure using a 3D coordinated data from a laser scanner. Allard et al. explored the potential of using 3D imagery data for mechanical damage inspection on an aircraft. They stated that the major advantage of using Laser scanning is to minimize the total time of inspection of the aircraft by fast decision making along with immediate on-site results. Lemmon (2011) has explained the feasibility of using laser-scanning technology for structural geometric calibration and deformation detection of large storage tanks.

Various 3D data processing algorithms developed in the past that can process the data obtained from a laser scan (Yang, Wang, & Chang, 2010, Tarsha-Kurdi, 2007, Girardeau-Montaut, 2011). Some
algorithms are computationally efficient enough to achieve real-time data processing that support decision making process of engineers (Girardeau-Montaut 2011). In this paper, the authors analyzed the 3D scans of the steel tank using existing algorithms and developed an approach for efficient geometric assessment of the large steel tank to correlate detected deformations. The following section details the data collection and processing procedure, and describes the diagnosis approach.

3 OVERVIEW OF THE TEST SUBJECT AND THE DATA COLLECTION PROCEDURE

In order to analyze the feasibility of using LIDAR data for geometric assessment, the authors selected an existing Steel Water Tank as a test subject. This Steel Water Tank is a combination of a cylinder at the bottom and a cone at the top. According to the as-built drawings, the tank has a radius of 21.34 meters and a height of 11.43 meters in total, in which 9.75 meters is of cylindrical part, and 1.67 meters is of the conical part. To identify the defects/deformations the authors use a cylindrical co-ordinate system.

The cylindrical co-ordinate system use ‘Radius’, ‘Azimuth’, and ‘Elevation’ to locate 3D points in space. The azimuth starts with 0 degree and ends with 360 degree to form a circle representing the cylindrical body of the tank. The authors define the East Direction as zero azimuth that serves as the origin to the cylindrical coordinate system (Figure 1 (a)). The authors collected eleven scans that comprise of four interior (inside the tank) and seven exterior scans. To filter the redundant data from the collected 3D scans, the authors pre-processed them for accurate data processing. Data pre-processing is an important step for obtaining efficient results. Scans collected for the Steel Water tank contains lot of redundant information, which influences the accuracy of geometric assessments. They contain large amount of noises such as reflections, unwanted background, movements of people, or other objects surrounding the test subject etc. The authors filtered the actual data from the noise and then executed the data processing algorithms in order to extract accurate information from the raw data. Most the pre-processing algorithms are available in many of the commercial software. The authors used Faro Scene (FARO Technologies Ltd.) pre-processing algorithm to filter the scans. The authors then performed the registration of all the 3D point cloud data collected at multiple locations together into a global coordinate system from their respective local coordinate axis (Figure 1(b) and Figure 1(c)).

![Figure 1: (a) 0° Azimuth Location. (b) 3D Point Clouds Collected outside the Tank after 3D Registration and Data Cleaning. (c) 3D Point Clouds Collected inside the Tank after 3D Registration and Data Cleaning](image)

4 GEOMETRIC AND DEFORMATION ANALYSIS OF 3D LASER SCAN DATA

The proposed framework involves segmentation of 3D Laser scan data of the steel tank into several individual components. Such components include roof, floor, rafters, and columns of the steel water tank. For analyzing the deformations of the tank, the authors aligned the registered 3D point cloud data against a cylinder with a radius of 70 feet. To compute the deviations of 3D data points, the authors extracted a cylinder from the point clouds. Such fitted model is a perfect cylinder, and deviations from it indicate
possible local deformations of the tank. Figure 2 shows the comparison of the 3D point cloud and the fitted model. This figure visualizes the deviations along the radial direction: red colors show “positive deviations” pointing outward the surface of this cylinder; blue colors show “negative deviations” pointing inwards the surface of this cylinder.

![Figure 2: Comparison between 3D point cloud and fitted model](image)

Table 1 shows the list of all the analyzed components and their respective detected deformations (Figure 3). Major conclusions for the geometric analysis include:

- The tank does not have obvious tilt, but the floor has a slight tilt that makes the West part of the floor lower than the East part. In addition, the central part of the floor observed to have higher elevation than the parts closer to the shell. Hence, these analyses may indicate settlements of the tank.

- The wall of the tank has elevation differences between the east part and the west part, such that the east slope of the roof is only 3.27 degree, smaller than the 4.42 degree slope specified in the as-built drawings.

- Both the conical shapes of the roof and floors have a smaller height than the as-built cones of the roof and the floor. The authors also detect that the central region of the floor is flat and horizontal, most of the slope angles measured on these two conical shapes are smaller than their as-built values, and the settlement of the central column may be the reason for such observations.

- The authors detected a Zigzag pattern on some rafters that are located on East part of the roof. The turning point of that Zigzag is around the connection between the internal rafters and the girders supported by internal columns.

- Curvature analysis of the roof shows that three regions on the roof have relatively larger curvatures possibly caused by deformations of the roof and girder.

CORRELATIONS BETWEEN THE OBSERVED DEFORMATIONS OF THE WATER TANK

Correlated deformations between components of a structure occur if those components are connected, are in a similar environmental condition, or have same axis of orientation etc. Connected components move together under load conditions that cause correlated changes in them. For instance, the cylindrical body and the floor of the water tank show similar variations under loading conditions. The observed inward and outward deviations of the cylindrical surface (Figure 3(a)) of the tank correlate with the upward and downward deviations of the floor (Figure 3(b)) of the water tank. Similar environmental conditions can also lead to correlated deformation patterns. For example, common soil settlements have led to correlated tilt in the floor and roof of the water tank. The combined deformations of the roof and girders have caused the floor to undergo relatively large curvature changes at certain points, which have same axis of rotation.

Figure 4 shows the correlated deformation of the central column and the rafters of the tank. The authors observed that the differential settlement of the central column has caused the connected rafters to warp under axial compression. These warping of the rafters correlate with the inward and outward deviations of the cylindrical surface of the tank. In addition to the warped rafters and the surface deviations, the central column settlement correlates with the deviations of the floor of the water tank. The authors have tabulated (Table 2) all the observed correlations between individual segmented components to identify systematic shape change pattern of water tank for geometric diagnosis.

Using such correlated deformation patterns, the authors identify certain traits that can help in reliable geometric diagnosis. For example, thermal variations around the water tank can lead deformations in its exterior cylindrical surface. Since these deformation correlate with those of warping of rafter, such variations in temperature of the tank can further deteriorate the condition of the rafters. Further deviations in the cylindrical surface can predict the future warping of the rafter, which will be inaccessible during the service of the water tank. Similarly, the differential settlement of the exterior surface of the water tank could place the rafters in axial compression causing lateral bowing. Thus, predicting the long-term deformations of the inaccessible components of the water tank using their correlated deformation pattern with other accessible components can help in reliable life-cycle maintenance cost optimization.

### 6 CONCLUSION AND FUTURE WORK

This paper explores the technical feasibility of diagnosing a water tank structure based on analyzing correlated visual change patterns of the water tank structure. The studied structure underwent certain deformations during its life cycle. A 3D laser scanner captured detailed as-is condition of the structure to analyze the changes in structures geometry when compared to its as-designed model. The developed approach in this paper shows clear potential of aiding engineers in observing and diagnosing correlated deformation patterns for supporting the maintenance decision making of the structure. Based on these explorations, the authors determined systematic change patterns in the components of a water tank for detecting anomalous spatial changes from the 3D point cloud data for identifying structural risks.

This data-driven study of a water tank indicates that 3D laser scanning technology can help in reliable documentation of accurate as-built conditions of as structure in short time with high level of detail. Using the presented approach, the authors plan to develop automated geometric diagnosis of the structure from the data collected from a 3D laser scanner. This step includes generating algorithms that can automatically detect deviations of a structure, identify correlations between the identified deviations and create deformation histories for risk assessments. Detailed scans before, during and after renovation can provide an approximate disaster pattern of the structure. This study will also help in identifying the root cause of the damage to a structure and in proper resource allocation and rehabilitation planning.

RISK OF WILDFIRES WITH KNOWN IGNITION POINTS: CASE OF RESIDENTIAL BUILDINGS

Elmira Kalhor\(^1,2\), and Vanessa Valentin\(^1\)
\(^1\) University of New Mexico, USA
\(^2\) ekalhor@unm.edu

Abstract: Wildfire is considered the dominant disaster in many regions of the world including the United States, Australia, Canada and parts of Europe. However, unlike other natural disasters, such as flooding, earthquakes and hurricanes, the risk of wildfire to the built environment is not vigorously studied. Most of the research in the wildfire risk management area is limited to the study and management of wildfire within the wildland. On the other hand, there is an increasing progress of housing projects towards the natural lands. The Wildland Urban Interface (WUI) is where the developed and undeveloped areas meet. Because of high vulnerability of the WUIs to wildfires, there is a need to identify, quantify and manage the expected damage of wildfires to the WUIs. This study calculates the risk of wildfires to residential buildings considering a specific ignition point. The model inputs include the spatial distribution of the buildings, an absolute or proxy value for the damage from wildfire, and atmospheric and landscape attributes needed to simulate the fire propagation on a specific land. The model outputs are the distribution of damage at each time interval from the initial ignition and total risk of a fire with a given ignition point.

1 INTRODUCTION

Wildland-Urban Interface (WUI) is where the undeveloped land intermixes or interfaces with man-developed land (Davis 1990). Also called flame zones, these WUI lands are developed areas vulnerable to wildfires. About 90% of the WUIs in the Western United States are classified as high severity fire regimes (Theobald and Romme 2007). However, this sensitivity has not suppressed the progress of housing development projects towards fire prone forest and park lands. WUIs have grown 52 percent in size during three decades from 1970 and are projected to increase by an additional 10 percent until 2030 adding up to over 510,000 square kilometers (Theobald and Romme 2007).

Chuvieco et al. (2010) defines a framework for fire risk assessment as an important component of risk management. In their model, they address the need of including vulnerability in fire risk assessment. The risk of wildfire is the product of fire danger and probability. The authors address ways to calculate and analyze different parameters of the risk assessment model from probability of ignition to a model of propagation prediction to finding tangible and intangible values at stake.

The probability of fuel-ignition on a specific land has been assessed using econometrics tools and neural networks. These approaches have been used for formulating the ignition as a function of the characteristics of the landscape and infrastructures (Romero-Calcerrada et al. 2007; Vasilakos et al. 2009; Chuvieco et al. 2010). Federal agencies in the United States such as the US Forest Service and its
associated labs have also produced the fire danger maps danger rating classes. These maps give information on the occurrence of fire.

There are different propagation models developed to provide decision support systems for specific forest management subjects. Chuvieco et al. (2010) assigned a propagation potential to each cell, in a coarse cell size, based on fuel type, moisture and wind. USDA's Rocky Mountain Research Lab has developed the Flammap software (Finney 2006). Flammap uses “Minimum Travel Time” to simulate the propagation of wildfire. Given the landscape, fuel, wind and ignition point, Flammap is able to return a set of outcomes including but not limited to the rate of spread, influence grid (number of nodes that succeeded burning from each cell), fire line intensity, and burn probabilities. However, Flammap does not consider probabilistic modeling for producing a probabilistic distribution of the expected fire propagation. Randig is the command line version of Flammap which can be used for random selection of wildfire ignition points and is used for estimating the efficacy of the treatment options in Oregon, USA (Ager, Vaillant, and Finney 2010).

Another approach that has the capability to do probabilistic modeling of wildfire propagation is known as Cellular Automata (CA)-based fire propagation model originally proposed by Clarke, Brass, and Riggan (1994). This model is used to simulate fire propagation and final wildfire perimeter. This model is also a command line program and gives the user flexibility in terms of choosing between using crisp or random variables. To model the behavior of wildfire, core concepts of fire propagation are adopted from Rothermel (1972) and the model is verified by simulating the Lodi Canyon fire of 1986, in California, USA. Due to its flexibility, simplicity and availability, this model is used in this study to assess the spatial and temporal distribution of buildings exposure to wildfires.

The probability that the fire can ignite a structure has received little attention in the literature. The fire attributes and the building materials and configuration can have an affect on this probability. Cohen (1995) proposed the Structural Ignition Assessment Model (SIAM) which links the flames and heat from wildfires and external material used in buildings to assess if a building will be ignited by specific heat from a fire or not. In his research, the author performed laboratory tests to define the ignitability of each component of the house.

Associated with wildfire, there are a variety of vulnerabilities in the WUIs from social to environmental, to economical, to the built environment. According to Cutter et al. (2008), along with the immediate and factual damage caused by the event, the vulnerability of the subject or the system should be accounted for in the calculation of the impact of the disaster. Vulnerability is a complex context (Cutter et al. 2008), however, exposure is a definitive element of the vulnerability (Hufschmidt 2011). Hollenstein (2005) defines exposure as an index of the spatio-temporal distribution of the elements at risk.

The elements at risk in this study are residential houses. In order to show the distribution of exposure to danger, an exact or proxy indicator should be adopted. Using historical records, Cohen (1990) assumes that once ignited, structures will be completely destroyed. One can justify this assumption since during a fire, suppression activities will be more likely diverted towards protecting un-burnt houses or assets; while for burning houses, the efforts will be spent on saving lives. However, in order for fire to ignite a building, the characteristics of the exposed materials play an important role in the probability of ignition of the house (Cohen and Saveland 1997).

In this study, structures ignition is formulated as a binary variable assuming that if a building falls inside the spatial burning cells of the fire, it will be ignited and totally destructed, and therefore, the expected damage of the house is its total estimated value. An ongoing study by the authors is the use of econometrics in order to formulate ignition probability as a function of the structural and neighborhood characteristics, which will help future research to represent ignitability of structures in probabilistic form. Since the analysis is in the form of raster data (some converted to matrices), a point is a virtual representation of a cell on the ground with an arbitrary resolution.
2 RISK AND VULNERABILITY ASSESSMENT MODEL

Wildfire is a complex phenomenon that is dependent on a variety of factors. The location of the ignition cell, the topography of the landscape, the fuel availability, the fuel moisture and the wind and atmospheric conditions, among others, affect the propagation scheme of a wildfire. In ecological assessments, the magnitude of wildfires is measured in terms of the amount of energy (in Kilowatts) released during different phases of the propagation of the fire; and sometimes the flame length is used as a proxy measure for this energy release (Keeley 2009).

As a danger, wildfire has a compound probability of occurrence. This probability is, at the coarse level, composed of the probability of ignition of a specific cell and the probability that the fire will propagate from that given cell and reach to the location of interest. Last, but not least, is the probability that the fire can damage an asset. Following Chuvieco et al. (2010), the risk of wildfire that has started on a given cell on the landscape \((x, y)\) to the location of a vulnerable asset of interest in the study area (denoted by \((i, j)\)) is shown in equation [1]:

\[
\text{Risk}(i, j, t)_{xy} = P_{\text{propagation}}^{ij|y;x,t} \times P_{\text{burn}}^{ij} \times V_{ij}
\]

Where, \(\text{Risk}(i, j, t)_{xy}\) is the risk of damage to an asset located on cell \((i, j)\) from a fire initiated on the cell \((x, y)\) of the study area, after \(t\) time. \(P_{\text{propagation}}^{ij|y;x,t}\) is the probability that the fire ignited on point \((x, y)\) will reach to point \((i, j)\) after \(t\) time periods and \(P_{\text{burn}}^{ij}\) is the probability that point or asset located at \((i, j)\) will start burning if the fire reaches to that point. \(V_{ij}\) is the value of the asset in danger located on point \((i, j)\).

As previously mentioned, an assumption made in this study is that the building that has been reached by a fire has been completely harmed. This assumption eliminates the need for detailed damage assessment while providing an upper bound for the calculation of damage.

Equation [1] represents the spatiotemporal distribution of risk of a wildfire initiated at cell \((x, y)\). The cumulative risk from the fire can be calculated as shown in equation [2].

\[
\text{RISK}(r)_{xy} = \sum_{i} \sum_{j} P_{\text{propagation}}^{ij|y;x,t} \times P_{\text{burn}}^{ij} \times V_{ij}
\]

\(P_{\text{propagation}}^{ij|y;x,t}\) is calculable through fire simulation. As previously mentioned, the propagation simulator used in this study is the CA based model proposed by Clarke, Brass, and Riggan (1994). At each time interval, the fire front will grow on the structure of the existing fire status resulting in a process oriented model. The growth of fire is defined as the movement of firelets\(^1\) from a burning point to a virgin (un-burnt) point. When modeling fire propagation, firelets are sent out of the existing burning cells (cells). The generation and direction of firelets is a function of the wind magnitude and direction, topography attributes (slope and aspect), availability of fuel on the destination cell, temperature and moisture. Except for slope and aspect, other attributes are of stochastic nature. As a result, the decision of fire front moving from each cell is modeled as a random process through a Monte Carlo simulation.

At the beginning of each simulation, the slope, aspect, and fuel layers (with unique cell size and projections) are input to the model along with a wind array representing climate of the study area. Wind array specifies the range of possible winds direction and magnitudes. A cell is selected as the place where the hypothetical fire will start. Eight immediate surrounding cells are weighted based on their slope and the direction of wind. These weights are associated with the probability that the firelets from the ignition cell will choose the cell as the destination. Using a roulette wheel-like selection procedure, firelets destination(s) will be selected. Once a new cell is selected as the destination of a firelet, it is treated as the original ignition cell. Random controllers restrict the number of propagations within each time interval.

\(^1\) Firelet is the term used by Clarke et al. (1994) to show the mobile elements of fire.
Next interval starts with current burning cells as the ignition points. The fuel load of burning cells is decreased by 1 at the end of each time interval. The termination criterion is reaching the time limit.

For a specific ignition point, the simulation will be run for a number of iterations to incorporate the randomness of the atmospheric conditions. During each simulation, a binary value \( j_{(i,j)}^{\text{iteration},t} \) is calculated for each cell to identify if the fire has propagated to that cell up to a specific time interval \( t \):

\[
[j_{(i,j)}^{\text{iteration},t}] = \begin{cases} 
1 & \text{if the simulated fire reaches point } (i,j) \\
0 & \text{otherwise}
\end{cases}
\]

The probability of propagation \( P_{ij}^{\text{propagation},(xy,\text{time}=t)} \) is then calculated as given in equation [4].

\[
P_{ij}^{\text{propagation},(xy,\text{time}=t)} = \frac{\sum_{\text{iteration}=1}^{n} j_{(i,j)}^{\text{iteration},t}}{n}, \text{ where } n \text{ is the total number of iterations (simulations).}
\]

As previously mentioned, another assumption made in this study is that if the fire can find a way to ignite the cell on which the building is located, then the building will get ignited. The probability of structural ignition is therefore calculated using equation [5]:

\[
P_{ij}^{\text{burn}} = \begin{cases} 
1 & \text{if } P_{ij}^{\text{propagation},(xy,\text{time}=t)} > 0 \\
0 & \text{otherwise}
\end{cases}
\]

The value of the expected damage is the total price of the building. The structures layer is overlaid on the time-dependent fire status layer in order to find the structures that are burnt according to simulation results (Figure 1).

![Figure 1: Overlaying structures layer and the fire status layer for calculating the value of the exposed asset](image)

The total risk from a fire ignited on point \( i \) is calculated using equation [2].
3 STUDY AREA AND DATA COLLECTION

The focus of this study is Los Alamos Census Designated Place (CDP) which is a town in Los Alamos County in the Northern New Mexico. The total population of the city in 2010 was 12,019 with median age of 43.5. There are 5,289 households residing in the city and 5863 houses. Among the unoccupied houses (i.e. 574 units), 221 are seasonal and recreational houses. According to US Census data, 3662 houses are owner-occupied and most of the remainder are rented. Median and mean income of the population are $106,016 and $116,563 respectively. Los Alamos is located within parts of Santa Fe National Forest, and it is also close to Bandelier National Monument.

In 2000, Los Alamos witnessed one of the greatest fires in the history of the United States. The Cerro Grande fire was initiated as a prescribed burn in the Bandelier National Monument when, due to adverse atmospheric conditions, the fire went out of control (Figure 2). The town was evacuated for a week and about 300 houses were burnt in the aftermath of this fire. The damage to the entire county was estimated to be about $1 million (PW Coopers 2001), almost all in the Northern part of the city (Los Alamos CDP).

A real estate investigation on physical and non-physical damage was done by Price Waterhouse Coopers consultants (2001). Aside from houses that were burnt during wildfires, 3 - 11 % value diminution was observed in un-damaged houses due to wildfire. A survey analysis contracted to a third party by Los Alamos county showed that 54% of owners of the damaged buildings decided to re-built their buildings in the same place, confirming the results by McGee, Mc Farlane, and Varghese (2009) that the experience of wildfire does not change the risk perception of the community. Interestingly enough, 35% of those who were re-building their homes on the same location said that they planned to build a similar structure (Price Waterhouse Coopers (2001)).

Case study data used for this study include topography data, fuel data, structures layer and value of the assets. Topography data (elevation, slope and aspect) are collected from the online database of the United States Geological Survey (USGS). Fuel data incorporated into fire propagation model is the Canopy Bulk Density (CBD) that is available through LandFire Project’s data set (Rollins and Frame 2006). Canopy bulk density is mass per volume (kg/m^3) of canopy fuel and is the property of a stand of trees rather than a single tree (in which case, it will be referred to as crown fuel)(Scott and Reinhardt 2001).

Amongst other types of fuel, buildings are highly exposed to fire in dense canopy and shrub fire (Menakis, Cohen, and Bradshaw 2000). On the other hand, when the wind magnitude and direction are in support, the embers from canopy fires can find their way to the roof system where they can ignite the structures.
Sometimes, through the ladder fuels\(^2\) surface fire can get elevated to the canopy fire (Scott and Reinhardt 2001). However, modeling the transition of surface fire to crown fire has a lot of complexities and reduces the efficiency of the analysis in the context of damage to the built environment.

The structures layer used for this study is limited to the single family housing in Los Alamos. The value for each house is the assessed value of the year 2013 provided by the Los Alamos County assessor’s office. The diminution of un-burnt house values after a fire is not seen in the damage assessments and only physical exposure to fire is accounted for.

4 SIMULATION RESULTS

The fuel and structures distribution is shown in Figure 3. The selected ignition point is close to the houses that were previously burnt due to the Cerro Grande fire; however, the fuel data are from year 2012. The study area is simulated in 505 rows by 272 columns. Each cell is 17m by 17 m in size (56 ft by 56 ft). The selection of the cells size is based on the finest resolution among the input raster files. Although it was possible to change the resolution in order to increase the accuracy of the model, longer run-times discourage pursuing higher accuracies. The result of the propagation model for a single iteration of the simulation is shown in Figure 4.

---

2 Ladder fuel is the fuels that will form the channel through which fire escalates from surface to crown or canopy of trees. (Menning and Stephens 2007)
The results of the model for a specific ignition point are shown in Table 1. The outcomes are narrowed down to represent cells that have been affected during simulations and received a value greater than zero.

</tr>
</tbody>
</table>

The average value of a single family housing in the study area is 190,004 USD. With the purpose of demonstrating the proposed methodology, two separate points, which were 68 meters apart, were selected as ignition points. One source \((129,29)\) is very close to the structures and unsurprisingly represents higher risk to the built environment under consideration: residential buildings. It is noteworthy that during all of the simulation runs, the fire initiated from the source \((120,25)\) reached the cell \((120,129)\) and ignited that cell. In other words, the vulnerability values to sources of fire on the wildland are not independent from one another. The relationship between the risk resulted from different sources is proposed in equation [6].

\[
\text{RISK}(t)_{xy} \leftarrow \text{RISK}(t)_{xy} + \text{RISK}(t-t')_{xyy}.
\]
where \( t \) is the time when source \((x',y')\) is ignited during propagation of fire from source \((x,y)\).

The results from Table 1 can be used to assess the time value of suppression activities in order to provide cost-benefit analysis of suppression cost and time. For example, in the case of the fire source \((120,29)\), there is \(685,940\) USD difference in the risk value between \(t = 10\) and \(t = 20\), which justifies any suppression activities costing less than this amount. However, the vulnerability value will be less than \(100,000\) USD after \(t = 20\) favoring the less cost suppression effort. Another notion is the difference between the total risk values for the sources. The total risk from source \((120,29)\) at each time interval is at least twice the risk from source \((120,25)\) and suppressing fire from reaching point \((120,29)\) is worth at least \(366,728\) USD. However, it is important to note that the value of the vulnerability in this study only reflects the residential houses as the value-in-danger and the results of risk assessment for different types of assets may not confirm the suppression cost trade-off described.

5 CONCLUSION AND FUTURE WORK

In this study, a risk model is proposed. A wildfire event is identified by the ignition point. The probability component of risk is composed of the probability of the propagation of fire from the specified ignition point to the location of the asset of interest multiplied by the probability of ignition of the asset when exposed to fire. Using a fire propagation simulator and landscape input including fire fuel and structures setting, the assessment of spatio-temporal distribution of the vulnerability was made possible. Results from this research can be used for assessment of treatment efforts and the evaluation of trade-offs between treatment and suppression costs, for raising social awareness about the effects of the risk mitigation activities and for studying policy and management implications in WUIs.

This study can support decision-making process for various managers. Identifying high risk ignition points on the forested lands helps the public land managers to prioritize their treatment effort accordingly, reduce the risk of wildfire and better protect assets. Furthermore, in case of a fire, firefighting efforts can be better invested on areas with higher risk. Last, but not least, zoning and housing departments can limit the progression of the built environment in order to cooperate with public land managers and to secure more assets or to increase the flexibility and efficiency of firefighting activities in the case of occurrence of a wildfire.

Potential future additions to the model will be the calculation of the probability of ignition on the wildland using regression analysis along with the calculation of the probability of ignition of the asset of interest using an expert-system. These additions enable the researchers to calculate the risk of wildfire initiated on any point on the wild landscape. The vulnerability that is accounted for is only the physical damage from wildfire. However, in the aftermath of most of the fires, un-burnt houses also undergo a value diminution which can be added to the total vulnerability. Ongoing research from the authors is addressing this issue.

One remaining noticeable remark is that although the social perception is that the occurrence of fire will reduce the risk, the simulation results showed that there are still vulnerabilities in the burn scar of Cerro Grande fire. Forested lands will restore the previous fuel stock and the fuel build-up coupled with the harmful atmospheric conditions exacerbated by climate change will reintroduce the risk.

PERFORMANCE INDICATORS FOR SUSTAINABILITY ASSESSMENT OF BUILDINGS

Mohammad. Kamali¹ and Kasun N. Hewage¹, ²
¹ School of Engineering, University of British Columbia, Kelowna, Canada
² Kasun.Hewage@ubc.ca

Abstract: During the past few decades, the construction industry has been exposed to “sustainable construction” processes, which address the triple bottom line (TBL) that is the environmental, economic, and social dimensions of sustainability, during the entire life cycle of a building. Due to the importance of sustainable construction, it is imperative to comprehensively assess the sustainability of the built environment, such as buildings. A significant step to evaluate the sustainability of buildings is investigating the existing building sustainability performance indicators (SPIs). In this paper, a list of building SPIs, including environmental, economic, and social, has been developed through conducting a content-analysis based literature review. The literature includes sustainable building rating systems such as Leadership in Energy and Environmental Design (LEED), Green Globes, Living Building Challenge (LBC), among others. In addition, other published literature related to sustainable construction is reviewed. Similar SPIs or those which have some overlaps are combined or modified. Finally, refined TBL SPI sets are created, which can be used for sustainability assessment of buildings. The results of this study indicate that among various environmental performance criteria used in different publications, 16 SPIs are the most significant ones. In addition, a total number of 9 SPIs and 12 SPIs are identified as the most commonly used criteria related to the life cycle economic and social performance of buildings, respectively.

1 INTRODUCTION

Since around 30 years ago, the “sustainability” concept has been widespread and various definitions have been provided (Forsberg and von Malmberg 2004). Nowadays, the percentage of the world’s population who live in urban areas is over 50% (UN 2010) and they spend 80% - 90% of their time inside buildings. This shows the importance of the built environment, e.g., buildings, in sustainable development (Andrade and Braganca 2011). Thus, sustainability performance assessments of the existing and new buildings can play a significant role in increasing sustainability (Ding 2008, Burgan and Sansom 2006).

It is widely accepted that sustainability has three main dimensions: environmental, economic and social, termed as triple bottom line (TBL). Therefore, to make a sustainable product, all these dimensions should be considered and addressed sufficiently. To evaluate the sustainability performance of a product, Kloepffer (2008) has proposed the life cycle sustainability assessment (LCSA) framework. By using the LCSA framework, product performance can be measured with regard to TBL. The LCSA framework can be applied by the following model (Kloepffer 2008, Finkbeiner et al. 2010):

[1] LCSA = LCA + LCC + SLCA
Where LCA is the environmental life cycle assessment, LCC stands for life cycle costing and SLCA is social life cycle assessment.

According to Traverso et al. (2012), the primary purpose of the LCSA framework, similar to LCA, is not to decide if a product should be produced, but to assist stakeholders and decision makers in making a more sustainable decision, thus producing a more sustainable product. In addition, one of the challenges faced by decision makers is to explore how separate environmental, economic, and social assessments can be used in practical situations to make trade-offs explicit (Swarr et al. 2011).

In order to enhance the likelihood of sustainable construction, the first step is to identify significant indicators of all the sustainability dimensions that can be used for assessing the sustainability performance of new and existing buildings over their life cycle. A sustainability indicator provides qualitative or quantitative information about the influence and impacts of a building project on the environment and society.

Currently, over 70 evaluation and classification tools (systems), based on sustainability indicators, have been developed. A building is regarded as a sustainable product only when all the sustainability dimensions, i.e., environmental, economic and social, are addressed and dealt with over its life cycle; however, the primary focus of most of the existing sustainability evaluation tools is on environmental characteristics (Braganca et al. 2010). In other words, they deal primarily with the environmental dimension of sustainability, and thus, they do not explicitly considering socio-cultural and economic dimensions which is a limitation. Furthermore, each sustainability evaluation tool has its own approach and accordingly provides different performance criteria and sub-criteria, which can be different from what other tools provide. Therefore, there are numerous indicators available, which can be confusing for the construction practitioners.

To address the limitations discussed above, the main objective of this paper is to develop generic and holistic building sustainability performance indicator (SPI) sets (i.e., environmental SPIs, economic SPIs, and social SPIs) that can provide a deeper insight into the most significant sustainability criteria currently used. The proposed TBL SPI sets are a key criteria list, which can be addressed in the design and construction of buildings. The results of this paper can assist different construction stakeholders in the development of sustainable construction.

2 METHODOLOGY

The research method in this paper is content analysis, which is a qualitative type of document analysis. Content analysis is a qualitative and systematic method to review and evaluate different documents. In other words, content analysis is the process of collecting and organizing information related to the primary research questions (Bowen 2009). Holsti (1969) gives a broad definition of content analysis as, "any technique for making inferences by objectively and systematically identifying specified characteristics of messages". All forms of documents, including electronic and printed, such as letters, books, survey reports, organizational papers, advertisements, etc., can be used as references.

First, a preliminary list of building SPIs was developed based on the review of two reference categories:

1- Sustainable building rating systems, such as Leadership in Energy & Environmental Design (LEED), Green Globes, Living Building Challenge (LBC), among others.

2- Journal and conference articles. The University of British Columbia (UBC) library databases, “Compendex Engineering Village” and American Society of Civil Engineers (ASCE), were used to retrieve the appropriate journal and conference articles. Key words used were combinations of: “building”, “sustainability”, “performance”, “life cycle”, “indicator”, “criteria”, “evaluation”, and “assessment”. These articles were further refined by reviewing abstracts and conclusions.

Then, using the content analysis method, the common SPIs were prepared, modified, and combined to form the refined SPI set for each of the sustainability dimensions.
3 SUSTAINABLE BUILDING RATING SYSTEMS

Sustainable building rating systems (also called green building rating systems or sustainability rating systems) that were developed to assist in the management of "green" building projects have a vital role in informing on progress in sustainability practices (Siew et al. 2013). Rating systems are qualitative tools that deal with sustainability performance of buildings by providing a set of performance criteria and scoring each building project based on those criteria. Rating systems examine the performance level or expected performance of a "whole building" and allow comparison of different buildings (Fowler and Rauch 2006).

Applications of rating systems are increasing worldwide and many tools have been developed for the environmental evaluation of the built environment, e.g. over 60 in the US (Economist 2007). The tools are not usually mandatory even though some jurisdictions have made them so (CEC 2014). The main focus of sustainability rating systems is on the environmental dimension of sustainability. Table 1 lists the well-known sustainable building rating systems around the world. In this paper, only the rating systems that are intended to be used internationally (LEED, LBC, BREEAM and SBTool) or in North America (Green Globes) have been selected for review.

3.1 Leadership in Energy and Environmental Design (LEED)

USGBC developed the Leadership in Energy and Environmental Design (LEED) rating system by using a coalition of construction industry practitioners, decision makers, contractors, owners and manufactures. LEED is one of the widely adopted rating systems worldwide. Over 148000 square meters of building space are daily certified by LEED in 147 countries. As of January 2015, nearly 50000 construction projects have registered and are participating in LEED (equal to over 800 million square meters of building space). This system is a voluntary, market-driven and consensus-based system that verifies green buildings. LEED was intended to be used for different building types, by which solutions to the green design, construction, use and maintenance of buildings can be identified and implemented. The latest LEED version (v.4) provides the following rating systems that address various project types (USGBC 2015):

- Building Design and Construction (LEED BD+C). Applies to new construction and major renovation projects;
- Interior Design and Construction (LEED ID+C). Applies to projects that are a complete interior fit-out;
Building Operations and Maintenance (LEED O+M). Applies to existing buildings that are undergoing improvement work or little to no construction;

Neighborhood Development (LEED ND). Applies to new land development projects or redevelopment projects; and

Homes (LEED-H). Applies to single family homes, low-rise multi-family (one to three stories), or mid-rise multi-family (four to six stories).

The performance of a building is assessed through a set of performance credits (points) (Castro-Lacouture et al. 2009). In fact, LEED assigns weighted credits to a building project based on a number of performance categories. For example, LEED for New Construction and Major Renovations addresses seven performance categories: Sustainable Sites, Water Efficiency, Energy and Atmosphere, Materials and Resources, Indoor Environmental Quality, Innovation in Design, and finally, Regional Priority (USGBC 2009). The total score is obtained by summing up the credits achieved in each performance category. For example, the total score can add up to a maximum of 110 points and 136 points for commercial projects and homes, respectively. Depending on the project type and earned score, each project is rated and awarded one of the four levels of certifications below (USGBC 2015, Kubba 2010):

- **Platinum**: 80 points and above
- **Gold**: 60–79 points
- **Silver**: 50–59 points
- **Certified**: 40–49 points.

Since the year LEED was launched, despite the reported benefits, several researchers and construction experts have argued its limitations. Some literature investigated the aspects of green versus sustainable building in LEED and concluded that the LEED rating system does not explicitly consider the socio-cultural and economic issues of buildings and mostly addresses the short term aspects rather than global and long term goals of sustainable building (Coleman 2004). According to Newsham et al. (2009), even though LEED certified buildings used 18-39% less energy per floor area, 28-35% of them used more energy compared with their conventional counterparts. In addition, they argued that there is little correlation between the real energy performance and certification level of LEED buildings. In another publication, it was shown that, on average, greenhouse gas emissions are not reduced in the use phase of LEED buildings due to no energy reductions in their operations (Scofield 2009). Ahn (2007) stated that, in addition to the many advantages of LEED buildings; however, the construction cost of green buildings is significantly higher than traditional buildings. Furthermore, it was shown that more capital is required depending on the level of LEED certification, from certified to platinum (Kats 2003).

### 3.2 Green Globes

The Green Globes system was intended mainly to assist construction practitioners and owners to self-assess their building performance (Kubba 2010). Green Globes is well recognized in North America and is endorsed by many states and provinces. For example, it has been used by the federal government of Canada in recent years. In addition, Green Globes and LEED were recommended by the US General Services Administration (GSA) for the construction projects of the US federal government (ECD 2015).

Green Globes is an interactive and affordable tool that enables building environmental design, operation, and management. The system provides a web-based self-assessment Yes/No/NA-type questionnaire-based package that comprises a protocol, rating system, and easy-to-use interactive guidance to assist the integrated design process implementation (i.e., goal and scope definition to construction documents) (Green Globes 2015, Smith et al. 2006). In addition, it provides market recognition of the environmental attributes of buildings by using third-party verification. Green Globes is available to be used in the following construction areas (ECD 2015):

- Existing Buildings;
- New Construction/Significant Renovations; and
- Commercial Interiors (i.e., office fit-ups).
Green Globes for existing buildings was developed based on six environmental performance categories: Project Management, Water, Energy, Resources, Emissions and Indoor Environment. For new buildings, the tool uses the same performance categories adding the seventh one: Site Impact. The total number of points listed in the seven categories is 1000.

It was discussed that although Green Globes is similar to LEED in terms of structure, Green Globes is more comprehensive and includes additional aspects, such as adaptability and durability. However, Green Globes does not address some aspects that are included in some other sustainability rating systems, such as project performance strategies and innovations (Kubba 2010).

3.3 Living Building Challenge (LBC)

According to ILFI (2015), the Living Building Challenge (LBC) is a building rating system that provides the most advanced sustainability criteria that can be used to measure the sustainability of buildings. LBC requires the highest and stricter standards in sustainable design and performance of buildings, and can apply to any type of building and any shape, size, and location including new, existing, single/multi-family residential, governmental, educational, and medical buildings, among others. LBC uses seven performance categories (Petals): Place, Water, Energy, Health and Happiness, Equity, Beauty, and Materials. Petals comprise of twenty mandatory Imperatives.

LBC certification is awarded based on the actual performance of projects (rather than the modeled or anticipated performance). Thus, projects are evaluated at least twelve months after the operational phase starts. However, through a preliminary audit, a number of Imperatives can be examined after construction. The latest version of LBC (v.3.0) was launched in 2014 (ILFI 2014).

LBC is significantly different from the other rating systems. Wang et al. (2012) pointed out that buildings need to meet all of the design and operations strategies of LBC to be certified, which may result in user dissatisfaction. In fact, LBC is a “all-or-nothing” not a point-base system. Nevertheless, other rating systems such as LEED and Green Globes need a minimum number of points (credits) in order to award a base level of certification, i.e., the more points achieved leads to higher levels of certifications.

3.4 Building Research Establishment’s Environmental Assessment Method (BREEAM)

The Building Research Establishment’s Environmental Assessment Method (BREEAM) was developed in 1990 for environmental evaluation of any type of new and existing buildings. BREEAM rating system is widely used in the world. According to BRE (2015), since it was first launched, two million projects have registered for performance evaluation and currently 425,000 buildings have been awarded BREEAM certificates. Construction practitioners (e.g., engineers, developers, managers) demonstrate the level of environmental performance of their building projects by applying this flexible, clear, and easy to use scoring system. BREEAM rates various types of building project including (BRE 2011):

- Commercial Buildings (offices, shopping centers, restaurants);
- Public Buildings (schools, universities, hospitals, museums, libraries, law courts); and
- Multi-residential Buildings (residential care homes, residential college/school, military barrack).

Ten environmental categories such as water consumption, energy consumption, materials, health, transport, waste, etc. and forty nine sub-categories are dealt with by BREEAM to promote life cycle sustainable buildings. Depending on the earned score, each building project is awarded one of the six levels of assessment (score percentage) as listed below (BRE 2011):

- Outstanding: 85%
- Excellent: 70%
- Very good: 55%
- Good: 45%
- Pass: 30%
- Unclassified: <30%
Compared to the straightforward approaches used in other rating systems (e.g., LEED), a complex algorithm is applied by BREEAM in order to evaluate the environmental performance of a building (Gu et al. 2006). The literature argued that one of the main differences between BREEAM and other sustainability rating tools is that the evaluation in BREEAM is based on absolute values while in others, such as LEED, scores are achieved based on improvements in design (Lee and Burnett 2008).

### 3.5 Sustainable Building Tool (SBTool)

The Sustainable Building Tool (SBTool), formerly known as Green Building Tool (GBTool), is an international rating system for evaluating not only green building issues, but also the sustainability performance of building projects. SBTool was developed based on various construction experts’ viewpoints and can be adopted in different regions with different building types (residential and commercial), environmental condition, economy, and cultural values. Accordingly, the scope and criteria can be modified (iiSBE 2015, Ruiz and Fernández 2009, Cole and Larsson 2002). According to Lee and Burnett (2005), SBTool is “the most comprehensive environmental assessment framework for building that explicitly includes the core elements of sustainable development”.

SBTool covers different life cycle phases of new and existing building projects. This system offers two distinct evaluation modules, one is used in the pre-design phase of site assessment, and the other is used in the design, construction and occupancy phases of buildings. The two modules are then combined to assess and rank building projects (Larsson 2012).

Due to its complex framework, SBTool may be difficult to use. According to Fowler and Rauch (2006), because of the flexibility inherent (in the application of SBTool), using SBTool needs more technical knowledge than other rating tools.

### 4 JOURNAL AND CONFERENCE ARTICLES

As mentioned earlier, the second source category was journal and conference papers. Several articles were found during the search period which can be grouped into two source sub-categories. The first sub-category encompassed those papers that a limited number of SPIs have been used to perform life cycle analyses such as LCA. In this type of papers, there were no SPI lists provided or discussed. The second sub-category included those papers that were mainly about SPIs and they provided appropriate sets of SPIs for one or more sustainability dimensions.

### 5 RESULTS AND ANALYSIS

In this section, the results of the content analysis are presented. First, the selected sustainable building rating systems and journal/conference articles were reviewed to develop a preliminary list of sustainability criteria related to each sustainability dimension (TBL). Regardless of different criteria naming styles used by different sources and also the frequency of each criterion, in this step, all of the criteria were included in the list. Second, the main ideas (concepts) that each of the above SPIs addressed were investigated and the similar SPIs that had different names but the same meaning were merged. A total number of 43 SPIs were found related to the environmental dimension. In the cases of the economic and social dimensions, 22 SPIs and 19 SPIs were identified, respectively.

The next step was to further modify the SPI list. As this study aimed to develop the main sustainability performance criteria, some of the SPIs were integrated and combined together to make the preliminary
list shorter. For example, “public transportation access”, “bicycle storage and changing room”, and “adequate parking capacity” were considered as sub-criteria, thus integrated into a new main criterion named “alternative transportation”. As another example, “reused content in building”, “recycled content in building”, and “waste collection and recycling” were combined to form a new main SPI named “construction waste management”.

The final step was to narrow the list down by identifying the frequency of each SPI in the reviewed literature. Since the sustainable building rating systems were developed based on many academic and industry experts’ opinions, more attention was paid to the rating systems than journal/conference articles. To refine the SPI list, in this paper, the instructions below were applied to select the most important SPIs:

- **Environmental Dimension**: If a SPI is used in more than 50% of the rating systems (i.e., 3 out of 5 and more), the SPI is selected regardless of its frequency in the second source category (i.e., journal/conference articles). If not, the frequency count in all references, including the rating systems and articles, should be more than 50% (i.e., 10 out of 20) in order for a SPI to be selected.

- **Economic and Social dimensions**: Since rating systems were mainly developed to address the environmental performance, if the frequency count of a SPI in all references, including the rating systems and articles, is more than 20% (i.e., 4 out of 20 and more), the given SPI is selected.

Table 2 summarizes the refined sets of SPIs for all TBL as well as frequency counts of each SPI. Using the method explained above, 16 SPIs were eventually selected as the most significant SPIs related to the environmental dimension of sustainability. A total number of 9 SPIs and 12 SPIs were identified as the most commonly used criteria for buildings life cycle economic and social performance assessment, respectively.

6 DISCUSSION

Sustainability rating tools are mainly based on qualitative assessment of buildings. Therefore, criteria used in these tools can be vulnerable to wide interpretation by users (assessors). In addition, there are different performance categories and criteria used in sustainable building rating systems. For example, LEED was developed based on Sustainable Sites, Water Efficiency, Energy and Atmosphere, Materials and Resources, Indoor Environmental Quality, Innovation in Design, and finally, Regional Priority; however, Green Globe’s performance categories are Project Management, Water, Energy, Resources, Emissions and Indoor Environment, and Site Impact. Accordingly, the criteria under each category were different. Furthermore, each sustainability rating tool has its own scoring criteria (weighting scheme) that can generate different performance scores for a given building. Even though there are many similarities between the various sustainability rating systems, there is a lack of full consistency due to the above mentioned reasons.

There are many published standards, reports and articles that address the environmental performance of buildings. For example, most of the current sustainable building rating systems were mainly intended to be used for buildings’ environmental performance evaluation. Therefore, numerous environmental performance criteria were developed and provided in the literature. The criteria in Table 2 show the environmental SPIs have the higher counts. Almost all of the reviewed rating systems in this study have emphasized the environmental SPIs proposed in Table 2. The next highly mentioned criteria are the economic SPIs that were mostly found in the second reference category, i.e., journal and conference articles. However, Table 2 shows lower counts of social performance criteria in both reference categories.

It should be mentioned that some references, such as LEED, provide some criteria that are mainly environmental indicators but they are indirectly related to the economic and social dimensions of sustainability. For example, “indoor air quality” is an environmental SPI that can lead to “health, comfort and well-being of occupants”, thus it has social impacts as well. As another example, using “regional (local) materials”, “renewable materials”, and “renewable energy” can save a considerable amount of money during the life cycle of buildings. However, fewer direct economic and social criteria were found in the reviewed rating systems.

</table>
As noticed during this study, sustainability performance criteria can be qualitative or quantitative. Many of
the criteria developed by the reviewed references are qualitative criteria and there are no clear methods
for quantifying them, although there have been advances made in the development of quantitative tools.
For example, LCA and LCC are capable of evaluating the life cycle environmental and economic
performance of buildings, respectively. However, there is no standard social life cycle assessment tool
available. Accordingly, there is a growing need for developing comprehensive and standard evaluation
systems for assessing all TBL of building, i.e., life cycle sustainability assessments (LCSAs).

7 CONCLUSION

During the last few years, there was a paradigm shift in the construction industry due to natural resources
limitations. Therefore, more attention is being paid to decrease the environmental impacts of the built
environment. However, it is not adequate to only protect the environment and ignore the socio-economic
impacts of construction projects. In fact, sustainable construction strives to find a balance between the
three primary sustainability dimensions, i.e., environmental, economic and social (TBL). Therefore, to
have a sustainable building all TBL should be addressed sufficiently. A comprehensive method to
address this need is a life cycle sustainability assessment (LCSA) framework, by which all TBL
performances are assessed during the life cycle of a building.

In order to assess the life cycle sustainability performance of buildings (using a LCSA framework), it is
necessary to identify significant indicators of all the sustainability dimensions. In this paper, the most
commonly recommended criteria were identified using a content-analysis based literature review. A broad
list of building sustainability performance indicators (SPIs) were collected, modified, combined and refined
to form final TBL-SPI sets, i.e., environmental, economic and social SPI sets. For assessing the
environmental performance of buildings, 16 SPIs were identified as the most significant SPIs. For the
economic and the social dimensions of sustainability, a total number of 9 SPIs and 12 SPIs were
identified as the most commonly used criteria, respectively.

This paper provides a deeper insight into sustainability in construction by providing the frequently used
sustainability criteria in different publications, including the sustainability rating tools and other published
references. The findings can help construction stakeholders, such as decision makers, policymakers,
clients, developers, contractors, engineers, architects, and designers in the development of sustainable
construction. The proposed TBL SPI sets can be applied in the design and construction phases of
buildings’ life cycle. In addition, they can be used as a generic reference list in order to assess after
construction the extent to which buildings are sustainable.

Since the refined environmental, economic and social SPI sets consist of both qualitative and quantitative
criteria, future research will need to investigate methods to measure and integrate them using appropriate
LCSA frameworks. It should be mentioned that this paper is part of an ongoing comprehensive research
project currently being conducted by the authors regarding the life cycle sustainability of off-site and on-
site construction methods. Therefore, the developed SPI sets will be used in a LCSA framework to
comparatively assess the sustainability of modular and conventional buildings.

FORECASTING BREAKAGE RATE IN WATER DISTRIBUTION NETWORKS USING EVOLUTIONARY POLYNOMIAL REGRESSION

F. Karimian1,3, H. Elsawah1, T. Zayed1, O. Moselhi1, A. AlHawari2
1 Department of Building, Civil and Environmental Engineering, Concordia University, Canada.
2 Department of Civil and Architectural Engineering, Qatar University, Doha, Qatar.
3 farzad.karimian@gmail.com

Abstract: The economic, social and environmental impact of water main failures impose great pressure on utility managers and municipalities to develop reliable rehabilitation/replacement plans. The annual number of breaks or breakage rate of each pipe segment is known as one of the most important criteria in condition assessment of these pipelines. A model is developed in this research to predict the annual number of breaks in water pipes. The developed model utilizes Evolutionary Polynomial Regression (EPR), which is an intuitive data mining technique. The model is applied to a case study to test its effectiveness. The case considers the water distribution networks of in the cities of Doha in Qatar; Montréal, Moncton and Hamilton in Canada. The results indicated that the developed models successfully estimated the breakage rate for the city of Montréal and the number of breaks for the city of Doha with a maximum coefficient of determination of 88.51% and 96.27% respectively. This demonstrates the accuracy and robustness of the developed models in forecasting the number of breaks and breakage rate in water distribution networks.

1 INTRODUCTION:

The Canadian Infrastructure Report Card 2012 (CIRC 2012) shows municipal drinking-water networks ranked “Good: Adequate for now”. Despite this overall rating, 15.4% of water distribution systems in Canada were ranked “fair” to “very poor” that can cause a total cost of $25.9 billion for replacement of the pipes. The “fair”, “poor” and “very poor” condition would be interpreted as deterioration beginning to be reflected, nearing the end of useful life and no residual life expectancy respectively (CIRC 2012). According to this report, 86 Canadian municipalities recorded a total of 719,630 km of water pipelines containing distribution pipes (≤350 mm diameter) and transmission pipes (>350 mm diameter). Based on the expertise’s viewpoint one of the most popular techniques in finding the leakage location in the water pipes is joining the pole to pipes. Therefore the approximate failure place can be discovered by hearing the leak sound. Obviously, this method is insufficient, inaccurate and sometimes cost consuming. According to the CIRC 2012, a considerable percentage of municipalities in Canada do not have complete data of buried infrastructures including water and sewer pipes. While, it is clear that testing, inspection and evaluating of the physical specification of pipes requires large amount of financial reserves, it can be more profitable if the prediction models develop based on the limited historical data instead of real physical data. Recently, a data-mining technique titled Evolutionary Polynomial Regression (EPR) was developed by Giustolisi and Savic. The EPR can be categorized as Grey Box Technique and is performed in two stages: 1) search for the best model using Multi-Objective Genetic Algorithm (MOGA), and 2) parameter estimation for the model using Least Square Method. This type of regression generates several symbolic expressions that are understandable by specialists and professionals, based on various independent variables. The main objectives of this study are: 1) estimate the number of breaks of water mains based on the pipe age to reconstruct the historical databases using regression; 2) develop failure rate prediction models using Evolutionary Polynomial Regression; and 3) develop deterioration curve of water mains with respect to the pipe age using sensitivity analysis.

2 PREVIOUS STUDIES:

Several researchers considered many factors that affect the deterioration of water mains and pipe failure. Stone et al. (2002) categorized these factors in two groups, namely; static and dynamic. The
characteristics of static parameters (e.g., diameter, length, soil type, pipe material, etc.) do not depend on the time, but dynamic factors (e.g., age, cumulative number of breaks, soil corrosivity, water pressure, etc.) change over time. Osman and Bainbridge (2011) tried to identify the effect of time-dependent variables like pipe age, temperature and soil moisture on the deterioration of water pipes. In addition, InfraGuide. (2003) classified the deterioration factors of water pipes into three main categories, namely; physical (e.g., pipe material, pipe wall thickness, pipe age, pipe diameter, type of joints, pipe installation, etc.), environmental (pipe bedding, trench backfill, soil type, pipe location, etc.) and operational (internal water pressure, leakage, water quality, O&M practices, etc.). Several researchers such as Berardi et al. (2008), Xu et al. (2011), Arsénio et al. (2014) and Kutylowska (2015) examined the impact of physical parameters on the water pipes failure. The most frequent explanatory variables in these studies are age, diameter, length and material of the pipe. Some others tried to add more parameters from various categories (environmental and physical) as the independent variables in order to improve reliability of the models. For example, Wang et al. (2009) and Shirzad et al. (2014) took into the consideration the operational factors like hydraulic pressure and burial depth in addition to physical factors. Asnaashari et al. (2013) considered soil type as the environmental factors, as well as the physical ones. Jafar et al. (2010) employed the pipe characteristics (physical), hydraulic pressure (operational), soil type and pipe location (environmental) as the inputs. Moglia et al. (2008) utilized corrosion rate, wall thickness, internal pressure and external loads as the inputs; while, typically corrosion rate is the output in the most of the previous studies.

During the last three decades, researchers introduced different models to predict the condition of the water pipes for a reliable infrastructure management system using various methodologies. The deterioration and water pipe failure prediction models could be classified into six categories; namely, deterministic, statistical, probabilistic and some advanced mathematical models such as artificial neural networks (ANN), fuzzy logic and heuristic. Recently, several efforts have been made to develop deterioration and pipe failure prediction models. A summary of the most prominent ones is shown in Table 1. The EPR does not require large data sets for training and unlike ANN, it enables recognition of correlations among dependent and independent variables. As such it is not a “Black-Box” technique, but it is classified as a “Grey-Box” technique that can provide insight into the relationship between inputs and output. The process of development and selection of EPR contains engineering knowledge that allows the user to understand the generated equations and the correlation between variables involved.

2.1 EVOLUTIONARY POLYNOMIAL REGRESSION:

The Evolutionary Polynomial Regression (EPR) technique was first presented by Giustolisi and Savic (2006). The technique utilizes the huge potential of conventional numerical regression techniques and
the strength of Genetic Algorithm in solving optimization problems (Xu et al. 2011). Later, this approach was used by other researchers in several fields. Savic et al. (2006) and Ugarelli et al. (2008) used EPR to model the sewer pipe failures. Several researches were conducted using EPR in different engineering fields. Berardi et al. (2008) and Xu et al. (2011) applied the EPR to develop deterioration models for water distribution networks. Rezania et al. (2008) utilized the EPR methodology to evaluate the uplift capacity of suction caissons and shear strength of reinforced concrete deep beams. Elshorbagy and El-Baroudy (2009) compared the EPR and Genetic Programming to develop the prediction model of soil moisture response. Guistolisi and Savic (2009) tested the EPR-MOGA (An improved EPR) to develop groundwater level prediction model based on monthly rainfall. El-Baroudy et al. (2010) utilized the EPR to develop the evapotranspiration process then compared efficiency of Evolutionary Polynomial Regression to Artificial Neural Networks (ANNs) and Genetic Programming (GP). Markus et al. (2010) applied EPR, ANNs and the naive Bayes model to forecast weekly nitrate-N concentrations at a gauging station. Ahangar-Asr et al. (2011) applied EPR to predict mechanical properties of rubber concrete. Fiore et al. (2012) used EPR to provide the predicting torsional strength model of reinforced concrete beams.

Evolutionary Polynomial Regression is data-driven technique and can be classified as a grey box method according to the color coding classification system categorizes mathematical models based on the existence of necessary information into three groups; white box models, black box models and grey box models (Giustolisi 2004). The process of creating the symbolic expressions contains two stages: in the first stage the EPR tries to find the best model structure using Multi-Objective Genetic Algorithm (MOGA). Then, the appropriate values for constant are estimated using Least-Squares optimization (LS) (Berardi et al. 2008). In the EPR_MOGA, seven assumed structures of expression are available and the best case according to the prior knowledge about the nature of the output can be selected by the user. In this study the following equation was chosen:

\[ Y = a_0 + \sum_{j=1}^{m} a_j \cdot f(X_1)^{ES(j,1)} \cdot \ldots \cdot f(X_k)^{ES(j,k)} \cdot \ldots \cdot f(X_k)^{ES(j,2k)} \]

Where, \( X_k \) is the \( kth \) explanatory variable, \( ES \) is the matrix of unknown exponents that should be defined by the user, \( f \) is inner function selected by the user (can be no function, logarithm, exponential, tangent hyperbolic, secant hyperbolic), \( a_j \) are unknown polynomial coefficients, \( m \) is the number of polynomial terms and \( a_0 \) is the bias term. It must be remarked that, the zero value should be considered in the matrix of exponent to make the EPR able to remove some variables, which are not powerful enough to predict the output, from the returned expressions.

During the modelling phase by EPR, it tries to return several equations based on accuracy and parsimony of the models. The model parsimony can be implemented by optimizing the number of terms, the number of independent variables, or both strategies. Each of these options can be selected by the user. Furthermore, the user can force EPR to generate the equations with only positive value of constant coefficients \( (a_j > 0) \). Also, the maximum number of terms in every equation in each run can be specified by the user. In addition, the normalization (if required) can be accomplished by EPR, therefore, the user just needs to identify the range in which the inputs or output should be scaled. The EPR can develop model to forecast the output based on either one input or several inputs, in other words it can construct Multi Input Single Output (MISO) and/or Single Input Single Output (SISO) models. It should be noted that, the limited missing data point can be recreated using linear interpolation by EPR; thus, the model can be developed with an incomplete historical database. During the generating symbolic expressions, if the EPR cannot find appropriate combination of terms containing \( f(x) \) (as an inner function), it deselects this function. The effectiveness of fitness of developed models was measured by Coefficient of Determination (CoD) equation as follows (Berardi et al. 2008):

\[ \text{CoD} = 1 - \frac{\sum_n (\hat{y}_{\text{exp}} - \bar{y}_{\text{exp}})^2}{\sum_n (y_{\text{exp}} - \bar{y}_{\text{exp}})^2} = 1 - \frac{n}{\sum_n (y_{\text{exp}} - \bar{y}_{\text{exp}})^2} \cdot \text{SSE} \]

Where \( n \) is the number of samples, \( \hat{y} \) is the value that predicted by the model, \( y_{\text{exp}} \) is the actual amount of the historical data and \( \text{SSE} \) is the sum of squared errors.

3 RESEARCH METHODOLOGY:

Fig. 1 shows the developed research methodology. It started by presenting a comprehensive literature review to investigate the deterioration and pipe failure prediction models. In the second step, the relevant data were collected from two different municipalities; City of Doha in Qatar and City of
Montréal in Canada. The database of the city of Montréal contains an inventory of pipes’ information and the related bursts. However, the number of breaks was not available in the database of the city of Doha. Lack of such data prevents working with EPR because this technique takes into account the number of breaks or breakage rate as a dependent variable in order to develop a pipe failure prediction model. Therefore, it was necessary to estimate the number of breaks for the city of Doha from similar infrastructure databases. Thus, the number of breaks for the city of Doha was estimated using two databases such as: Moncton and Hamilton. Several attempts were carried out using different regression models to predict the number of breaks of water mains based on the pipe’s age. The model that provides large number of data points as well as the best R-Square was used to predict the pipe bursts for city of Doha. The third step, the model implementation, the databases were cleaned and classified into homogeneous groups based on age and diameter of the pipes. It means that all pipe segments of each class have the same value of age and diameter. Also, all missing data points were removed from the databases. At this point, data sets of Montréal and Doha are ready to be analyzed using EPR_MOGA_XL. In this study, two different scenarios were implemented; the first one considered the number of breaks as an output and the other one assumed that the dependent variable is the breakage rate (Breaks/Length (Km)/Age (Yr)). Finally, the sensitivity analysis was carried out for both cases to develop different deterioration curve and to identify the effect of each variable on the breakage rate.

Figure 1 Research Methodology

4 DATA COLLECTION:

In this study, four sets of data from various municipalities were used, namely; city of Moncton, city of Hamilton and city of Montréal in Canada and city of Doha in Qatar. The city of Moncton, Hamilton, Montréal and Doha own 517 km, 1,891 km, 70 km and 4,682 km of water distribution networks respectively (SOIR, 2005, KAHRAMAA Report). The physical characteristics of water pipes in different databases are generic. In fact the results obtained using the Hamilton and Moncton data were very close. In view of this finding and the insufficient data collected from Doha, it was required to use the model developed based on Hamilton and Moncton to predict the number of breaks in Doha. Estimation of number of breaks was implemented by applying regression analysis using data sets of Moncton and Hamilton. Three different models were developed. In the first two models the data of each city was used separately, while, in the third one the combined data for both cities was utilized. In each model the data was clustered into different groups based on the pipe age. The breaks per length (m) was calculated for each age-class by computing the average of number of bursts. Several attempts were conducted to reach the best model using different types of databases. Since, in the database of Doha, there are not pipes older than 33 years, it was not necessary to keep the pipes with the age of 34 and more, therefore they could be deleted in the new inventories. Finally, the model
which provides large number of data points and gives the best performance based on the Coefficient of Determination ($R^2$), was chosen to estimate the number of breaks for the city of Doha.

Fig. 2 shows the result of regression (based on the No. of Breaks per Length (m)) of Moncton, Hamilton and mixing of both cities, respectively. The equation of each inventory and determined $R^2$ are shown in Table 2. It can be seen that the developed models of Moncton and both Cities are acceptable; while, the one that belongs to city of Hamilton is not promising enough to be used in Doha. Then, number of breaks per length that obtained from these equations should be multiplied by length of related pipe segments to calculate the estimated number of breaks of Doha’s database.

The completed database of Doha, including the estimated number of breaks, and Montréal data set was filtered before applying with EPR. Each of them comprises several factors: Table 3 shows the collected variables for both inventories. The units of age, length, diameter, depth of laid and pipe elevation are year, Km, mm, m and m respectively in collected data. For cleaning and organizing databases, several steps performed. Some segments with having either the missing pipe information or inconsistent data were totally removed from databases. The qualitative variables such as pipe type and soil type were translated to numerical ones. For example, if there are four different types of soil, each number from 1 to 4 was assigned to a specific soil type. It is noteworthy mentioning that the maximum number was assigned to the hardest pipe type; in other words, the harder the material, the larger the allocated number and the vice versa. As it was mentioned before, there are two different scenarios in considering the output in the current study; number of breaks and breakage rate. The breakage rate of each segment should be calculated by dividing number of breaks by age (or observation years) and length (km) of the pipe. Finally, two databases were classified into homogeneous groups based on age and diameter of the pipe. A detailed discussion about classification is presented in model implementation section.

5 MODEL IMPLEMENTATION:

5.1 EPR SETTINGS:

In the database of Montréal, the following factors were considered as independent variables; pipe length, diameter, pipe type and age of the pipe. Whereas, inputs in Doha data set were pipe length, diameter, thickness, pipe type, age, pipe elevation and depth laid. Also, the settings which are followed were same for both cases. Nomination of exponents were limited to [-2, -1.5, -1, -0.5, 0, 0.5, 1, 1.5, 2] in which the positive and negative value represent the direct and inverse relationship between dependent and independent variables and their amounts show how significant the inputs are. The maximum number of terms in each expression was three and the bias term was considered as zero. In the Regression Method tab, the Least Square parameter estimation was forced to search for just positive value of $a_j$ as a coefficient. The exponential was selected as the inner function. EPR rounded the output to the nearest integer number if the classification is selected as the Modelling Type. Thus, in the scenarios in which the breakage rate was assumed as a dependent variable, Statical Regression should be chosen for considering the output as a real number. The range of variables was constrained to [0.01, 1] for scaling all inputs and output data. The “GA” is the number of generation and depends on several attribute such as number of independent and dependent variables, number of terms and exponents, and was selected as 40 based on the previous experience. There are three different choices in Optimization Strategy; namely, \( \min(a_j, SSE), \min(X_i, SSE) \) and \( \min(a_j, X_i, SSE) \). Among them the \( \min(X_i, SSE) \) was selected. Maximization of the parsimony and the accuracy of the model caused by minimization of \( a_j \) and \( X_i \) respectively.

* Estimated by Other Databases

5.2 CLASSIFICATION:

Once, the process of cleaning and reconstruction was conducted, pipe segments were classified into several homogeneous groups based on age, diameter and pipe material. In the database of Doha there were only three nonmetallic pipes out of 1599 pipes, which were removed. Thus the classification of Doha was based on only age and diameter. The following equations were used to group the data:

\[
A_{\text{class}} = \frac{\sum_{\text{class}}(L_p \cdot A_p)}{L_{TA}}, \quad D_{\text{class}} = \frac{\sum_{\text{class}}(L_p \cdot D_p)}{L_{TD}}
\]

Where, \( L_{TA} \) and \( L_{TD} \) are the total length of pipes with the same age and diameter respectively. Also \( L_p, A_p \) and \( D_p \) are length, age and diameter of each segment in the group. Thus, there are several categories with the same class of age, diameter and material for each inventory. It should be mentioned that the other features of pipe (such as thickness, length, etc.) can be utilized as grouping criteria in different studies. But in this research age was selected for classification to take into account the indirect effect of time-varying solicitation on water mains. Because as an engineering point of view, the higher the duration of solicitation, the higher the chemical and mechanical harmful effects (caused by soil condition, traffic loads, etc.) on pipes (Berardi et al. 2008). Furthermore, the other equivalent attributes in each database can be calculated by different mathematical functions (such as
sum, average, etc.). In the database of Montréal, the length and the number of breaks of each class were computed by summing corresponding ones of each pipe segment. Likewise, in the Doha database, the same calculations were performed for the length and the number of breaks; while, the other variables such as pipe elevation and burial depth were calculated by computing the average of related features of pipes in that group.

6 ANALYSIS OF RESULTS:

In this study, two databases; the city of Montréal and the city of Doha were utilized to forecast the number of breaks (for the city of Doha) and the breakage rate (for the city of Montréal) using EPR. Among all symbolic expressions that were developed by EPR, the best one was chosen based on the fitness to the historical data and parsimony of the equation. Tables 4 and 5 show different pipe burst prediction models for the city of Montréal and the city of Doha with their corresponding R-Square respectively. It can be seen that in both cases the expressions accuracy is increased when equations get more complicated. It can be understood from Tables 4 and 5 that the age of the pipe has a direct impact on the breakage rate as well as the number of breaks. In addition, the equations describing the number of breaks for the city of Doha has higher coefficient of determination than the equations describing the breakage rate for the city of Montréal.

Table 4 shows twelve breakage rate prediction models that were generated by applying the EPR with database of Montréal. It can be seen that equations 5 considers the age, length and diameter of pipes and has a coefficient of determination of 79.58%. In equation 6, the material of pipes was added to the model which improves the coefficient of determination by 5.71%. While, the coefficient of determination increased from 85.29% to 88.51% from equation 6 to 12, the models became more complicated. Thus, in this study, equation 6 was selected to be the best one to describe the pipe breakage rate as it has the acceptable coefficient of determination with reasonable number of variables.

Table 5 shows the twelve symbolic expressions that were generated by EPR to estimate the number of breaks for the City of Doha. It can be seen that age, length and diameter of the pipes are the most commonly used variables for estimating the number of breaks while depth laid and pipe elevation has been introduced in only the last five equations. It can be notice that as the age of pipes increases the breakage rate increases. However, when the diameter of the pipes increases the breakage rate decreases. It can be remarked that equation 2 has a coefficient of determination of 94.33%. However, it only considers the length and the age of the pipe. In order to test the sensitivity of the prediction model by changing the inputs, model number 9 was chosen as it considers all variables that has a significant effect on the pipe bursts.

Figure 3 and 4 show the Pareto graphs of different models based on Montréal and Doha result respectively. In these graphs each point represents one returned equation and vertical axes shows the number of selected inputs while the horizontal axes demonstrate the fitness of models (1-CoD).

7 SENSITIVITY ANALYSIS:

In this study, the sensitivity analysis was performed to identify the effect of each variable on the pipe bursts when the water pipes get older. Figures 5 to 9 show the deterioration curves for the city of Montréal and the city of Doha. Figures 5 and 6 illustrate the breakage rate for the city of Montréal for different pipe diameters and pipe lengths respectively while keeping all other inputs as constants. The value of these constants were considered as the average of that variables in the database. Figure 5 and 6 show the effect of pipe diameter and pipe length on the breakage rate. The breakage rate of pipes with different diameter has increasing trend as the pipe become older. It is clear from the Figure 5 that the bigger the diameter of the pipes, the higher the value of breakage rate. In addition, Figure 6 shows the breakage rate of pipes with various length are increased when the pipes get older. The same analysis was carried out for city of Doha. As it was mentioned before the equation 9 of database of Doha was used to develop graphs including different deterioration curves. Figure 7, 8 and 9 show the sensitivity analysis for length, depth laid and pipe elevation respectively. It is confirmed in these graphs that, the number of breaks is increasing while the pipes are aging.

8 CONCLUSION:
The process and specifications of Evolutionary Polynomial Regression technique were described in
this paper. The setting of EPR_MOGA software was explained in details. Four different aggregated
data sets were utilized in different parts including city of Doha, Montréal, Moncton and Hamilton. In
the database of Doha, the number of breaks of pipelines was not available. Therefore a regression
model developed to predict the number of breaks based on the pipe age. This was performed using
city of Moncton, city of Hamilton and mixing of both cities. The EPR was applied with databases of
Doha and Montréal. For each attempt several symbolic expressions were returned by EPR and their
fitness was measured by Coefficients of Deterministic. Then, the results were analyzed and sensitivity
analysis was implemented to identify the effect of each factor on the number of breaks and breakage
rate of the water pipes. As it was confirmed by previous studies, the most critical factors that affect
deterioration of water pipes are age, length, diameter and material. Finally, for each data set, one
predicting model was selected to be used by utility managers and decision makers of Water Distribution Networks.

COMPARATIVE ANALYSIS OF EXISTING BUILDING INFORMATION MODELLING (BIM) GUIDES

Susan Keenliside
S8 inc., Canada

Abstract: The current approach to development of building information modelling (BIM) guides has catered to each specific client in a unique way. There has been no universal standard format or standardized content employed in the development of these guides from one organization to the next. Conversely, many organizations have pioneered the development of their guides to support the need for standardized methodologies in developing and deploying BIM capability within their organization and/or supported by industry deliverables. Further, published BIM guides around the world define similar or the same terms and concepts in unique ways (and vice versa). The BIM guides project is the first project to leverage existing publications within an open process of consensus standardization, in pursuit of harmonization of concepts, definitions, terms and the organization of how this content is delivered. It uses a review template to capture common metadata fields for comparative analysis within a database. A database of BIM guide information can inform on real-world procedures and requirements from industry. Guidelines are for the user, and this project gives insight and direction to those needing, using and creating BIM guidelines. It is hypothesized that this approach will deliver guides more efficiently, contribute to BIM adoption and standardized use within industry and provide a needed baseline from which the end-user can effectively build their knowledge, skills and abilities.

1 INTRODUCTION

In the construction and facilities industries, clients and professionals currently need to perform or outsource a major amount of work to review existing BIM guide documentation in order to develop their own version of a BIM guide for their company or organizational needs. The process of reviewing, analysing and drafting guide documents is labour-intensive and results in parallel or duplication of effort without value added to the achievement of standard procedures or best practices. Recognizing the opportunity for greater efficiency through harmonization of efforts, a group of experts working collaboratively under buildingSMART International launched the “BIM Guides Project” to determine if and how standards and the standards developing process can aid in improving the process of creating, implementing and using BIM guide documentation.

The project’s goals when initially established included publishing a publicly accessed database of pre-defined and user-defined search criteria and then using these results to make recommendations on an international framework for BIM guidance documentation. Additional questions the project seeks to answer include: Can the plethora of global BIM Guides be reverse-engineered down to a few pioneering documents? What are the roots to today’s foliage of guidance documentation? What published documents are used in popularity, and thus becoming de-facto industry standards? What are the common elements of BIM guidance documentation across the majority of publications? Where are there gaps in
existing BIM guidance documentation? How can new concepts in standardized applications be used to the benefit of BIM guidance development?

1.1 Definitions
For the purposes of this project, "Guides" refer to any documentation that has been published to support the end-user in applying standardized processes, procedures or technical requirements in Building Information Modeling (bSI BIM Guides Project Team 2014.).

1.2 Current Guidelines Development Process
The current process of developing BIM guidelines typically involves one or all of the following steps:
- duplication, modification and/or addition of content to an existing guide;
- compilation of existing content within a new organization of information (table of contents); and
- development of original content.

It takes a lot of time for someone to get up to speed on all major guide publications, as they consider each for content, organization of content, and scope. The results vary in quality, applicability to the ‘real-world’ and achievement of the client’s objectives.

Overall, most clients and consultants will agree with the adage of “not wanting to re-invent the wheel” when it comes to BIM standards and best practices. If information can be available, the general consensus is that this content would be welcomed and leveraged for greater industry use. That said, issues of intellectual property and a general comfort level of openly sharing content developed continues to lead to clients or consultants, willingly or forced, to develop guideline and other standard or best practice documents independently and often uniquely.

1.3 An Industry Project to Benefit from Academic Rigour
This project identifies a gap in the current ability to achieve consensus and consistency on BIM guide content. This gap varies from country to country, but exists everywhere nonetheless. This is evident by the amount and variety of guides publically available. Although not initiated as a research project, this industry-identified project recognizes the role that the academic process can bring to achieving rigour in the methods and outcomes, including substantiating results and recognizing value. Future work is anticipated and encouraged within academia in collaboration with this project team to bring best value to industry.

2 BACKGROUND
The BIM Guides Project started out of a recognized need during the delivery of the United States’ National BIM Standard, version 3 (NBIMS-USv3). At that time, there was little to no known literature available that provided a way to categorize or classify content of and within guides. Specific focus on comparing guidelines was first introduced by a work group within FIATECH, but limited in scope to focus only on the AutoCodes project (FiatechAutoCodes), and then left to this project to take further.

The BIM Knowledge Content taxonomy (BKC) (Succar 2013) has since been identified and should be reviewed for relevancy in the metadata fields captured within the database via the review template. Identification of the noteworthy BIM publications (NBP)’s concept and metrics (Kassam 2013) also provides opportunity to fine-tune the review template for metadata capture that can assist in supporting existing research areas and overall industry needs.

A standard is a document that provides requirements, specifications, guidelines or characteristics that can be used consistently to ensure that materials, products, processes and services are fit for their purpose (International Standards Organization 2015). Building off of existing guide content to achieve standardized parts, methods and terms would support greater efficiency in BIM adoption and use. Recognizing that a guide document needs flexibility to achieve its purpose, where trying to standardize on
too much is not useful or realistic, the project has set its ultimate goal to achieve a framework with sample language and agreed terminology/concepts for easy population of content.

3 METHODOLOGY

The project uses a template approach as the key method to establishing a baseline of common fields, or metadata, about the majority of BIM guide documentation available globally. A template approach is defined as the review of a document captured in a commonly defined template in order to provide a method for comparison of disparate document content. This metadata capture provides the ability to search across document content and make comparisons. The culmination of the analysis places the document in a chart comparing content and scope, where all guidance documentation can be related from a high-level. The choice to use a wiki was based on the capacity to create a searchable compendium of reviews of all known BIM standards, guidelines, and best practices. The Wiki format makes it open to the worldwide BIM community.

Prior to this project there were no real efforts to harmonize BIM guides, whether at a national or an international level. Given the number of established and implemented BIM guides we cannot start over and propose one common international guideline. But harmonization of the content can be accomplished on multiple levels:

1. The first level is to harmonize or map the understanding of its field of application and aimed users. Human interpretation is required to tease out the metadata. The result is being able to query across documents.
2. The second level is mapping content (mainly by chapters) to a common table of contents. The result is the establishment of a common structure or framework, either to aid in comparison or to use when creating new guides.
3. The third level is harmonizing or mapping definitions. Also referred to as searching for keywords, the level of effort to identify and harmonize terminology is significantly greater than the first and second levels. All three levels contribute to the made-to-measure concept of building out guides with consistent or standard terms, definitions and structure.

Figure 1 below illustrates the project's 3-level concept:
The goals of the project include:

- support a common framework for BIM guides based on the results of the project;
- promote BIM guide content that employs open BIM based file exchanges and processes; and
- deliver a product application of the database tool for public consumption and use.

3.1 Developing a Matrix for Comparative Analysis

The initial approach was to intuitively identify common categories of information type, based on expert experience within the project team, and to plot that content against an implementation level. Captured in Table 2: Guide Mapping Matrix, the comparative analysis hypothesis was that as content within existing standards and guidelines documentation was mapped to this matrix, awareness, consent and agreement on what (level of) content belongs where along the implementation continuum would begin to form from intuitively interpreting the results and recognizing trends or patterns.

Table 2: Guide Mapping Matrix

3.2 Review Template for Common Metadata Fields

The review template was created to capture these common metadata fields, thus providing the method by which to compare guides at a comprehensive level. Overall the capture and completion of a review of a guide document is not intended to be a labour-intensive or exhaustive exercise. Recognizing that BIM guides are so diverse in their content, the intent was to capture overall scope and subject areas from a generalization perspective. Sections are completed from drop-down menus, with a comment field at the end of each section for manual text entry at the reviewer’s discretion for additional information or specificity.

The template splits content into two (2) sections, with multiple sub-sections:

- Part A: Document Overview (Intended Use and Audience)
  - Section 1 – Document Details
  - Section 2 – Intended Use and Audience
  - Section 3 – Document position by type and content (see Table 2 above)
- Part B: Document Content
  - Section 1 – Project Definition and Planning
  - Section 2 - Technical Specifications
Section 3 – Implementation Processes
Section 4 – Supporting Tools
Section 5 – Legal Aspects

The goal is to have each document reviewed three (3) times to ensure accuracy and completeness. Ideally, the document author or authoring organization representative completes one of these reviews. This approach is especially important for documents that require purchase, as users will only want to purchase documents if they can see that they are applicable to their effort.

3.3 Using the wikiX platform

It was determined that using a wiki would serve the database and public-access requirements best. NOTE: This wiki does not host the source documents under review. A link is provided to the source document within the review. Some source documents may require purchase. The database at the metadata level can be used to query guides for items such as general scope and audience, including drilling down to specific topics such as Level of Development, Project Execution Planning or COBie, for example.

3.4 Mapping to a Common Table of Contents

Parallel to the effort of trying to compare guides at an overall scope level, is getting down to the table of contents level (ToC). Mapping existing guides to a generic table of contents could be used when assembling from any BIM guidance document the sections within the database that are relevant to their organization or project. Developing a standardised TOC for the BIM Guides Wiki can provide a framework for users wanting to assemble their own customised guide based on content found in the guides included on the Wiki. This can contribute to harmonization of BIM guidance and, in turn, BIM practice.

3.5 Using Keyword Search Functionality

The third level of granularity is to achieve functionality that supports keyword searches. This implies that the document content is accessible and set up to be able to be searched at the keyword level. Alternatively, keywords can be tagged to the document by human interpretation that are not already captured at the metadata or table of contents levels. Likewise, this functionality must be completed in conjunction with how the buildingSMART Data Dictionary (bsDD) is used and in support of harmonization of terms and concepts.

3.6 The Made-to-Measure Concept

The made-to-measure concept is a logical extension to having a database of i) standardized terms, ii) a standardized structure, and iii) access to existing content that can be used with appropriate citation. The idea of being able to have a tool that builds out a BIM guide based on these three levels of available content is theorized to deliver industry efficiency and repeatability in administering BIM guides for project use. Likewise, this kind of tool does not detract from organizations needing organization- and/or project-specific content within their guide(s). The focus is on delivering common content in a common way. This concept is already being leveraged in at least two (2) countries: buildingSMART Norway’s BIM Manual efforts and known activity through buildingSMART Korea. (Note: Both chapters have participants on this project team. The project does not necessarily have the goal to create another, similar tool if an existing tool can be leveraged for the needs of the project.)

3.7 Copyright and intellectual property

A licensure letter and accompanying project prospectus document was identified as necessary to engage with document authors and authoring organization on the subject of copyright. The goal of the project is to leverage existing content for mass consumption via a standardization process. It is imperative that authors maintain their IP over existing content. Therefore, a requirement within the project is to ensure that accurate referencing is enabled when content is re-used and that content authors understand and agree to how their content can provide benefit to industry adoption and use of BIM.
3.8 Using the buildingSMART Data Dictionary (bSDD) to harmonize terminology

The buildingSMART Data Dictionary (bSDD) stores concepts with associated definitions to house a common ontology for the building and construction industry (buildingSMART International 2014a.). The open international data dictionary is a service based on [the] IFD Standard (ISO 12006-3) which allows users, architects, engineers, consultants, owners and operators on one side and product manufacturers and suppliers on the other from all around the world to share and exchange essential product information (buildingSMART International 2014b.). Although not the traditional use of the bSDD, the BIM Guides Project is currently exploring how the bSDD will be used to support this context.

The bSDD group has been engaged and steps have been taken to identify the following:

a) understanding and usage of the bSDD (general)
b) choice in how the bSDD is used affects the outcome (project-specific)
c) the processes for defining, inputting and using standard content in the bSDD
d) the harmonization process of content, pre- or post-input to the bSDD
e) a BIM guide project interface that accesses the bSDD in the background
f) pilot projects that can show proof of concept

3.9 ISO/TS 12911:2012 – Framework for building information modelling (BIM) guidance

ISO/TS 12911:2012 establishes a framework for providing specifications for the commissioning of building information modelling (BIM) (International Standards Organization 2012). The design intent behind the technical specification is to deliver structured, computable and therefore testable requirements, including how these requirements cascade down the contractual chain. The contractibility and checking functionality is predicted to be the key to the next generation of the standard.

The concept is to provide a framework that stands above any guide, taking a generic view. It is more ambitious than just a table of contents. It is meant to be used to deliver documents small in size, aimed at one particular deliverable, with multiple documents put together into a handbook for any particular project. The clause layout makes them computable: 1. Applies; 2. Select; 3. Except; 4. Require.

The overall structure divides the content into 3 Framework sections as shown in Table 1 below:

<table>
<thead>
<tr>
<th>Framework Section*</th>
<th>Level of Responsibility</th>
<th>Topic</th>
<th>Description</th>
<th>Application Example (UK)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Strategic</td>
<td>Principals</td>
<td>Outcomes (Outputs)</td>
<td>Intended Deliverable from BIM</td>
<td>Employer Information Requirements (EIR)</td>
</tr>
<tr>
<td>Management</td>
<td>Design Management</td>
<td>Controls</td>
<td>Management of BIM</td>
<td>Project Execution Plan (PxP)</td>
</tr>
<tr>
<td>Implementation</td>
<td>Design Team</td>
<td>Inputs (Data)</td>
<td>Operational Requirements</td>
<td>Digital Plan of Work (DPoW)</td>
</tr>
</tbody>
</table>

*Table developed by author to harmonize content and verbal descriptions of content

Under the three (3) framework sections, three (3) levels of guidance are to be established:
A. International
B. National or Regional
C. Project- or Facility-specific

ISO/TS 12911 was not on the radar of any of the experts within the team when this project began. A goal within the project was to use the comparative analysis to inform a framework for BIM guidance at the
international level. Currently, ISO/TS 12911 has been brought to the team’s attention as definition of said framework. Therefore, the team has efforts underway to continue to evaluate the applicability of ISO/TS 12911 to this body of work. Current discussion includes accepting this body of work as a technical standard of a technical standard compared to the fundamental definition of what a guide is.

4 DISCUSSION

Harmonization of content (and concepts) when coupled with end-user consensus is a powerful tool to achieving standards and best practices that are respected and used within industry practice. It is not the project’s goal or vision to see one single guide as a standard. Instead, the project team sees value in focusing on key parts that can benefit from the standardization process. The idea is to have a tool available for creation of BIM guidance documentation based on standard terms and structure, with access to sample content referenced from existing sources. In doing so, a “standardized” approach can be taken to align all the various activity and achieve a compendium of (searchable) best practices without diminishing the need for guides to be localised.

Prior to this effort there was no single place to go for this information nor has there ever been an established set of criteria, or methodology, for the comparative analysis of guide documents. It is wasteful for practitioners to attempt to read and digest all the available material each time they wish to validate previous work accomplished. Likewise, it is unreasonable to expect those looking for guidelines for a specific purpose to adopt an existing document without assessing its suitability relative to ‘what is out there’.

The project could help answer the following questions:
• How do you know what guidelines and best practices have been developed throughout the world related to Building Information Modelling?
• Some of these guidelines are based on previous efforts; what is their relationship to them?
• How do you ensure that new initiatives are taking advantage of previously accomplished work?
• What International Standards are in place, and which ones have an impact on BIM?
• How can you align your work efforts with best practices already in place?
• How do you ensure you are not reinventing the wheel when developing a new business practice?

The challenge with this project is identifying sufficient funding and resources to achieve the goals. Alignment to existing research cells, terminology groups and educational curriculum development would help broaden its reach and refine its implementation.

4.1 Highlighting BIM as a Process

This project is a way of building up standard parts and best practices based on industry use and acceptance. What it also does is highlight BIM as a process. The purpose of guides is to direct and inform the end-user on tasks, deliverables, processes and practices. Through review of guide content and then building a purpose-specific guide, BIM as a process is highlighted.

4.2 Client-specific needs

A strength of the project is the goal to engage directly with authoring organizations as well as to provide a tool for them, and industry at large, to use. It is expected that this project will help raise awareness, provide an educational role, and be a guide in itself for industry’s uptake and standardization around BIM terms, concepts, processes and frameworks.

That said, it should be explicitly recognized that each client has specific needs. By providing a framework and harmonized concepts and definitions, the client is free to tailor their guide to their needs in a standardized way. As the project is launched and we are better able to gauge industry uptake, we can better determine where specific value is being achieved (or not) and develop additional functionality accordingly.
Authors and authoring organizations in support of this project can expect the following benefits:

- added visibility to their organization and published guide(s);
- harmonization of content across global BIM guides, including terms and definitions;
- informs future versions of their organization’s BIM Guide documentation;
- contributes to standards development; and
- supports industry adoption of BIM.

4.3 End-user acceptance

A guidance document has to be user-friendly. User-friendly means easy to use, operate and understand. A certain level of standardization as outlined in this project can help to produce guides that are more user-friendly and predictable. End-users typically have to follow a different BIM guide for every different client or even project. Having guides that follow a standardized structure and employ the same definition of terms would make it easier on the end-user and would support end-users delivering the BIM aspects of their projects more consistently across the board.

4.4 Showcasing the use of open standards

The project team have discussed and agreed that under the banner of buildingSMART International, “the home of open BIM”, showcasing the use of open standard end deliverables should take precedence to proprietary-focused guides. Whereas there is value in BIM guides with proprietary deliverables outlining important process changes and collaboration methods, there is also a need to recognize milestone deliverables versus final project deliverables in terms of open standards. It’s not always a clean cut, and it’s important to recognize that disparity continues to exist around the world on the functionality and usability of Industry Foundation Classes (IFC) deliverables without also including the originating platform files. Certainly, needing to highlight uses of IFC as the final deliverable are needed to dispel the myth that IFC and open standards don’t work.

4.5 The need for a degree of standardization within guidelines

Although there will always exist discussion around the ‘degree’ to which standardization is important or practical, certainly a basic requirement is to achieve greater consistency and compatibility between guidance documents.

As mentioned, there is a sweet spot to hit between the flexibility required for clients to define their unique requirements and all end-users having a baseline standard to work from. It seems logical that any end-user would accept an easier way of working.

4.6 Guidelines use as a medium for education

At a minimum, guidelines have an opportunity to link to further discussion on topics relative to the end-user level of competency and experience. They are informative, descriptive and cater to a specific audience for a specific need.

Guidance documentation can serve a needed role in the following areas:

- help owners/clients define their needs;
- communicate corporate and/or project requirements; and
- educate industry (or other members of the client organization) on BIM processes, deliverables, technology requirements, among others.

5 CONCLUSION

Within the construction and facilities industries, each client feels they do things differently. And they do – to a degree. But doing things differently without attempting to identify commonalities and standard pieces does nothing to improve overall industry productivity. Likewise, authoring organizations, in pursuit of their
own guide, often would like to build off existing ‘de facto standard’ content, but don’t have access to a database or tool that does this.

This project is a unique opportunity for industry to be engaged in the process of standardization. It leverages existing content being used as ‘de-facto’ standards, and sets out to achieve harmonization of concepts, terms, definitions and the overall structure or framework that guidance documentation is delivered within. What is exciting about it is the level to which industry can be engaged and learn from the process, with an eye to making achievements in efficiency and productivity.

Acknowledgements

This project has been developed out of the work started in the US-NBIMS Planning Committee (Chris Moor, Former Chair of NBIMS), and specifically within the Product Development Subcommittee (Susan Keenliside, Former Chair of NBIMS-PDS), supported by Deke Smith (Former Executive Director, buildingSMART Alliance). The NBIMS-PDS had already begun to do reviews using the template approach, and it was within the PDS that this work was recommended to be elevated to the bSI forum for international participation. The Process Room group adopted the methodology used by the NBIMS-PDS and agreement was made to move ahead with the guideline reviews and create a wiki to support it at the buildingSMART International Technical Summit Process Room meetings in Munich, Germany, in October 2013, and taken on by Sylvain Marie (VTREEM, France). The current bSI BIM Guide Project team includes (alphabetical order by first name) Deke Smith (United States), Ghang Lee (Republic of Korea), Jan Karlsheoj (Denmark), Mark Baldwin (Switzerland), Neil Greenstreet (Australia), Nick Nisbet (United Kingdom), Steen Sunesen (Norway), Susan Keenliside (Canada), Sylvain Marie (France), and Tomi Henttinen (Finland). Thanks to the NBIMS-US PDS members that contributed to the original project: Alan Redmond, Andrew Baranowski, Andy Smith, Chris Moor, Dominique Fernandez, Igor Starkov, Jason Reece, Jeffrey Ouellette, John Grady, John Messner and Monte Chapin. Special thanks to those who participated independently or as past-members of the team: Ingo Kittel, Zeynep Aydin.

HOW WELL DID A MULTI-STAKEHOLDER MANAGEMENT FRAMEWORK FOR REMOTE SITES MODEL THE REALITIES ON AND OFF-SITE OF A SCOTTISH HIGHLANDS INFRASTRUCTURE MARINE PROJECT - REFLECTIVE CASE STUDY

Linda Kestle
Unitec Institute of Technology, New Zealand
lkestle@unitec.ac.nz

Abstract: The next 20 years will see inward investment of up to £100 billion in construction (and energy) projects in northern Scotland, particularly in the Highlands and Islands. The majority of these projects will take place in locations which are, to a greater or lesser extent, remote. However the performance of many remotely-sited projects across the world highlight the need for more effective management strategies and models. The multi-stakeholder management framework for remote site projects, developed by Kestle (2009), synthesised production and sociological design and management approaches, and has already been tested and validated on Antarctic, humanitarian aid and post-disaster reconstruction projects globally. Participants for this research were designers, construction, and project managers involved on a commercial scale marine infrastructure project in the Scottish Highlands. Semi-structured interviews were conducted and the findings analysed to establish and reflect on whether the framework modelled the realities on this remote site project, and actually provided the value-added sought by the multi-stakeholders involved. The findings suggested that the stakeholders’ value criteria expectations were indeed met, and that the management framework did reflect the realities of designing and managing this particular remote site project.

1 INTRODUCTION

Design and construction processes have become more complex and fragmented over the last few years, resulting in an increasing need for a shared and early understanding of the project objectives amongst the stakeholders. What is valued in the project, significantly impacts upon how and when decisions are made on design/construction issues. In the design management field the integration of those who have knowledge that contributes to the design, construction and management, is critical to developing and achieving value on projects. The added dimension of remote site projects, increases the complexity, and makes early decision-making; knowledge integration; logistical implementation planning absolutely critical and central to the potential success, or failure, of the project. The project team has to not only address the traditional management problems, but also those that specifically occur as a result of the remote locations of these often environmentally, and politically sensitive sites (Kestle, 2009).

The selected project for the this reflective case-study was the Ullapool pier improvement project, as it met the majority of Kestle (2009) typological criteria for remote sites, and aim was to utilise the Kestle (2009) management framework to establish and reflect on how well it modelled the realities of designing and managing an innovative infrastructure marine project in the remote Scottish highlands.
2 THE BASIS OF THE KESTLE (2009) MANAGEMENT FRAMEWORK

The development of the conceptual design management model (for remote sites), was in part a response to a call by design management researchers Koskela et al. (2002) for example, for research collaborations that improved the discipline of design management, and provided a solid conceptual foundation. Similarly, Winter et al. (2006) observed that “theories about practice can also be used as theories for practice”. In particular it was suggested that future research needed to focus on ‘in the field realities’ and offer practitioners realistic and contemporary management frameworks, that helped deal with the complexity issues of projects in the ‘midst of practice’ and recognised that an interdisciplinary approach was useful.

The conceptual model by Kestle (2009), was originally informed at the exploratory stages, by the key concepts and principles of design management and lean design management literature, and developed in conjunction with a typology for remote site projects (Kestle and London, 2002). The latter involved investigations into three historical project case studies on remote sites in Australia (Kingfisher Bay eco Resort), New Zealand (Tongariro National Park huts and ski lodge sites), and the Ross Sea Region scientific bases in Antarctica. The end result was a theoretical conceptual model which highlighted the factors or drivers that needed to be considered in the development of a conceptual design management model for remote sites (Kestle, 2009). Those factors were value generation, knowledge integration, process integration and timely decision-making, and were arrived at by contextualising the typological descriptors for remote sites, identifying the contributions made by the sociological and production oriented worldview literature, and in turn became the synthesis described by the four factors/drivers for the theoretical model.

Conceptual Design Management Model for Remote Sites (Kestle, 2009)

'Value Generation' - refers to the value that the client and stakeholders place on the project outcomes, and will vary according to the differing clients’ and stakeholders’ expectations of the projects, and these can vary not only between stakeholders but also between client groups.

'Knowledge Integration' - is concerned with capturing and integrating the specialist knowledge of all those personnel involved on a particular project, prior to and during the project phases. This suggests that key personnel be involved with any pre-briefing, pre-planning, and in the regular monitoring and review of the planning and operational stages, as the project progresses. Specialist knowledge is required to ensure the best solutions and results, despite frequently working with non-negotiable timelines.
‘Process Integration’ - involves the timely and cost-effective co-ordination and planning of a range of processes across the total project, such as planning methodology, logistics, information management, and the management of design/production interface. Logistical planning and implementation is complex, as well as critical in post-disaster response and recovery coordination.

‘Timely Decision Making’ - refers primarily to financial and design decisions, which are critical to the successful management of collaborative international projects. These decisions are made within the context of frequently non-negotiable windows of buildability timeframes, fixed or controlled budgetary constraints, and/or health and safety concerns.

The (doctoral) design management model for remote sites by Kestle (2009), has now been used for a few years as a management framework/tool on a range of multi-stakeholder international projects to gather data from in-field personnel and compare the in-field realities with the designers’ and managers’ pre-construction stage design and management planning for the project, in order to add to learnings from these remote site and often environmentally sensitive projects.

Researchers Salvatierra et al. (2010), recently noted that the concept of value varies across time, is context dependent, is relative/comparative, and very subjective, and tends to be restricted to just achieving value for end-users and clients, rather than society as a whole. Salvatierra et al. (2010), also referred to research by Ballard (2006) who was working on a model of project definition with a value generation perspective and which gives importance to the stakeholders’ perspective of value.

The stakeholders’ involvement is considered a key element in generating value, therefore it is important to underline the contribution of Emmitt et al. (2004), where the concept of value was divided into ‘external value’, which is the client/customer value, the value that the finalised project should have achieved, and the ‘internal value’ achieved by, and between the delivery team. The Kestle (2009) management framework, and the research work by Kestle published in Emmitt (2012), referred to adding-value, and that the integration of a team with knowledge contributing to planning, design, construction and management, was critical to developing and achieving value on projects for the client and stakeholders.

3 METHODOLOGY

The decision to undertake a reflective case study of the ‘Ullapool harbour pier/berthing improvement’-a marine infrastructure project in the Scottish highlands, was made on its perceived ability to resonate with the Kestle (2009) management framework and provide data and insights into how well the framework resonated/fitted with this multi-stakeholder remote site project.

The qualitative data were collected using semi-structured interviews with 5 selected participants and these were later codified, and analysed to identify whether and how the stakeholders’ added-value expectations had been met, and if the management framework did in fact reflect the realities of designing and managing this particular remote site marine infrastructure project.

Participant selection for this research was made on the basis of the participants’ roles and disciplines, and whether they played a management role, and/or were key players on the Ullapool Harbour Pier Improvement project in the Scottish highlands. The selected participants were stakeholders, designers, construction managers and project managers. The aim of the participant selection, and subsequent qualitative semi-structured interviews with them in September 2014, was to try and establish the participants’ perceptions and realities of their first-hand experiences in the design office, and in-the-field, and how the project ran, on reflection, and whether and how value was added for the various stakeholders. The interviews ran for a minimum of an hour and thirty minutes per participant, using the ethically approved open-ended interview questions (refer Appendix A). The interviews were conducted within the context of the participants’ official roles on the project. This involved exploring the management approaches, the challenges at the pre-planning and operations stages, the reflections and learnings from the project in Part A, and seeking detailed participant responses to the relevancy of the four key factors of the Kestle (2009) management framework to this particular project in Part B.
4 RESULTS AND REFLECTIONS

4.1 Overview of the case study project

The project, located in the northwest Scottish highlands was initiated by the clients/stakeholders (Ullapool Harbour Trust, Stornaway Port Authority and CEMAL (Caledonian Maritime Assets Ltd)/CalMAC - Caledonian, Macbrayne ferries), as a result of a decision to increase ferry passenger capacity between Stornaway and Ullapool, and which involved the commissioning of a new 13000 tonne, 115m long ferry for delivery in late 2014. The new ferry weighed 50% more than the existing ferry, and was15m longer. There was originally only one pier, and one linkspan at Ullapool, whereas there were already two piers at Stornaway, hence the decision by the various Port and Ferry service stakeholders to extend the current Ullapool pier by 35m, and call for interested marine infrastructure designers to compete for the appointment to design and manage the tendering of the project.

4.2 Key factors for consideration and resultant design challenges

The Ullapool pier and berthing improvement project was designed, consented and tendered in the period from 2010 till 2013. Factors for consideration included the fact that winds are often over 25knots. This fact had previously meant 1/3 to 1/2 of existing ferry sailings being cancelled, so the capacity of the new pier extension thrusters needed to be increased for when winds are over 25 knots to help the ferry when reversing into the extended pier. The berthing velocity needed to be 0.2m/s, as the energy absorption of the current pier of 3500 ton displacement, could not resist the 6054 tonne displacement of the new ferry. Hence new and innovative 8m long fenders, known as ‘parallel motion fenders’ were designed and installed on the pier extension. According to the interviewed participants, energy absorption is absolutely critical when designing piers. The design of the fenders had to be undertaken first before any of the other considerations were addressed, and the fenders were only to be attached once the caisson was installed at the Ullapool pier. The thickness of the caisson walls was critical as well, too light it would fail under hydrostatic pressures, too heavy and it might sink.

4.3 Stakeholder criteria and consequent impacts on the type and installation of the pier extension structure

Avoiding disruptions to the use of the harbour by ongoing ferry passenger services, cruise ships, fishermen, tourists, and avoiding disruptions to tour bus operations, and local residents’ and businesses, was absolutely pivotal to meeting the stakeholders’ value criteria/added expectations of the project. Therefore, after several piling options were considered, the decision was taken to increase the budget to facilitate the construction of a 35x14mx15m high caisson off-site, some 140miles/230 km away at Greenock, Glasgow and float it north along the coast to the Ullapool pier over a 2.5 day period. This called for design, construction and logistical innovations, to ensure that the right design solution, safe delivery and installation at Ullapool. The risks were significant, on reflection, according to the participants, given the fact that this off-site prefabrication and delivery approach was a first, the dramatic off-shore coastline to be navigated, the unpredictable weather, challenging spring tides, and the constant risk of capsize of the 4000 tonne caisson that consisted of 12 cells filled with water ballasting to weigh it down sufficiently for the trip to the pier site. When the caisson was floated in a fenderless state to the pier, there were on average 5.5m tide changes.

4.4 Management Frameworks, Pre-planning, Operations, and Communications

In summary, neither the designers, nor contractors operated a hierarchical management framework. Instead teamwork, partnership, a no-blame organisational culture, and an open-company approach was the norm. The resultant pier improvement project personnel were a team of informed, included and acknowledged staff, sub-contractors, and clients/stakeholders. Significant pre-planning was a constantly held view by participants of how and why the project succeeded in meeting stakeholder expectations. Pre-planning by the designers and contractors included extensive, thorough, albeit exhaustive detailing of every element, component, pre-fabrication process, operational logistics, installations, coordination of trades at the pier and foreseeing harbour-use contingencies. Communications were collaborative,
inclusive and regular during all of the design and operational stages. All the design and construction staff were expected to be quick problem-solvers and deal with any problems immediately. Daily communication meetings were held between the client, designers and contractors once site work commenced, resulting in positive progress, open frank discussions and collaborative decisions, resulting in a very positive work environment and best end product. Staying on top of the details was suggested as another reason for the success of this (and other) project(s), and was a commonly held view amongst the participants’

4.5 Reflective Analysis of the (Part B) management framework factors’ findings

a) Value Generation

The clients and stakeholders non-negotiable value criteria were that this project had to be completed by August/September 2014, for the new ferry service to potentially commence late 2014, and that there be minimal disruption to ferry schedules, any and all harbour users, tour operators and local residents.

In addition, the Ullapool pier improvement project had to be well project managed, timing and keeping to budget was also absolutely critical for client/stakeholders. All of these criteria were met, and the ongoing feedback from clients/stakeholders as work progressed, and as it completed have been very positive on all counts. The off-site caisson decision was the right one as was the decision to award the contracts to the successful designers and contractors who paid significant attention to pre-planning, detailing, logistics and an inclusive non-hierarchical team approach. The resultant was a project that met all of the stakeholders’ and client’s value criteria – no disruptions to harbour users, met the strict timelines and was definitely fit for purpose.

b) Process Generation

This project was all about forward planning and logistics from a process integration perspective - building the 35x14x15m high caisson off-site at a considerable distance (230km) from the pier site, and then also ensuring that the pier was ready to receive the caisson. The work platform was very tight (35x14m), with 4 very different contractors there at any one time, including teams of divers, grit blasters, concrete pumpers, and crane operators. A total team involvement, including the designers, clients, designers, contractors, sub-contractors, caisson prefabricators et al from day one, and even before day one, was obviously key to the successes achieved within the very tight 6 month construction timeframe, embracing specialised design and construction innovations, and logistical risks.

c) Specialised Knowledge Integration

The fact that the designers and contractors’ had previous specialist pier experience, even though the caisson approach was a first for them. Apart from the prefabrication of the caisson, the project utilised local people, local knowledge/solutions, and local networks proved invaluable for this project from the stakeholders’ perspective. Specialist knowledge was definitely needed though on this site, for example, previous and detailed knowledge of ground conditions under the future caisson position, ballasting specialists were essential, divers experienced in attaching anodes to the steel piles and thence to the caisson, painting and concreting below water, and the need for very specialised marine specific IT knowledge. Early contractor and sub-contractor involvement with local knowledge across all or most of the tasks was invaluable on this project. Achieving demanding ‘tolerance controls’ under water for caisson work was a significant lesson learned for future projects according to the participants.

d) Timely/Critical Decision Making

The start time in January 2014 was a difficult time of the year to start such a project, being winter, and northern Scotland. However, according to the participants the extensive pre-planning meant that everything went as planned in terms of the caisson and foundation aspects of the project. Funding constraints meant that monies had to be spent by the end of March, so working through some of the worst months weatherwise, with limited daylight was a real challenge at times. Deferring end-budget to
end-summer might help future projects. However, in future a new challenge for infrastructure projects is that consents have to be in place before any funding is sought. Decisions were always made cooperatively and collectively between on-site and off-site personnel, and were always unambiguous in terms of the tight construction times and tides, creating trust, buy-in and best solutions. Delegated authority was key. Workable tides only ever occurred 3 times/fortnight, which together with strong seasonal winds created pressure points on the project that had to be met, no question. This was particularly important, as it significantly affected decisions around when diving operations could be undertaken, especially painting, anode attachments, and concreting activities best conducted at those lower tide levels.

4.6 Overall reflections, learnings and relevance of the model to the focus project in the Scottish highlands

The client/stakeholder representative provided feedback at daily meetings with the on-site including the designers, and this at times included off-site staff as well. This in their view resulted in clear and timely communications throughout the project, and avoided potential misunderstandings and programming holdups. In terms of the pre-planning, it was noted by the participants that the designers, client, stakeholders, the potential contractors and sub-contractors were meeting regularly around the table. At these meetings the potential contractors were made aware that they had to provide a method in their tender for the caisson, rather than for piling, and had to demonstrate and explain how they planned to mitigate disruptions to all the harbour users. The caisson approach was a new experience and challenge for those who had been involved with previous pier construction, so it carried a modicum of risk and the chance for innovation as well. The resultant design, logistics and construction methodology worked well according to the stakeholders and the participants interviewed. The caisson was floated into position in June 2014, and the completed project handover was 25th September 2014, meaning the project was on-budget and well ahead of the scheduled ferry delivery time in late 2014.

The participants all commented that the four factors did in their view model the key aspects of the design and management on and off-site for this project, and when undertaking a multi-stakeholder remote site projects. Participants were quick to identify ways in which the process integration, value generation, specialist knowledge and timely/critical decision making applied to this and other remote site projects that they had been involved on, and often answered giving some in-depth examples. They found the semi-structured interview research process very useful in terms of offering them a chance to reflect on their experiences and identify the areas of reassurance around their on and off-site practices, and the lessons learned from the Ullapool pier improvement project. One of the commonly held views amongst the participants in terms of best practice management of the project, was how well the collaborative approach involving all the on-site and off-site staff, and stakeholders had worked, both before and during the construction stages.

5 CONCLUSIONS

The objective of this research was to establish and reflect on how well the Kestle (2009), multi-stakeholder management framework for remote site projects modelled the realities/experiences on and off-site, and added value for the stakeholders in terms of their expectations and requirements, on the Ullapool pier improvement project in the Scottish Highlands. The methodology undertaken involved conducting semi-structured interviews with designers, stakeholders, construction and project managers on the pier project, in September 2014 as the project concluded, and was handed over to the client/stakeholder representatives. The findings suggested that the reasons for the project achieving the stakeholders goals and a value-added result resided in the extensive pre-planning, thorough detailing, quick problem-solving, and working collaboratively at all times across all the players, before and during the construction stages, therefore keeping everyone informed on a regular often daily basis. In addition, specialist knowledge of pier design and construction, local labour, local networks, and the local challenges (such as tides and weather, ground conditions), were invaluable to the success of this project being delivered to budget, to stakeholder criteria, and well ahead of schedule in readiness for the new ferry at this remote site location in the Scottish Highlands.

Appendix 1

INTERVIEW SHEET

Part A
The focus of this part of the interview is on the official role that you play(ed), from a management/managed perspective.

Name of Interviewee                                                         Date
Name of the Project

Q1
In your role (and your official capacity) as ............................................ on this project, please identify
a) Your job description, briefly, in terms of your key responsibilities on this project, and how they may have changed during the course of the project.

b) If there were changes during the course of the project, how did these impact on your role and/or on the project overall

Q2
(a) What in your official role, were the main (management) challenges that arose during the project. Please answer this question as concisely as possible, under the bulletted headings below.

• Management framework and approaches,
• Pre-planning and detailed planning stage(s)
• Operations stage
• Communications
• HR
• Funding
• Other challenges
(b) Recommendations / lessons learned for future projects

Part B
The next few questions are related to the exploratory conceptual design management model/framework developed by Kestle (2009) for multi-stakeholder international remote site projects.

Please find a copy of the model/framework attached to this questionnaire, as we would like to test some of those ideas with you relative to this particular project.

Q3
In terms of this Project in particular, and your role on that project, please comment on:

a) Value Generation – (the value that the client/stakeholder places on the particular site and the project, and the value various roles add to the outcomes)

• what are/were the clients value criteria,
• what are/were the stakeholders value criteria
• how do you know or measure the effectiveness of your role on this project
• are there any rules-of- thumb that you intuitively apply(ied)
• how and what type of feedback do you get/ have you received from clients
b) Knowledge Integration - (a combination of relevant specialist knowledge across IT, design briefing, pre-planning/early contractor involvement and at the construction/operational stages)
• specialist on-site construction knowledge expectations/challenges
• IT for remote site coordination challenges
• are there gaps in the specialist knowledge that you are aware of in your area of involvement on the project, and if so what
• how is what you have learned on this project passed on to others during the course of the project, and for future projects
c) Process Integration
• logistics and site accessibility challenges
• design and the production interface challenges construction/operational planning/methodology
• alternative procurement strategies
• what methods or approaches do you employ to achieve your goals and fulfil your role
• how have you improved/added value to this approach, or to the system(s) used
• what role does HR play, or could it play (staff training /upskilling)
d) Decision Making
• how are the decisions made – and are they decentralised or centralised
• what are the expected performance criteria expectations on staff and their accountability
• are there limited operational windows, and if so when and why do they occur
• what are some of the economic constraints (are there tight/impossible budgets?) and how are budgets maintained
• how are any environmental sustainability sensitivities of the site, and likely impacts addressed and managed

Q4 Other comments, that you consider may be relevant to this research
CHALLENGES AND OBSTACLES FACING TENDERERS ADOPTING E-TENDERING IN THE PUBLIC SECTOR OF THE CONSTRUCTION INDUSTRY IN EGYPT

Cherif A. Khalil1,2 and Ahmed F. Waly1
1 Department of Construction and Architectural Engineering, The American University in Cairo, Egypt.
2 cherif88@aucegypt.edu

Abstract: The construction public sector in Egypt, like most countries in the world, is tendering its projects through the traditional paper-based tendering procedure, which has many weaknesses including bureaucracy and lack of transparency. Due to the considerable volume of projects tendered each year, it was essential to study the possibility of implementing another more efficient mechanism “E-Tendering” that overcomes the drawbacks of the paper-based tendering procedure. This on-going research examines the readiness of the construction industry in Egypt to adopt E-Tendering for public tenders and provides recommendations to improve its uptake. This paper provides a model of the barriers, challenges and concerns of the Egyptian tenderers towards accepting and adopting E-Tendering. This is accomplished through extensive review of the literature together with expert identification and analysis. 19 challenges are highlighted and categorized into 4 categories: security challenges, user acceptance and staff resistance, accessibility issues and legal barriers. These challenges are then examined and ranked with respect to their importance by a panel of academic and industry experts to reflect the Egyptian public tendering context. The most important highlighted barriers are the SMEs access difficulties, the expected technical malfunctioning of the portal, the reluctance/resistance to change and the breach of confidentiality of information. These findings present a cornerstone in the development of a framework that presents practical solutions to the success of E-Tendering for the construction public projects in Egypt.

1 INTRODUCTION

The construction industry in Egypt is one of the most active and dynamic sectors of the economy. It accounts for 7% of the Gross Domestic Product (GDP) and by the year 2015, the investments in this sector are expected to reach US$7.3 billion (General Authority for Investment and Free Zones [GAFI] 2014). Unfortunately, a number of research have shown that bribery and corruption are rampant in the construction sector worldwide according to Transparency International’s 2002 to 2011 Bribery Payers Index (BPI) (Hardoon and Finn 2011). Concerning Egypt, the European Bank for Reconstruction and Development (EBRD) has published a report in 2013 containing a review of its public procurement practices. The report highlights that companies in Egypt face a high risk as the procurement process is burdened with lack of transparency, bureaucracy, ineffective monitoring and review mechanisms together with unethical public procurement officials (Business Anti-Corruption Portal 2013). Moreover, it is argued that the traditional paper-based tendering process in Egypt is full of inefficiencies (EBRD 2013). It is also worth noting that according to the Canadian Construction Association (CCA), in a typical construction
project, the cost of tendering to a client accounts for up to 5.85% of the total cost of a project (Hore et al. 2007).

Consequently, it is imperative to find a more efficient mechanism to replace/complement the traditional paper-based tendering processes of the construction public works in Egypt in order to reduce the considerable cost of tendering, save lots of money wasted due to the inefficiencies of the traditional tendering, increase transparency, and reduce corruption in the public sector. The proposed solution is the adoption of E-Tendering.

2 E-TENDERING IN CONSTRUCTION

2.1 Definition and processes of E-Tendering

According to the Royal Institute of Chartered Surveyor (RICS 2007), the basic principles of traditional tendering are preserved in E-Tendering while enhancing the way of communication through finding an alternative medium through which the tender documents and information are exchanged. This medium is further defined by Amarapathy et al. (2013) as E-Tendering portals that are “secure dedicated websites, specifically set up for the exchange of information and tender documents electronically over the internet”. The ultimate goal/objective of E-Tendering as clarified by Amarapathy et al. (2013) is a complete shift from paper-based manual tendering, to fully automated electronic means of communication. This would significantly decrease or even eliminate paper handling, speeding up interaction and communication between the different parties involved, and hence increases productivity and efficiency (Seah 2004). Technically, the E-Tendering concept/process combines a number of processes that take place before the award of the contract. It mainly involves E-Notification, E-Access, E-Submission, E-Evaluation, and sometimes E-Awarding.

2.2 Advantages/Benefits of E-Tendering

Kajewski and Weippert (2004) cited the NSW Government and Department of Commerce highlighting the benefits that construction professionals and governmental departments/agencies could gain when implementing Electronic Tendering processes. These benefits and advantages are grouped in 3 categories: General Perspective, Industry perspective and Government perspective.

General Perspective: streamlines the entire tendering process; provides secure and improved access to tender documents; makes it easier for businesses to obtain tender documentation and to submit an offer online on time as the postal system is no longer needed (Lavelle and Bardon 2009); maintains an audit trail of all communication (RICS 2007); virtual elimination of errors due to strict process (MERX 2014); ability to automatically eliminate noncompliant bids, hence saves time (MERX 2014); saves money and time as the electronically submitted tenders are downloaded in a suitable form that facilitates evaluation without requiring the client’s representatives to re-enter the data manually.

Industry perspective: increases tender opportunities, competitiveness and promotes transparency; provides easy and fast access to private and public tender information; facilitates remote accessibility to the tendering system which improves access for geographically isolated industry practitioners/organizations (Amarapathy et al. 2013), and hence assures fairness regardless the tenderers’ geographical area (MERX 2014); reduces the cost of printing and copying which saves time and resources (Lavelle and Bardon 2009).

Government perspective: better value for the money of the taxpayers; increases effectiveness and efficiency; standardizes the tendering processes across the government; promotes E-Government initiative; environmentally friendly due to a predominantly paperless process, so no waste generated (RICS 2007).

In addition, Lavelle and Bardon (2009) demonstrated additional benefits for E-Tendering such as the reduction in administration processes via providing one single source of information. Consequently, duplication of documents does not occur and any revisions to the documents are kept track of and notified to the tenderers as audit trail/log is provided through the system. Moreover, Tindsley and Stephenson (2008) indicated that E-Tendering can provide full automated assessment with computerized analysis, hence, fairer and faster evaluation of the tenders submitted. Also, the system could automatically identify incomplete or unusual entries, thus reduction in communications and faster analysis
as well. Furthermore, according to the International Data Corporation (IDC) (2013), EU public contracts
tendered electronically and processed with electronic submission were 13% lower on average than public
contracts traditionally tendered.

3 RESEARCH AIM AND SCOPE OF THIS PAPER

In many developing countries, E-Tendering is regarded as unnecessary and unfeasible given the number
of social, cultural and economic barriers that are expected to hinder its implementation. So this on-going
research investigates the readiness of the construction industry in Egypt to adopt E-Tendering and
provides recommendations for its implementation.
The scope of this paper is limited to the identification of the barriers, challenges and concerns of the
tenderers towards accepting/adopting E-Tendering in Egypt.

4 RESEARCH METHODOLOGY

Since this is an exploratory research in nature, qualitative approach is adopted in identifying from the
literature a list of the most common challenges that influence the tenderers' acceptance/adoption of E-
Tendering worldwide. These challenges are then categorized in 4 categories: Security Challenges, User
Acceptance and Staff Resistance, Accessibility Issues and Legal Barriers. The list of identified challenges
is then presented in a form of a survey questionnaire to a panel of 15 knowledgeable experts in the field
of tendering in Egypt in semi-structured interviews. The experts were required to mark/check on a 5-scale
Likert item the probability/likelihood that a tenderer considers the challenges as obstacles against the
adoption of E-Tendering in Egypt. The survey output is analyzed using the adjusted relative importance
index to identify and rank the highest obstacles against the tenderers. Hence, the sampling design used
is non-probability sampling and more specifically purposive sampling. The expert interviews are
conducted since their expertise and experience add more depth to the research taking place. The panel
of experts is composed of academic and industry professionals, which included consultants and
contractors. The experts are selected based on their expertise in the field of tendering in Egypt and based
on the criteria and they carried out/participated in more than 50 tenders.

5 THE IDENTIFIED CHALLENGES/CONCERNS OF THE TENDERERS

The preliminary findings for the barriers, challenges and concerns of the tenderers are grouped in the
following 4 categories: security challenges, user acceptance and staff resistance, accessibility issues, and
legal barriers. These challenges/barriers were developed and grouped after extensive review and
analysis of the literature in order to identify the barriers hindering the adoption of E-Tendering.

5.1 Security Challenges

- Document tampering i.e. when a person makes unauthorized and unfair modifications to the tender
  (Eadie et al. 2010).
- Problems with data integrity after reassembly - possibility of inaccurate, incomplete, corrupted data
  after reassembly (Davila et al. 2002).
- Confidential documents getting leaked to competitors (Davila et al. 2002).

5.2 User Acceptance and Staff Resistance

- High investment costs to adopt and maintain E-Tendering with no substantial benefits realized
  (Samuelson 2008).
- Reluctance/Resistance to change i.e. general attitude that old ways of doing things have worked well
  throughout the years and changes are unnecessary (Olukayode and Adeyemi 2011).
- Unethical investors and corrupted officials will fight to continue with the traditional paper-based
  tendering which is full of leaks (fear of potential loss of bribery) (Mastor et al. 2006).
- Automation is a threat to the employees' jobs.
• E-Tendering is more time consuming than traditional tendering.
• E-tendering is an additional workload with no compensation/reward.
• Lack of leadership/upper management support (Eadie et al. 2010)

5.3 Accessibility Issues

• Fear of using non-compatible software with the client/consultant system hence tender submission could get rejected "noncompliance" (Samuelson 2008).
• Irregular electric power supply will affect the E-Tender processes especially the tender submission (Olukayode and Adeyemi 2011).
• A fear that a technical malfunctioning of the portal could cause disturbance to the electronic submission of the tenders.
• Poor telecommunications infrastructure will affect the E-Tendering processes (Olukayode and Adeyemi 2011).
• E-Tendering requires high speed expensive internet services.
• A large portion of the Small Medium Enterprises "SME’s" especially in Upper Egypt are computer illiterate hence will face difficulty to apply, prepare and submit tenders electronically.
• The contractors will bear the costs and responsibility of copying and printing the drawings for the subcontractors.

5.4 Legal Barriers

• Complex, time consuming and onerous regulatory procedures (IDC 2013).
• Problems with proof of intent of the tenderer (Eadie et al. 2010).

6 THE CONDUCTED SURVEY QUESTIONNAIRE

After being introduced to the list of identified challenges from the literature, the experts were asked to check/mark on a 5-scale Likert item, the probability/likelihood that a tenderer considers the challenges presented in the list as obstacles against the adoption of E-Tendering specifically in Egypt. In addition, the experts were asked to identify more challenges/barriers if any.

The scale consisted of the following 5 points:

<table>
<thead>
<tr>
<th>Scoring Number</th>
<th>Scoring Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Score 1 - Strongly Disagree</td>
<td>The challenge will strongly motivate tenderers to accept E-Tendering</td>
</tr>
<tr>
<td>Score 2 - Slightly Disagree</td>
<td>The challenge will slightly motivate tenderers to accept E-Tendering</td>
</tr>
<tr>
<td>Score 3 – Neutral</td>
<td>The challenge will neither motivate nor prevent tenderers from accepting E-Tendering</td>
</tr>
<tr>
<td>Score 4 - Slightly Agree</td>
<td>The challenge will slightly prevent tenderers from accepting E-Tendering</td>
</tr>
<tr>
<td>Score 5 - Strongly Agree</td>
<td>The challenge will strongly prevent tenderers from accepting E-Tendering</td>
</tr>
</tbody>
</table>

It is debatable whether the distance between each response in a 5-scale Likert item is equal or not since numerous research provided different conclusions as highlighted by Holt (2014). In this research, the Likert items are symmetric (5-scale) and interval in nature, hence the difference between each response can be considered equal in distance (Holt 2014).
6.1 Data Analysis

The survey output is analyzed using the adjusted relative importance index (RII) to identify the rank (relative importance) of each barrier/challenge hindering the uptake of E-Tendering in Egypt in order to address and tackle them. The adjusted RII equation used in this research is shown in Eq.1 (Holt 2014).

\[ \text{Adjusted percent equation} = \text{RII } \% \text{ adjust} = 125\times\left(\frac{\sum P_i}{N\times n}\right) - 25 \]

RII = Relative Importance index

RII % adjust = Relative Importance Adjusted Percent using scale (Rmin=1 to Rmax=5)

\( P_i \) = Participant’s rating of the barriers/challenges hindering the uptake of E-Tendering

\( N \) = Total number of experts

\( n \) = Highest attainable rating for one trial = 5

The above equation yields “the true percentage for scales where Amin = 1 and, achieve unity (i.e. 0-100 per cent)” as shown below (Holt 2014).

- The minimum rating is RII % adjust = 125\times[15\times1 / 15\times5] - 25 = 0
- The maximum rating is RII % adjust = 125\times[15\times5 / 15\times5] - 25 = 100

Initially, 5 experts were only selected to conduct this survey questionnaire, but since there was variance in the data they provided and each expert added valuable information to the research, it was essential to conduct more expert interviews in order to reach the point where the data converges i.e. limited variance and hence good coverage of the research in consideration. As highlighted earlier, the final number of interviewed experts is 15.

6.2 Results and Discussion

The below table shows that all the experts agree that 16 challenges (RII above 3 or above 50\%) out of the 19 identified from the literature can be considered as obstacles against the widespread adoption of E-Tendering in Egypt; whereas 3 challenges (RII below 3 or below 50\%) are considered a motivation to the tenderers in Egypt. It is important to note that no more barriers were identified by the experts other than the ones that were provided in the list of preliminary challenges provided to them.

The highest challenges against the widespread adoption of E-Tendering in Egypt are the SMEs access difficulties (RII\% = 88.33\%), the expected technical malfunctioning of the portal (RII\% = 86.67\%), the reluctance/resistance to change (RII\% = 80\%), the breach of confidentiality of information (RII\% = 76.67\%), the electronic signature problems (RII\% = 76.67\%) and the document tampering (RII\% = 75\%).

</tbody>
</table>

Shown below is a detailed analysis of each of the challenges together with its corresponding RII adjusted percentage.

1. **SMEs Access Difficulties (RII% = 88.33%)**

There is a great concern that the small and medium enterprises will be unable to participate in the E-Tendering processes especially that smaller enterprises in Egypt are probably computer illiterate and lack the basic needs (computer, internet, etc.) which are necessary for the participation in the E-Tendering processes.

2. **Technical Malfunctioning of the Portal (RII% = 86.67%)**

Given the fact that Egyptians lack trust in any governmental provided service, there is a strong fear that the portal could malfunction (i.e. broken links, service unavailability, slow page load,…) especially during the submission of the tenders. Furthermore, if technical malfunctioning of the portal occurred and it was impossible for the tenderers to submit their tenders, many will be suspicious and will file claims of corruption against the entity running the portal especially that Egyptians nowadays believe in conspiracy theories.

3. **Reluctance/Resistance to Change (RII% = 80%)**

This is a very strong cultural trait in the Egyptians and humans in general. It is always perceived that if old ways of doing things are good, there is no need for going the extra mile and doing something unconventional (i.e. moving to paperless processes) to the norms is unnecessary.

4. **Confidentiality of Information (RII% = 76.67%)**

The experts have a great fear that the confidential data sent to the government personnel before the deadline are prone to breach and leak to other competitors even if the tenders were password protected. This stems from a number of reasons, mainly, that the corrupted people will always find a way and that hackers are unstoppable as they always infiltrate through finding vulnerabilities/weaknesses in the system.

5. **Signature Issues (RII% = 76.67%)**

Most of the experts do not accept putting their handwritten signatures on a document and sending it online (i.e. electronic signature) since their signatures could be copied and pasted on other documents by unethical government personnel or unethical competitors.

6. **Document Tampering (RII% = 75%)**

Almost all the experts agree that sending tender documents online is not safe since their data could be altered/modified by unethical government personnel or by hackers who could infiltrate into the system.
7. Lack of Support (RII% = 73.33%)

The interviewed experts believe that in Egypt the upper management of the companies would not support adopting E-Tendering. This stems from the fact that most of the upper management figures are old people that are not used to have a computerized system; they do not know how to run an electronic system nor have the time to learn it. In addition, it is also important to note that the decision-making figures of the companies, before submitting their tender envelopes to the client, make last second changes (addition or reduction of a certain percentage) to their tenders. Mainly, this happens because they want to make sure no one knows the submitted tender price especially that they fear the presence of corrupted personnel in their companies who could inform their competitors of the submitted tender price. Consequently, these decision-making figures, in case they will not be capable of using the E-Tendering system (i.e. due to complexity, computer illiteracy, etc.) will never trust an employee to deal with a system on their behalf without their full control and awareness.

8. Irregular Electric Power Supply (RII% = 70%)

Unfortunately, there is irregular power supply nowadays in Egypt especially during summer time and this is expected to continue for few more years. The electricity goes down without any notice, for different durations, and in different areas unequally. Consequently, most of the interviewed experts (more than 70%) believe that this irregular electric power supply could disturb the tendering process especially if the tenderers were unable to submit their tender responses before the deadline due to electricity shortage. It is important to note that not all the tenderers have an Uninterruptible Power Supply (UPS) and also the UPS have time limit capacity.

Moreover, sometimes, when there is electricity shortage, the landlines (internet) stop working. Hence, the usage of a UPS will not help in submitting the tender online; unless a USB internet modem is used in addition to the UPS.

9. Poor Telecommunications Infrastructure (RII% = 70%)

This is one of the very important challenges that need to be carefully addressed by the government since most of the experts believe that there is a serious problem with the network of telecommunications in the different governorates in Egypt, which will seriously impact the adoption of E-Tendering. It is argued that some areas do not have internet services at all in Egypt.

10. Software Non-Compatibility Issues (RII% = 68.33%)

Given the fact that the tender response will be electronic/softcopy, not a hardcopy, most of the experts believe that a problem of software non-compatibility between the tenderers' computers and the computer of the client will arise, which will seriously affect the submitted tender documents. In other words, the documents sent from the tenderers, will not open on the computer of the tender evaluators due to software non-compatibility issues (different software, different version of the software, etc.).

11. Corruption Seekers (RII% = 66.67%)

In Egypt, although most of the plans proposed by the different governments are always important to be implemented, one of the major problems that hinder their implementation is that that there is always a strong resistance from within the governmental entities in order to not adopt such plans that could have major impact on the unethical personnel working in the different entities. Also, this problem aggravates when such proposed plans impact negatively the unethical investors and the illegal tycoons who control the market and who would exert all the necessary efforts to halt such plans.
12. Subcontractors Dependency on Contractors (RII% = 65%)

Most of the experts believe that always the subcontractors depend on the contractors in the transmission of the tender documents; in other words, there is no difference in the transition from traditional paper-based to electronic tendering. The experts believe that this dependency negatively affects the contractor as he loses both time and cost.

13. Bureaucratic Regulatory Procedures/Requirements (RII% = 61.67%)

All the experts stress on the fact that the bureaucratic regulatory procedures required by the government are a major reason that makes the Egyptian tenderers uninterested, unwilling and unable to participate in governmental tenders. Almost one-third of the experts believe that the introduction of E-Tendering will not have any positive impact to solve these bureaucratic requirements (the problems will persist in both traditional and electronic tendering). Another third believe that E-Tendering will actually make the process more complex (especially for the proof of intent and authentication of the tender documents - signature) and the last third believe that E-Tendering will make the process much easier (especially concerning the discovery of the tender opportunities and the submission of the tender documents).

14. High Speed Expensive Internet Services (RII% = 60%)

Most of the experts believe that E-Tendering does not require a high speed internet services in order to have smooth operations, however, a number of experts (27%) expect that small tenderers will face difficulties and will have to subscribe in higher bundles than the ones they use.

15. E-Tendering High Investment Cost (RII% = 55%)

Almost 50% of the interviewed experts agree that there is a high investment cost needed in order to operate/function adequately on the E-Tendering Portal. This investment cost includes buying new computers, specific software, licenses, hiring competent personnel, training sessions, etc.

16. Data Integrity (RII% = 51.67%)

Problems with data integrity, which includes possibility of inaccurate, incomplete or corrupted data after reassembly since the tender response is not sent as a hardcopy, is only perceived by 27% of the experts as a challenge/obstacle towards the adoption of E-Tendering. On the other hand, some experts argued that whenever there are problems with the submission of a tenderer, they get contacted by the client representatives to clarify the ambiguities/unclear data in their tender response.

17. Time Consuming (RII% = 35%)

27% of the interviewed experts believe that E-Tendering is more time consuming than the traditional tendering and hence this will be an obstacle against its adoption by the Egyptian tenderers.

18. Additional Workload (RII% = 33.33%)

27% of the interviewed experts believe that E-Tendering is an additional workload since they expect that, after finishing their tender response, they will be required to fill in different forms in order to comply with the tender electronic submission; hence, wasting time without compensation/reward. Furthermore, all the experts affirm that structuring the tender documents in Egypt is too hard to be accomplished.

19. Automation Job Threat (RII% = 28.33%)

Automation of the tendering processes is only perceived by 27% of the experts as an obstacle towards the adoption of E-Tendering since the automation of the processes will have a negative impact on a limited number of jobs within the company (i.e. the secretaries, the drivers, etc.).
7 FUTURE RESEARCH DEVELOPMENT

The next step of this research is to develop a set of recommendations to tackle the obstacles and concerns perceived by the experts. Then verification and validation to the recommendations and solutions should be accomplished.

The verification will examine whether or not the proposed solutions and recommendations are applicable and doable technically. The verification should be accomplished qualitatively through introducing the recommendations to a panel of experts from different fields (computer experts, construction engineering experts, finance experts, etc.).

The validation will tackle the effectiveness of the proposed solutions to address the concerns of the Egyptian tenderers. The effectiveness of the developed recommendations should be validated quantitatively through introducing them to a bigger sample that represents the whole population of the construction industry practitioners to examine whether or not the presented solutions will address their concerns. The sample should include different construction professionals (project managers, quantity surveyors, designers, etc.) and different construction entities (contractors, subcontractors and suppliers).

8 CONCLUSION

This research provides an identification of the barriers, challenges and concerns that are expected to face the Egyptian tenderers when the government reveal its plans of the full adoption of E-Tendering. Further to thorough examination of the literature, 19 challenges were identified and categorized in 4 categories: security challenges, user acceptance and staff resistance, accessibility issues and legal barriers. Then 15 semi-structured interviews with academic and industry experts were conducted and the qualitative analysis showed that 16 challenges (RII above 50%) out of the 19 identified from the literature can be considered as obstacles against the widespread adoption of E-Tendering in Egypt; whereas 3 challenges (RII below 50%) are considered a motivation to the tenderers in Egypt.

Furthermore, the highest challenges against the widespread adoption of E-Tendering in Egypt are the SMEs access difficulties (RII% = 88.33%), the expected technical malfunctioning of the portal (RII% = 86.67%), the reluctance/resistance to change (RII% = 80%), the breach of confidentiality of information (RII% = 76.67%), the electronic signature problems (RII % = 76.67%) and the document tampering (RII% = 75%).

This research is a cornerstone in the development of a framework that aims to identify and address the barriers, challenges and concerns of the Egyptian tenderers towards the adoption of E-Tendering, hence improving the uptake of E-Tendering specifically for the construction public works in Egypt.

References

Abstract: Indoor Environmental Quality (IEQ), being one of the main pillars of sustainability, stretches its effect far beyond ensuring a pleasant environment for the occupants to live in. In fact, IEQ plays a major role in defining the level of productivity within organizations. Recent studies acknowledge the link between IEQ and employees' overall satisfaction at work, and in turn, productivity. The ultimate goal of an ongoing research project is to propose and validate a decision making tool that optimizes office buildings renovation projects based on maximizing occupants' satisfaction with the IEQ conditions at their workplace, and in turn, maximizing their productive time. The first step in this direction requires an understanding of the relationship between IEQ and productivity. This is achieved in this paper through a survey of corporate employees, which provides a correlation between the level of IEQ in an office setting and the overall level of satisfaction with the workplace. The latter is, in turn, correlated with the level of occupant productivity at work, as measured by the amount of productive time. The paper concludes with an empirical model based on statistical regression analysis, depicting the relationship between IEQ satisfaction and productive time.

1 INTRODUCTION

The overarching objective of any for-profit firm is to maximize profitability. The cost of employees is considerably larger than any other cost incurred in running most businesses. In fact, the cost of employees is more than 130 times the cost of energy in a typical workplace, and is 85% of the total costs incurred in a typical office building (Annika et al. 2013). Hence, to ensure a profitable operation, the benefits associated with the employees' productivity must outweigh the associated costs. In fact, a slight increase of 0.1% in employee productivity - by enhancing Indoor Environmental Quality (IEQ) factors such as occupant comfort and satisfaction - can yield a dramatic increase in profitability (Singhvi et al. 2005).

IEQ is defined as "a generic term used to describe the physical and perceptual attributes of indoor spaces. These include the indoor air quality and the thermal, acoustic and visual properties of the environment, as well as various characteristics of the furnishings, facilities and fitouts" (Newton et al. 2009). Fifteen different IEQ factors define the indoor environmental quality of a workplace; these are: thermal comfort, air quality and ventilation, amount of light, visual comfort, noise level, sound privacy, amount of space, visual privacy, ease of interaction, comfort furnishing, adjustability of furniture, colors
and textures, building cleanliness, workspace cleanliness, and building maintenance (Kim and de Dear 2012). Each of these factors has a unique impact on the physical and mental well-being of the occupants.

The main hypothesis tested in this study is the existence of a relationship between productive time and occupants’ satisfaction with IEQ conditions at the workspace. The relationship is said to exist due to the proven influence of the different IEQ factors on the well-being of the occupants, which, in turn, influences the level of productivity. The level of performance of the IEQ factors at the workplace is indicated via the self-assessed satisfaction levels reported by the occupants, and the level of productivity is estimated by measuring the productive time. Accordingly, the first null hypothesis tested in this study is:

\[ H_0 : \text{The level of productive time does not correlate with the level of satisfaction with the IEQ conditions at the workplace.} \]

The literature includes several studies that offer quantitative post-occupancy evaluation of the correlation between employee productivity and satisfaction with the workplace. However, the results of these studies differ widely due to the different approaches used for measuring satisfaction and productivity. The purpose of this study is to redevelop this relationship using a new method that targets the possible gaps spotted in previous studies. This method includes estimating productivity through measuring productive time, a more quantifiable parameter to assess. Satisfaction with IEQ is measured by self-assessing the level of satisfaction with each of the factors of IEQ, and then aggregating the assessments to estimate the level of overall satisfaction with the IEQ at the workplace, while taking into consideration the different level of influence of each IEQ factor on the overall satisfaction at the workplace.

In the next section, a literature review on IEQ is presented and related to the well-being, satisfaction, and productivity of building occupants. The third section presents the objective and the methodology adopted in this paper to test the existing relationship between productive time and occupant satisfaction, taking into consideration the spotted gaps in the literature. The fourth section begins with testing the hypothesis of this relation, and ends with a regression curve that raises a concern regarding extremely low satisfaction levels. The paper concludes by comparing the results with those of previous studies.

### 2 LITERATURE REVIEW

This section presents a literature review on the correlation between post-occupancy IEQ and the following three conditions: Occupants’ well-being, overall satisfaction, and level of productivity at the workplace. Based on the reviewed literature described in this section, the relationship among the three mentioned conditions can be depicted as schematized in Figure 1.

The four factors of IEQ, nature of work, psychological environment and space management, do not equally influence physical and psychological status; however, all four play a role in influencing occupants' satisfaction level, which, in turn, influences their level of productivity. It is important to note that the direct causality between all these factors as presented is only a simplified representation that is yet to be ascertained and validated, since the existing relationship among these factors is of high complexity.
2.1 IEQ Conditions and Occupants’ Well-Being

IEQ conditions at the workplace can have physical and psychological implications on the employees. Many studies examined the health implications of each of the 15 IEQ factors on occupants’ well-being (Singh 2009, McGrory 2012). As summarized in Table 1, many of the implications are common across several IEQ factors. This shows the complexity of the relationship between IEQ conditions and occupants well-being.

2.2 IEQ Conditions and Occupants’ Overall Satisfaction with the Workplace

Several studies examined the relationship directly between IEQ factors and occupants’ overall satisfaction at the workplace (Agha-Hossein et al. 2013, Frontczak et al. 2012). Of particular interest is Kim and de Dear’s work, which goes a step further in relating IEQ to satisfaction by giving weights to the IEQ factors. Kim and de Dear (2012) present a tool that allows for quantifying the level of occupant satisfaction with the IEQ conditions in the workplace by breaking it down into its 15 factors and applying the weighted effect of each factor on the overall resulting satisfaction level. Some of these 15 factors, named Proportional Factors – such as air quality, amount of light and sound privacy, have a direct relation with the overall satisfaction; i.e. as the level of perceived satisfaction with these IEQ factors increases or decreases, the level of overall satisfaction increases or decreases respectively, each with a different magnitude. Other IEQ factors, named Basic Factors – such as temperature, noise level and amount of work space, have a non-direct relation with the overall satisfaction. When such factors are perceived negatively, they inflict a negative effect on the overall satisfaction, while perceiving them positively barely adds to the overall satisfaction; quoting, “it is not easy to impress occupants with IEQ”. This classification indicates that every IEQ factor affects the overall satisfaction of the occupants differently, depending on their type and on how well they perform at the workplace. Some have linear relation with the overall satisfaction, while others do not. For this reason, it is highly important to include the weights of the IEQ factors while quantifying the overall satisfaction at the workplace.

2.3 IEQ Conditions and Occupants’ Productivity

Productivity, being the essential organizational outcome, forms the main indirect economical benefit of IEQ enhancements. As shown in Figure 1, IEQ is among the four main factors that describe the overall satisfaction and comfort of employees at their workplace, which in turn affects their level of performance and productivity at work. Enhanced indoor environments in office buildings have a positive correlation with occupants’ satisfaction, yielding higher levels of well-being, which, in turn, positively correlates to productivity. The approaches followed in analyzing the relationship between productivity and IEQ can be categorized into three methods. The first method consists of qualitatively analyzing IEQ investments and yielding benefits. A detailed conceptual relation presented by Seppanen and Fisk (2003) show that health and productivity are highly improved when proper measures are taken to enhance IEQ conditions. The second method, such as the one used by Wyon (2004), relies on statistical techniques to examine the effect of IEQ conditions on productivity. This method analyzes the effect of each IEQ factor independently. For example, air quality is among the IEQ factors that could highly affect office work performance by up to 9%. Despite the fact that segregating the many IEQ factors simplifies the analysis, the sum of their individual effects on performance would not be equal to the combined effect of all factors acting together. The third method looks at IEQ as a whole as opposed to analyzing the effect of individual IEQ factors on productivity independently. Oseland (2004) found a linear relation between productivity and both, environmental and facility factors at the workplace. However, Oseland’s measuring of productivity was based on two self-assessed questions which ask the respondents about the effect of the facility and the environment on their productivity, along with several other questions of which are concerned with downtime such as waiting for lifts, walking between buildings, and other similar questions that might not link to IEQ conditions specifically. Moreover, the IEQ factors were not weighted while calculating the overall satisfaction, such as the case with Kim and de Dear’s study.

Contrarily, Somers and Casal (2009) proposed a nonlinear U-shaped relation between productivity and satisfaction. No explanation was reported regarding this unexpected relation: as satisfaction increases, productivity decreases for the lower levels of satisfaction. Artificial Neural Networks were used to model nonlinearity. Job performance measurements of the employees were taken from the organization’s formal performance appraisal process and reflected supervisor ratings of employee job performance. Beside the possible inaccuracy and bias associated with such productivity measuring techniques, the sample was limited to nurses and psychiatric technicians drawn from a university medical center. Despite the limited sample of this study, it presented the possibility of having nonlinear relationships between IEQ and performance, and hence productivity, which could negate the generalization of Oseland (2004)’s findings.
It is important to note that all of the three methods described in this section use similar means for measuring job performance and productivity level. Productivity is measured by either self-assessments or by simulating office activities (typing, proof-reading, addition, etc.) Self-assessments are not quite accurate primarily due to the lack of reliable benchmarks. Moreover, being aware of the fact that they are being studied, occupants’ might report biased self-assessments of productivity. Simulating office works, on the other hand, includes uncountable tasks to be properly measured. In addition, some tasks might not always be affected by the level of IEQ satisfaction, depending on the difficulty of the task at hand. This makes it challenging to quantify job performance and productivity, and highly lowers the accuracy of the results. Moreover, simulating office work would inevitably include bias since, again, the studied sample is aware of being observed. Another important point is the fact that adding or averaging productivity measures for the sampled employees might be misleading. The level of output for the same state of satisfaction might significantly vary from one employee to another, depending on their nature of work, experience, psychological or physical status, etc.; thus employees with low satisfaction might have outputs equal to or higher than that of satisfied employees.

The best way to attain valid measures is by studying employees’ productivity level at their own offices, while performing their routinely tasks, and without being aware of a direct assessment of their abilities (Haynes 2008). Such a technique has rarely been used in a job performance versus job satisfaction study due to being practically infeasible. This fact is due to the complexity of controlling the many possible combinations of IEQ conditions if analyzed as a whole, difficulty of measuring irregular day-to-day tasks, and difficulty in studying the productivity of employees while at work without having biased results. Due to the complexity in objectively measuring the level of productivity on all its aspects, this paper focuses on productive time related to IEQ conditions. Non-productive time, in this context, is defined as the working time wasted by not being productive due to poor IEQ conditions specifically, subtracted from the total working time of an employee. Measuring productive time rather than productivity could give lower estimates since IEQ conditions might have an effect on productivity parameters other than productive time, such as task productivity: the amount of work done during productive time. However, the level of influence of IEQ per se on task productivity is very difficult to quantify due to the complexity of other influencing factors, and could include biasness since it directly assesses the performance of the individuals who are aware of being tested. Instead, and by asking the employees about the time lost due to external factors or due to causes out of their control, all related to IEQ, they are more likely to reply with objective and more accurate estimates, since erring seem to have neutral influence on their benefit. Moreover, measuring time rather than productive work is a much easier task to do. Several peer-reviewed questionnaires present in the literature measure productivity by focusing on quantifying productive time, such as the Migraine Work and Productivity Loss Questionnaire (MWPLQ), and the Health and Performance Questionnaire (HPQ).

3 METHODS

In order to examine the null hypothesis [1] and further investigate the potential relationship between occupant satisfaction with the IEQ and productive time, a survey questionnaire consisting of three sections was proposed. The first section gathers demographic information related to the respondent. The second section measures time lost during working hours due to poor IEQ conditions as self-assessed by the occupants via expressing their level of satisfaction with IEQ conditions. The aim is to quantify the working-hours lost without performing productive work due to IEQ related causes. Productive time is measured by a set of questions adopted in part from previous productivity-related questionnaires, such as Work Productivity, Work Productivity and Activity Impairment General Health Questionnaire, QQ Instrument, etc. The questions were modified to portray IEQ-related lost time at work. This section directs respondents towards estimating their time lost due to poorly performing IEQ factors or related physical and mental problems faced at work. The third section of the questionnaire directs the respondents into self-assessing their level of overall satisfaction towards their workplace using the same questioning and scaling technique used in Kim and de Dear (2012)’s study, including the weighted parameters presented for the different IEQ factors to estimate an accurate level of overall IEQ satisfaction. Table 2 discloses a few sample questions from the questionnaire, as shown in their related sections.

<td>Scale 1 to 7</td>
</tr>
</tbody>
</table>

The responses of the survey were used to compute three parameters out of each questionnaire: *Longevity, Percent Productive Time and Percent IEQ Satisfaction.*

- **Longevity:** Question 1 of Section I asks participants about their time spent at their current workplace. Longevity in this context does not imply the number of years of employment, but merely the number of years spent at the currently occupied office, which might be much less than the total years of employment.

- **Percent Productive Time:** Question 2 of Section I through Question 15 of Section II of the questionnaire are used to calculate the respondent’s percentage of utility of their potential productivity. For example, a *Percent Productive Time* of 70% means that the respondent is, on average, wasting 30% of their working time. This is calculated by summing up the time lost due to the several IEQ-related impediments at the workplace that hinder the respondent from being productive. The lost time due to each of the impediments is self-assessed by the respondents by responding to Section II of the questionnaire. The summed lost time is subtracted from the total working-time supposed to be spent at the workplace; yielding *Productive Time*.

- **Percent IEQ Satisfaction:** Section III of the survey questionnaire is used to calculate the percentage of satisfaction of the respondent with the IEQ conditions, which influences their level of overall satisfaction with the workplace. In total, 15 questions, each relating to one of the 15 IEQ factors, ask the respondent to self-assess their perceived level of satisfaction towards the related IEQ factor on a scale of 1 to 7, similar to that used in Kim and de Dear’s study (2012). The responses are then accumulated after being factored by the weighted influence effect of each IEQ factor, as proposed by Kim and de Dear, to yield the overall IEQ satisfaction at the workplace. A *Percent IEQ Satisfaction* of 80% means that the respondent is 20% short of being completely satisfied with the IEQ conditions at the workplace. This also means that the IEQ conditions are contributing to the overall satisfaction 80% of what they could at an ideal situation.

The total sample size included 102 participants divided among offices of six organizations of different types: engineering, pharmaceutical, banking, industrial, governmental, and educational; each of which completed between 15 and 20 questionnaires. The aim behind selecting different types of organizations
was to include a various combination of white-collar employees working on different types of office-work tasks, to generalize the validity of the tested relationship. A total of 20 hard copies of the questionnaire were kept at the lobbies of each of the consenting organizations, and the employees were invited to fill them in; voluntarily and anonymously. The gathered data were then checked against random responses and any outliers using the ROUT method. The ROUT method in brief attempts to fit the regression model to the data where outliers have little impact. Then, it detects the points that are far enough from the predicted model, basing its prediction on a predefined false discovery rate. The remaining data is then statistically analyzed to reveal the descriptive statistics of the three parameters, longevity, percent productive time and percent IEQ satisfaction, of the studied sample. To study the null hypothesis, a bivariate (Pearson) correlation is carried out on the resulting data, testing the proposed relationship between productive time and overall satisfaction with IEQ conditions at the workplace. The next natural step after testing the null hypothesis is to further investigate this relationship by trying to infer a statistical regression model that relates the two parameters. The obtained regression curve is then validated by comparing the results of this survey with those of Oseland (2004)’s and Somers and Casal (2009)’s statistical regression models, since these two models address the same problem, yet yield possibly contradicting results; the latter claims a linear relation, while the former presents a nonlinear U-Shaped regression curve.

4 RESULTS

4.1 Data Analysis

One response out of the 102 was eliminated since it was found to have been filled arbitrarily; the calculated lost time was greater than the reported total working hours per day. For the remaining responses, and using the previously described calculations, each questionnaire was reduced to a coordinate point (Percent IEQ Satisfaction; Percent Productive Time). Two outliers were filtered out of the data set using maximum False Discovery Rate of 1% (Motulsky and Brown 2006). For the remaining responses (total of 99), the three variables are statistically summarized in Table 3.

<table>

<td>12</td>
<td>3.1</td>
<td>2.9</td>
</tr>
</tbody>
</table>

- **Percent Productive Time:** The percent productive time mean of the sampled employees is 72.6% with a standard deviation of 15.0%; i.e. on average, employees are performing their jobs at 72.6% of their ability. The minimum recorded time productivity is 31%, while the highest is about 99%. This suggests that employees tend to utilize their productive time at a wide range of levels, depending on several parameters, among which, the level of IEQ satisfaction.

- **Percent IEQ Satisfaction:** The percentage of satisfaction with the IEQ conditions averages to 54.3%, with a standard deviation of 23.9%. The levels of satisfaction with the IEQ seem to range across the whole 100% scale, with a minimum of 2.3%, and a maximum of full satisfaction.

- **Longevity:** The longevity mean of the sample is approximately three years. The logical explanation for this apparently low number goes back to the first question of the survey, which states: “How long have you been working at your current workplace?” The aim of this study is to measure the level of satisfaction of the employees with the IEQ conditions of their currently occupied office. Since many employees throughout their employment tend to get transferred from one workplace to another due to
several reasons; getting promoted, moving to a new office building, department switching, etc., the average longevity is as low as three years.

** Correlation is significant at the 0.01 level (2-tailed).

As summarized in Table 4, the bivariate (Pearson) correlation test shows that there is a statistically significant correlation between the two parameters, thereby enough evidence to reject the null hypothesis \( H_0 \). This result further confirms the findings of Somers and Casal (2009) and Oseland (2004).

4.2 Best-Fit Regression Curve

After performing the regression analysis on the collected data to find the best fit curve that would model the relationship between Percent Productive Time and Percent IEQ Satisfaction, the three regressions with the highest R-Square values are found to be the linear, quadratic and cubic curves. In addition to featuring the highest R-Square value, the cubic model offers a more logical fit especially for cases of high levels of satisfaction, since 100% productive time is practically infeasible as shown by the quadratic fit in Figure 2. Similar to the finding of Somers et Casal (2009), the relation between Productive time and Satisfaction with IEQ thus appears to be non-monotonic with a U-shaped cubic regression curve. As the satisfaction increases to 25%, the productive time drops from 70% to 60%. This value then increases at a slower rate to 95% as satisfaction increase until 100%.

![Figure 2: U-Shape cubic relation between productive time and IEQ satisfaction.](image)
4.3 Discussion

Despite the approach used in measuring satisfaction and productivity, which is validated by previous literature to have more accurate results in comparison to other approaches used in other studies, all three regression curves show relatively low R-Squared values. A possible cause behind this outcome is the fact that productive time and satisfaction level with the different IEQ factors had been self-assessed by the respondents, who could have estimated their lost time inaccurately, or reported their level of satisfaction based on the momentarily situation they were in at the moment of assessment, rather than responding in a general manner. Another cause could be due to the complexity of the relationship between IEQ conditions and occupants' comfort, well-being, satisfaction and productivity. This complex relation stretches far beyond the frame of this study, which relies on several assumptions that simplify this relationship to a quantifiable dimension. For example, feeling dizzy at work and not being able to be productive could be due to reasons that have nothing to do with IEQ, such as feeling ill or pregnancy. A third important observation spotted in Figure 2 that could be associated with the low correlation factors attained is the scatter plot for low values of IEQ Satisfaction (below 20%). The scatter plot at that region of the graph seems to lie randomly above all three regression curves, which could influence the best-fit curves into falsely depicting the relationship between very low IEQ satisfaction levels and productive time. Unlike the first two causes presented, this is not an error in estimation or bias in assessment, but could be a phenomenon that needs to be looked at more closely. If there is no correlation between Percent Productive Time and Percent Satisfaction for such low satisfaction levels, then the proposed model is not applicable for extremely low satisfaction levels, which should be excluded from its domain.

5 CONCLUSIONS

In this paper, the relationship between post-occupancy perceived satisfaction with the indoor environmental quality of office buildings and the self-assessed level of productive time of the occupants is tested. To the contrary of most reviewed studies, productive time rather than productivity per se is measured, linking it solely to poorly performing IEQ or related health problems. The level of IEQ satisfaction, on the other hand, is based on Kim and de Dear (2012)'s regression model, which takes into consideration the weighted influence of the IEQ factors on the overall satisfaction. A survey questionnaire was used to gather the sample data that links the level of productive time to the level of IEQ satisfaction at the workplace. Running a Pearson Correlation test on the gathered data shows a significant relationship. After the initial plotting of responses, a cubic U-shaped behaviour of the studied relationship is observed, similar to what Somers and Casal (2009) concluded. However, and after analyzing the causes behind this unexpected increase in productive time at lower levels of satisfaction, it appears that there might be no correlation between the two. This leads to the conclusion that the curve might not hold valid for such cases; an observation that calls for further studying the hypothesized relationship. The significance of this study is that it validates the existence of the relationship between occupant productivity and satisfaction at the workplace, presents a quantitative empirical model for the relation between productive time and IEQ satisfaction specifically, and presents a possible explanation to the counter-intuitive U-Shaped regression curve attained. Possible future work on this subject could focus on the relation between productive time and extremely low IEQ satisfaction levels. Future work could also address one of the limitations of this paper, i.e. its reliance on self-assessment methods of productive time as proxy for productivity. More direct measurements of productivity are needed to confirm the relationship between IEQ conditions and productivity.

A COMPARISON OF GEOGRAPHIC INTERVENTION GROUPING METHODS FOR INFRASTRUCTURE INTERVENTION PLANNING ACROSS MULTIPLE NETWORKS

Clemens Kielhauser¹,², Bryan T. Adey¹ and Nam Lethanh¹
¹ Swiss Federal Institute of Technology (ETH), Switzerland
² kielhauser@ibi.baug.ethz.ch

Abstract: Interventions on infrastructure networks in municipalities cause disruptions to the service provided by the network that requires the intervention. They also cause disruptions to the service provided by other networks that have to be at least partially shut down so that the intervention can be executed. Due to these effects, there is substantial benefit to be obtained by grouping interventions on all networks that are spatially close to one another, i.e. work programs for spatially close networks should be developed together. This benefit is principally due to reduced interruption to services and reduced costs of intervention. The challenge of determining such combined optimal work programs is made more difficult as it requires quantification of the value of lost services, which depends on how different stakeholders value the services as well as how the services are interrupted. In this paper the difference between two methodologies to be used to develop work programs on spatially close infrastructure networks is shown: 1) a traditional methodology based on a grid-cell based grouping method, and 2) a methodology based on a combined topology / Voronoi cell / density based clustering of interventions. Both methodologies exploit recent developments in the area of critical infrastructures and GISs. The differences are illustrated by using both methodologies to determine combined work programs for five spatially close infrastructure networks (electricity, gas, water, sewage, roads) in a municipality with approximately 1'500 inhabitants. The advantages and disadvantages of each are discussed.

1 INTRODUCTION

Infrastructure networks (INs), such as electricity, gas, road, sewer, and water distribution networks are some of the main assets but also some of the main cost drivers of a municipality. Therefore, interventions on these networks should be carried out in a way that minimises the costs of intervention and the disruption of the service, i.e. an optimal work program (OWP) should be determined. Traditionally, the managers of each IN produce their own work programs. Example methodologies to find OWPs for single INs can be found in Fenner, Sweeting, and Marriott (2000), Miyamoto, Kawamura, and Nakamura (2000), Stillman (2003), Cardoso et al. (2004), Arthur et al. (2009), Dehghanian et al. (2013), Zayed and Mohamed (2013), Lethanh, Adey, and Sigrist (2014). These work programs are then discussed with those responsible for the other INs in order to reduce the impact on service disruption and costs by manually combining the work programs to create synergy effects. In this paper a case study on a dynamic geographic intervention grouping method is presented. This method can be used to take into consideration the structural and functional differences, as well as the different ways that the networks are typically monitored, in an automated way. The resulting work program is compared with the work program
from a static geographic intervention grouping method presented in Kielhauser, Adey, and Lethanh (2014), herein referred to as the traditional methodology.

2 METHODOLOGY

The concept of the herein presented dynamic neighbourhood methodology (DNM) is based on the concept of neighbourhood. The neighbourhood of object A is defined as the region around object A, where object B would be considered close if it lies within that region. The basic process for the DNM follows 7 steps, which are explained in the following sections and shown in Fig. 1.

![Methodology Flowchart](image)

2.1 Step 1: Determine Level 1 objects

In this process, objects with high priority (level 1 objects) are determined. In this paper, level 1 objects are defined as follows:

*Level 1 objects are objects, which are in such a state (e.g. failure probability, condition, age, level of service) that an intervention on this object is justified on its own, i.e. the decision to do an intervention is independent from other objects.*

In the first step of this process, triggers for selecting an object as a level 1 object are defined. These triggers are thresholds of one value or a combination of values of the object attributes. The attribute can be of the object itself, denoted as \( \zeta_n^i \) with the subscript \( n \ (n=1, \ldots, N) \) representing the object ID, and/or of the network, denoted as \( \xi_m^i \) with the subscript \( m \ (m=1, \ldots, M) \) representing the network ID. The superscript \( i \) denotes the level 1 objects. An example of the former is object condition. An example of the latter is change in network reliability. Then, objects are compared with the triggers by using a selector function \( f_i \). It is defined as a logical function, with \( f_i = 1 \) (true) when an object is selected, and 0 otherwise. This selector function is applied to a set of all objects considered (based on the boundaries of the physical area to be analysed and the jurisdiction of the manager) \( \delta_{i,n,m}^j \) in order to obtain the logical selection vector for the level 1 objects \( \bar{\delta}_{i,n,m}^j \):

\[
[1] \quad \bar{\delta}_{i,n,m}^j = f_i(\bar{\alpha}_{i,n,m}, \zeta_{n}^i, \xi_{m}^i)
\]

with \( \bar{\alpha}_{i,n,m} \) ... object vector consisting of all objects \( \alpha_{n,m}^i = (\alpha_{n,1}, \ldots, \alpha_{n,1}, \ldots, \alpha_{n,M}) \).
2.2 Step 2: Calculate Neighbourhood

This process is used to determine the neighbourhood of all level 1 objects being investigated. This is accomplished by determining the topological neighbourhood, the distance neighbourhood and the Voronoi neighbourhood. The first two of these neighbourhoods refer to objects in the same network, the last refers to objects that are in the spatial neighbourhood of the level 1 objects but are in different INs than the level 1 object. To better explain the used three different neighbourhoods, Fig. 2a shows an example network with 7 objects. Logical nodes (denoted with $\bullet$) are nodes that signify a join between two or more objects. Geometric nodes (denoted with $\circ$) are used to detail the object shape in between the endpoints (logical nodes). Lines with the same number are used to denote one object.

![Figure 2: Network definitions](image)

(a) Example network with objects 1-7  (b) Voronoi cells for network nodes  (c) Voronoi region for network element 1  (d) Voronoi region for network element 5

2.2.1 Topological Neighbourhood

The topological neighbourhood of an object is based on the topological distance, i.e. the number of objects between two logical nodes. In that sense, two objects are neighbours if the network distance between their closest logical nodes is below a certain threshold. For example, if the focus is on object 6 and the distance threshold is 1, then objects 1, 2, 5, and 7 can be considered to be in the same neighbourhood, as at most 1 object (namely 5) has to be crossed to reach them. Mathematically, neighbouring objects can be found as follows: Starting from the incidence matrix $C_n$ (i.e. a matrix describing which edges are connected to which nodes), all nodes reachable in a distance $k$ can be calculated by:

$$K_{n} = sgn(\sum_{i=1}^{m}((C_{n} \cdot C_{n} - \text{diag}(C_{n} \cdot \overline{I})))^k))$$

with $K_{n}$. … Reachability matrix of network $m$ for $k$ steps. Each element from $K_{n} = \lbrack k_{n,j} \rbrack$ shows if a node is reachable from another node with a maximum of $k$ steps. Combining those reachability matrices to a grand matrix gives the topological neighbourhood matrix $N_{c}$:

$$[3] \quad N_{c} = \begin{bmatrix}
    K_{i} & 0 & 0 \\
    0 & \ddots & 0 \\
    0 & 0 & K_{i}
\end{bmatrix}$$

2.2.2 Distance Neighbourhood

As the sizes of network objects can differ by orders of magnitudes (e.g. compare one valve with a 300m stretch of straight pipe), neighbourhoods can also be defined by distance along the network. This is an alternative neighbourhood definition, which only takes into account the physical distance of objects along the network. For this, an object is defined as a neighbour, if it can be reached within a certain distance along the network. For example, objects 3 and 5 are within a distance $d_{\text{travel}}$ of each other, as shown in
Fig. 2a, as their closest nodes are within a distance of $d_{travel}$. Mathematically, the shortest path between all logical nodes $q$ of all objects has to be calculated (or loaded from the database if available).

$$[4] \quad D_{m,q} = APSP_m(m, q)$$

with $D_{m,q} \ldots$ all logical node pairs distance matrix for network $m$, $APSP_m \ldots$ all node pairs shortest path algorithm for networks as described in Johnson (1977). The minimal distance between all object pairs is then the minimum of the minimal distances between each objects' logical nodes:

$$[5] \quad D_m = \min(dist(D_{m,q}, D_{m,q})) \quad q_m \in n_m$$

with $D_m \ldots$ minimal distance matrix for all objects in network $m$, $q_m \ldots$ logical nodes of network $m$, and $n_m \ldots$ objects of network $m$. Comparing this minimal distance matrix with a distance threshold $d_{im,m}$ for each network $m$ gives the neighbourhood matrix $D_{d,m}$:

$$[6] \quad D_{d,m} = D_m \leq d_{im,m}$$

Combining those distance matrices into a grand matrix gives the neighbourhood matrix $N_N$:

$$[7] \quad N_N = \begin{bmatrix} D_{d,i} & 0 & 0 \\ 0 & \ddots & 0 \\ 0 & 0 & D_{d,j} \end{bmatrix}$$

### 2.2.3 Voronoi Neighbourhood

Both topological and distance neighbourhood definitions have the prerequisite that all objects have to belong to the same network. To overcome this limitation, the neighbourhood can also be defined by Voronoi cells (Lejeune Dirichlet 1850). Figure 2b shows a Voronoi tessellation of the example network. Starting from a given set of core points $p_i$ (in this case: all network nodes, both logical and geometric), Voronoi cells $V_v$ consist of every point in space whose distance to $p_k$ is less or equal to any other core point $p_{j,k}$. A Voronoi region $R_i$ for one object is then the set of all Voronoi cells emanating from the nodes of that object (Fig. 2c,d). Combining those regions gives the set of all Voronoi regions $\tilde{R}_{n,m}$ for all objects $o_{n,m}$. This can be used to define the neighbourhood as follows: objects A and B are neighbouring, if object B touches object A's Voronoi region. The neighbourhood can then be defined as:

$$[8] \quad N_N = \tilde{R}_{n,m} \cap \tilde{o}_{n,m}$$

with $\tilde{R}_{n,m} \ldots$ Voronoi regions of objects $\tilde{o}_{n,m}$, $N_N \ldots$ neighbourhood matrix for Voronoi methodology and $\tilde{R}_{n,m} \cap \tilde{o}_{n,m} \ldots$ the dyadic geometric intersection between $\tilde{R}_{n,m}$ and $\tilde{o}_{n,m}$.
2.2.4 Neighbourhood combination

In the last activity of the dynamic neighbourhood calculation, all neighbourhoods are combined to a grand
neighbourhood by combining all neighbourhood matrices to the dynamic neighbourhood matrix \( N_D \):

\[ N_D = N_T \lor N_N \lor N_Y \]

with the symbol \( \lor \) denoting the logical "or", which only returns a value of "1" if at least one input is "1". In
words, two objects are neighbours if they are either topological, distance or Voronoi neighbours.

2.3 Step 3: Determine close objects

As next step, the so-called close objects are determined. Those objects are objects that are located in the
neighbourhood which is defined by the dynamic neighbourhood matrix \( N_D \). This process ensures that
only close objects, i.e. objects that are sufficiently near to level 1 objects are considered as level 2 objects
in the next step, where the object condition is compared against a threshold likewise to the determination
of level 1 objects. Mathematically, the whole process can be expressed in one equation:

\[ \delta_{n,m}^{C,D} = \left( (N_D \otimes \Delta_j) \cdot 1 \right) \rightarrow \delta_{n,m}^{C} \]

with \( \delta_{n,m}^{C,D} \) the binary variable vector indicating if object \( O_{n,m} \) is part of the close object set. The superscript
\( C \) denotes the close objects, the superscript \( D \) denotes the DNM, and the symbol \( \rightarrow \) denotes the
material non-implication, which is an operator that only returns a value of "1" if the first input is "1" and the
second input is "0". In this case: an object is only a close object for the DNM if the object is within the
same neighbourhood as a level 1 object but has not been already selected as a level 1 object.

2.4 Step 4: Determine Level 2 objects

In this subprocess, objects with lesser priority (Level 2 objects) are determined. In this paper, level 2
objects are defined as follows.

Level 2 objects are objects, which are in such a state (e.g. failure probability, age, level of service) that an
intervention on this object is not justified on its own but the synergies created by doing a combined
intervention with a level 1 object justify an intervention, i.e. the decision to do an intervention is dependent
on other proximate objects.

The selection process is similar to the one for level 1, just with different trigger values.

2.5 Step 5: Group objects

In this process, the level 1 and level 2 objects which have been identified in the previous steps, are
combined into intervention groups, i.e. sets of interventions that are executed together, using the
DBSCAN algorithm as described in (Ester et al. 1996). This algorithm takes the centroid point coordinates
of the objects requiring intervention and two values as inputs: 1) Eps - the maximum distance in which
two interventions should be grouped into one intervention group, and 2) MinPts - the number of
interventions, that form an intervention group. Then, the points are classified as either belonging to a
group or being single objects. If they belong to a group, then the interventions are included in the work
program as a group, otherwise it has to be discerned between level 1 and level 2 objects. Level 1 single
objects are also included in the work program as intervention, despite not being grouped, because per
definition level 1 signifies that an intervention is justified even without grouping, whereas level 2 objects
belonging to no group will be discarded. Mathematically:
[12] \( I_D = DBSCAN(\delta_i^j, \delta^H_{x, y}, \text{Eps}, \text{MinPts}) \)

with \( I_D \) intervention group matrix for the DBSCAN clusters. The cost of each group is the sum of the setup costs \( C_i \) for executing all interventions in group \( s_j \) and the unit costs without setup costs for each intervention on each object of each network \( c_{n,m} \) multiplied by its size \( u_{n,m} \).

\[ C_j = c_j + ((I_D \otimes (c_{n,m} \odot u_{n,m}) \cdot \bar{1}) \]

with \( C_j \) cost vector of intervention in all groups \( s_j \). The WP is simply the whole set of intervention groups, i.e. all rows of \( I_D \). The total costs are then simply the sum of the cost vector \( C_j \):

\[ C_{WP} = \sum_{j=1}^{J} C_j \]

### 2.6 Step 6: Rank groups

If there are constraints (e.g. budget constraints) and not all intervention groups can be included in the work program, a priority (related to the consequences that would be incurred due to service interruption if a failure occurred) is calculated so that the groups with the highest priority can be included in the work program. It is in this methodology based on two components: a) The object priority value, which relates to the object itself and its role in the network, e.g. for a sewer network object how many upstream objects will also be blocked if this object has to be blocked for maintenance, and b) a multiplicative factor related to the location, e.g. population density of the area with service interruption. Although this is multiplicatively connected with the object priority value, it is kept separate because the population density for example is not network dependent, whereas the object priority value is. Mathematically:

\[ W_i = (I_D \otimes (\lambda_{n,m}) \cdot \bar{1}) \]

with \( W_i \) priority vector of group \( s_i \), \( \lambda_{n,m} \) object priority vector based on object \( n \) and network \( m \), \( \lambda \) group priority vector based on group location, and \( \odot \) representing the element-wise multiplication of vectors. From there, the rank \( r_i \) of a group can be calculated:

\[ r_i = \text{rank(sort}(W_i|\text{desc.})) \]

This results in the group with the highest priority \( W_i \) having the lowest rank \( r_i \).

### 2.7 Step 7: Add group to constrained work program

The work program with constraints is constructed from the unconstrained work program: The groups included in the unconstrained work program are added one at a time to the constrained work program (i.e. a selection variable \( \lambda^g \) is changed from 0 to 1) starting with the group with the highest priority (i.e. where \( r_i = 1 \), then where \( r_i = 2, 3, \ldots \) etc.) and then the budget is checked. If the budget is not exceeded,
the group is kept and the group with the next highest priority is tried. This process is repeated until the
sum of the costs of the groups in the work program reaches the budget limit \( C_{lim} \): 

\[
\Lambda^e_g = 1 \text{ for } \sum_{k \subset N}^N C_i \leq C_{lim} \text{ or } 0 \text{ otherwise}
\]

with \( \Lambda^e_g \) the binary vector indicating inclusion in WP (1=yes, 0=no), \( C_{lim} \) the budget limit. The WP is the whole set of intervention groups \( I_D \) subsetted by the inclusion variable \( \Lambda^e_g \): 

\[
I_D^e = \left( I_D \otimes \Lambda^e_g \right)
\]

The total costs are the sum of the cost vector \( C_i \) times the inclusion vector.

\[
C_{\text{WP}} = \sum_{g=1}^{G} C_{i} \Lambda^e_g
\]

3 CASE STUDY

The DNM was used to determine a work program for five proximate municipal infrastructure networks. This work program was then compared with the work program generated using a traditional methodology Kielhauser, Adey, and Lethanh (2014). The advantages and disadvantages of each will be discussed.

3.1 Overview

The infrastructure networks (electricity, gas, roads, sewage, and water) used in this case study belong to a municipality with a population of ca. 1'500. The single network maps are shown in Fig. 3a – Fig. 3e.

![Network maps](image)

(a) Electricity  (b) Gas  (c) Roads  (d) Sewer  (e) Water

Figure 3: Network maps

The objects in the electricity, gas, and water networks were considered to be in one of 2 condition states, operational and not operational, the objects in the sewer network were considered to be in one of 5 discrete condition states, and the road objects were considered to be in a continuous-range condition state between 0 and 5 (Tbl.1). The thresholds for level 1 and level 2 are shown in Tbl. 2, the costs for the interventions (given in monetary units mu) in Tbl. 3.
Using steps 1-7, a work program (with a budget constraint of 200'000 mu) was calculated and compared to the WP obtained by using the method described in Kielhauser, Adey, and Lethanh (2014). To facilitate the comparison, the work programs will be referred to as WPD (with the D representing the DNM) and WPT (the T representing the traditional methodology). Tbl. 4 shows the results.

Table 4: Results

<table>
<thead>
<tr>

<td>72'168</td>
<td>72'168</td>
</tr>
</tbody>
</table>

This table shows that the traditional methodology selects 4 objects for the work program. A total amount of 861.6m will be renewed. With only 300'000 mu available, the total cost is 287'387 mu, which means a budget utilisation of 96%. The DMN selects 6 objects with a total length of 874.5m for the work program.
A total amount of 874.5m will be renewed. With total costs at 288'672 mu, the budget utilisation is also 96%. To be better able to compare the methodologies, we have used a proxy B which is the average amount of financial resources used to improve the age of the infrastructure, expressed as monetary units divided by the amount of removed age, multiplied by extent of the object. This indicator is based on the concept, that if it is assumed that an adequate level of service is always provided, the main goal of an infrastructure manager becomes the improvement of the infrastructure for the least cost. In this case, the best work program is the one that gives the highest improvement in the infrastructure provided for the least cost. For example, when a gas pipe is 70 years old and is replaced with a new identical pipe, it is considered to have improved the condition of the infrastructure by 70 years. When this is coupled with the costs to improve the condition, one gets the costs per time.

4 COMPARISON

One of the first things that can be seen by comparing the two methodologies is the difference between the numbers of interventions proposed. For the case study, this difference originates in a part of the network that is shown in Fig. 4. The left half shows the WPT, the right shows the WPD. The dashed line represents the boundary of a grid cell. The line weight represents the different levels (thick: level 1, medium: level 2, grey: no selection). For the WPT, it can be seen that within the grid cell, the level 1 object also triggers an intervention on the adjacent level 2 object, because it is in the same grid cell. For WPD, additionally, another object is included, as it is only at a topological distance of 1 from the level 1 object. This shows the main benefit of the DNM: as the neighbourhood is calculated dynamically from the network, such boundary situations can be taken into account in contrast to the traditional methodology.

As can be seen in Tbl. 4, the cost/improvement ratio B varies between the work programs. The work program determined using the DNM gives the best (i.e. lower) ratio (33.1 vs. 36.1). Therefore, the DNM performs better than the traditional methodology. This is due to the synergy effects created by the topological approach in contrast to the traditional approach.

5 CONCLUSION

In this paper, two methodologies to determine work programs for municipalities possessing multiple infrastructure networks were investigated and compared. In the investigated example, the methodologies were used to determine work programs for five infrastructure networks in a municipality with a population of ca. 1'500. It was found that the DNM for grouping objects in need of intervention within a network and on multiple networks leads to improvements over the traditional methodology. This demonstrated that the explicit consideration of the proximity of objects within multiple networks should be systematically done. It was found that the DNM leads to work programs that generated lower per unit improvement costs than the traditional methodology. This is because the traditional methodology relies on predefined grid cells, while the DNM dynamically calculates those from the individual network data.
Keeping this in mind, future research in this direction should include:

- the enhancement of the investigated methodologies to determine work programs using more direct consideration of the costs of service interruption
- the extension of the investigated methodology to determine work programs over multiple time periods
- the adaptation of the investigated methodology to take into consideration functional relationships between the objects within one network and within multiple networks, e.g. the effect on the amount of water flowing in a waste water network due to interventions being executed on a sewer network and a heavy rain fall occurring
- the enhancement of the investigated methodology to better take into consideration real world costs, i.e. more accurate representations of the variant and invariant costs involved with intervening on one or more networks, and on one or more objects
- the comparison of these methodologies with a real world situation to investigate the potential advantages and disadvantages of its use in practice

References

Abstract: As an approach to mitigate the harmful effects of Urban Heat Island (UHI), the use of glass cullet in the production of asphalt roof shingles has the potential to be employed as a cool roof strategy. The objective of this study was to test the hypothesis that the use of recycled glass cullet increases the solar reflectance index (SRI) without affecting the performance of asphalt roof shingles. In order to evaluate the feasibility of using recycled glass cullet in this new application, the engineering properties of glass cullet were investigated and compared to conventional aggregates used in the production of asphalt roof shingles. Laboratory shingle specimens were then prepared in order to measure solar reflectance properties and strength characteristics of conventional and recycled glass roof shingles. Results show that while the use of recycled glass cullet as a replacement to standard ceramic coated black roofing granules on the top surface of asphalt shingles increased the SRI, the addition of white pigment powder (anatase ultra-fine titanium dioxide [TiO₂] particles passing mesh #320) to the surface granules greatly improves the reflectance properties of the roof to a level that meets the cool roof threshold.

1 INTRODUCTION

With the continuous consumption of energy from non-renewable sources, many cities worldwide with a population that equals or exceeds 1 million people experience an increase in annual mean air temperature of 1-3°C when compared to its surroundings. Further, evenings can experience a difference as high as 12°C (USEPA 2014). This phenomenon is known as heat island effect. It is becoming increasingly intense as summertime temperatures rise due to global warming. The objective of this study was to evaluate the feasibility of integrating recycled glass cullet in the manufacturing of fiberglass roof shingles and to investigate the interactions that occur when recycled glass cullet is blended with traditional roofing materials. The impact of diverting materials from disposal and reusing Construction and Demolition (C&D) materials includes reduced extraction and consumption of virgin resources. Glass food and beverage containers can be recycled endlessly, and economic benefits of the reuse of glass include: cullet cost less than raw materials, reduces energy demand, prolongs furnace life, and creates 8 jobs for every 1,000 tons recycled (Glass Packaging Institute 2013). Environmentally, benefits include the reduction of emissions, energy consumption, consumption of raw materials, and waste ending in landfills. For every six tons of recycled container glass used, a ton of carbon dioxide, a greenhouse gas, is reduced (Glass Packaging Institute 2013).

2 BACKGROUND

Recycling of glass cullet can be categorized into two main groups: (1) new glass and bottle containers; and (2) other applications. Secondary recycling applications are categorized into eight main groups (Reindl 2003): (1) building materials; (2) concrete production; (3) construction aggregates; (4) industrial mineral uses; (5) building insulation; (6) asphalt paving; (7) remelt; and (8) others. While the recycling of glass cullet is beneficial in most applications, the performance of the product should not be compromised as compared to products prepared with virgin materials. Numerous advantages can result from the recycling of glass cullet: (1) reduced emissions and energy consumption during processing and manufacturing of virgin materials; (2) reduced consumption of virgin materials; (3) diminished consternation of public concerning emissions; (4) improved economic competitiveness of construction and manufacturing; and (5) reduced glass cullet disposed in landfills.

The most common roofing product is asphalt shingles, which account for approximately 85% of roofing products used in the residential sector in the US (Leavell 2006). A fiberglass roofing shingle is comprised of four major components: a substrate, asphaltic coating with mineral fillers, surface granules, and backdust. Conventional materials used to produce shingles include fiberglass matting as the substrate, air-blown asphalt as the coating material, and aggregates. Aggregates are classified by particle size as top surface granules, filler material, or backdust particles. Typical particle sizes are listed in Table 1. Materials most widely used as top surface granules include crushed slate, basalt, and trap rock (Pagen et al. 1986). Finer silt-sized granules are used as backdust, and ideal materials are non-cementitious minerals, such as mica flakes, talc, or sand (Bondoc et al. 1988). Examples of filler material include fly ash, recycled rubber, recycled shingles, fine grained carbonate rock, dolomite, trap rock, sand, stone dust, and limestone. Limestone has dominated the market due to its naturally occurring abundance, satisfactory performance, and positive reactions with asphalt as it does not make it brittle or loose granules (Leavell 2006).

3 EXPERIMENTAL PROGRAM

The objective of the experimental program was to evaluate the suitability of incorporating recycled glass cullet into the manufacturing process of asphalt roofing shingles and to test the hypothesis that the use of recycled glass cullet will increase solar reflective properties without affecting performance of asphalt roof shingles. Table 2 provides an overview of the experimental conditions, variables, properties testing, and ASTM specifications. The experimental program was divided in two phases. The first phase of the experimental program was to characterize the engineering properties of glass cullet in comparison to conventional materials used in producing fiberglass shingles. The engineering properties of interest included particle size distribution, specific gravity, absorption, void content, and soundness. The second phase consisted of preparing laboratory shingles in order to measure and compare the solar reflective properties and strength performance of conventional and recycled glass roof shingles. Conventional and recycled-glass modified fiberglass reinforced asphalt roofing shingles were prepared in the laboratory by varying the amount of glass cullet and conventional materials used in asphalt roof shingles, and acceptability was based upon the standard specifications described in ASTM D 3462.

3.1 Materials Description and Processing

Three sources of recycled glass cullet were collected from C&D processing plants. Each source was presorted by color and included one source of green glass and two sources of clear glass. Approximately
85% of the glass fragments received were larger than the maximum size aggregate (2.36mm) used in producing asphalt roof shingles and needed to be processed into a smaller size. With the use of a high performance mixer, the fragments were reduced, sieved, and fractionated into sizes used in the production of conventional shingle particle sizes, see Table 1. The ground glass cullet was then utilized in lieu of conventional mineral aggregates as surface granules, filler material, and backdust.

Conventional shingle aggregates were collected and included ceramic coated roofing granules for the top surface, high calcium limestone filler material, and crushed limestone (stone dust) as the backdust. The #11 grade top surface igneous roofing granules were coated with a black ceramic pigment and were comprised of pulaskite, which is variation of syenite with little or no quartz. The limestone filler material was a ground Calcium Carbonate product (96.7% CaCO₃) with 98% passing the U.S. Standard Sieve Mesh #50 (0.300mm) and 70% passing the #200 mesh (0.075mm). For the backdust, crushed limestone #10 was obtained, reduced, and then sieved to the required size and amount. Materials used to produce both conventional and glass modified shingles included air blown asphalt binder and fiberglass matting. The binder consisted of oxidized air-blown asphalt that is suitable for use as shingle coating. The fiberglass mat consisted of a non-woven web of glass fibers and served as the substrate for the shingle.

A white pigment powder was used in the fabrication of the asphalt shingles. To this end, the powder was mixed, saturated, and oven-dried with the glass surface granules prior to placement on the surface of the asphaltic coating. The powder consisted of 98% pure titanium dioxide (TiO₂) and was added at 8% by weight of the top surface granules. The anatase-based ultra-fine powder had a specific gravity of 3.9. The cool roof attributes of the modified shingle samples were evaluated with and without the addition of pigment powder.

### 3.2 Asphalt Shingle Preparation

In order to prepare fiberglass reinforced asphalt shingles in the laboratory, the process was divided into three steps: preparation of the formwork, preparation of the asphalt blends, and aggregate preparation. The preparation of the formwork included the thorough cleaning of an ample working surface for the
placement of a fiberglass mat substrate and then securing metal forms to ensure uniform dimension of the prepared samples. The prototype sample dimensions were 76mm x 76mm x 3mm.

Prior to pouring the asphalt binder in the prepared forms, all aggregates were weighted and fractionated to produce the samples described in Table 3. For the specimens that did not include pigments, the following weights were used per sample: 25 grams of top surface granules, 5 grams of backdust, and 23.4 grams of filler materials. The second embodiment consisted of the addition of the white (titanium dioxide) pigment powder to the surface granules. To include pigment powder, two grams of powder were mixed with 23 grams of surface granules, saturated with water, and then oven-dried.

The filler material was then uniformly mixed with 12.6 grams of liquefied asphalt binder for each sample, which was heated to 204°C. After mixing the filler material, 36 grams of asphalt coating mixture was reheated to become liquefied at 230°C. The asphalt coating mixture was then poured in the formwork of each shingle and then placed into the oven at 204°C for impregnation of the fiberglass. After one hour, the samples were removed from the oven and firm pressure was applied on the top surface granules in order to achieve 100% surface coverage. Upon cooling of the shingles, the forms were removed and the shingles were separated from the working surface by applying heat using a forced air heat gun. Finally, the backdust particles were applied to the back surface while keeping the underside heated.

3.3 Reflectance and Emittance Testing

The main purpose of using recycling of broken and waste glass cullet in the manufacturing of asphalt roofing shingle is to alleviate heating and cooling loads in buildings by reducing solar heat flux on the roof and heat island effects by increasing the reflectivity of the roof. To assess this ability, samples were exposed to a controlled light source from a spectrophotometer in order to measure solar reflective properties in accordance with the Standard Test Method for Solar Absorptance, Reflectance, and Transmittance of Materials Using Integrating Spheres (ASTM E903). Solar absorptance and reflectance were measured by using a spectroreflectometer with an absolute integrating sphere, 15°/h (Model: LPSR 200IR, AZ Technology). Measurements of emittance were produced by a spectrafire with an absolute ellipsoidal cavity, 15°/h (Model: TESA 2000, AZ Technology). Prepared samples for reflectance testing are presented in Table 3; sample dimensions were 76mm x 76mm x 3mm. To consider variability in reflectance and emittance measurements, two to six readings of three replicates were conducted.

Calculations of Solar Reflectance Index (SRI) under standard solar and ambient conditions are based on Approach II of the Standard Practice for Calculating Solar Reflectance Index of Horizontal and Low-Sloped Opaque Surfaces (ASTM E1980). Based upon measurements of solar absorptance and thermal emissivity of the shingle samples, the SRI was calculated for three convective coefficients that correspond to low, medium, and high wind conditions at 5, 12, 30 W•m⁻²•K⁻¹, respectively:
3.4 Tear Strength Testing

To assess roof shingle tear strength, prepared asphalt shingles were tested using a pendulum tear strength tester according to the Standard Test Method for Propagation Tear Resistance of Plastic Film and Thin Sheeting by Pendulum Method (ASTM D 1922). Conventional and glass-modified shingles were compared to industry minimum strength performance standards as specified in Standard Specification for Asphalt Shingles Made from Glass Felt and Surfaced with Mineral Granules (ASTM D 3462). Tear strength was determined using a Thwing-Albert ProTear Electronic Elmendorf Tear Tester. Initial tear strength testing included sample types X1, C1, and D1 shown in Table 3. These samples were made using 36 grams of asphalt coating mixture as outlined in the aforementioned asphalt shingle preparation process. However, results were inconclusive due to the thickness of the shingle, which increased strength values beyond the testing capabilities of the Elmendorf Tearing device. To achieve measurable results, the procedure was modified to reduce the thickness of the shingle by using 20 grams of asphalt coating mixture.

4 RESULTS AND ANALYSIS

4.1 Particle Size Analysis

Table 4 illustrates the particle size characteristics of the three sources of glass cullet. Based on these characteristics, collected glass cullet sources appear to be well-graded. However, glass cullet sources are too coarse to be directly used in glass-modified asphalt shingles without processing. The glass cullet particle sizes were reduced with the use of a commercial grade blender with 101.6mm blades and were then fractionated into sizes suitable for use in roof shingles as top surface granules (2.36mm – 595µm), backdust particles (595µm – 75µm), and filler material (150µm – 45µm). The cumulative particle size distribution curves of the ground glass cullet are shown in Figure 1 (a to c) and are compared to the particle sizes of conventional aggregate used as top surface granules, backdust particles, and filler material. Results show that the laboratory grinding process effectively reduced the size particles of the recycled glass cullet and the nominal maximum aggregate size of the glass cullet, rendering it similar to conventional ceramic coated top surface granules at 2.36mm with 7.4 to 7.7% fines. The fineness modulus was calculated for each aggregate type, and glass sources and ranged from 2.59 to 2.78 whereas the markedly smaller conventional aggregate fineness modulus was 1.93.

4.2 Reflectance, Emittance, and Solar Reflective Index (SRI)

The mean solar reflectance and thermal emittance results are summarized in Table 5. In general, reflectance results were influenced only by the top surface material employed and were unaffected by the type of filler material used. Figure 2 shows the ceramic-coated roofing granules on the top surface of the conventional shingles and compares it to the shingles prepared with top surface glass granules, with and without the addition of white pigment powder. To measure the effectiveness of glass cullet as a top surface material, mean reflectance values were compared for samples with the same filler material. Samples A, B, C, and D include glass cullet as a top surface material, which resulted in an increased reflectance as compared to Samples E and F. The utilization of glass cullet as top surface granules
resulted in a mean reflectance range increase from 0.029 to 0.050. T-test statistical analyses with 95% confidence level were performed and showed significance for Samples E vs. A (P-value = 0.004), Samples E vs. B (P-value = 0.015), and Samples F vs. D (P-value = 0.0005).

(a) Green Glass (b) Limestone (c) Clear Glass 1 (d) Green Glass & Pigments (e) Clear Glass 1 & Pigments (f) Clear Glass 2 & Pigments
Although the increase was statistically significant, glass granules on the top surface alone do not meet the standards to be classified as a cool roof material. Samples C1, D1, and G1 represent the case in which a white pigment powder was added to enhance the reflectance performance of the glass-modified shingles. The addition of white pigment powder to the top surface granules resulted in a mean reflectance increase from 0.168 to 0.194 for the samples with glass cullet top surface granules. T-test statistical analyses with 95% confidence level were conducted and showed significance differences for Samples C vs. C1 (P-value < 0.001) and Samples D vs. D1 (P-value < 0.001). The overall mean increase in reflectance from conventional materials to top surface glass granules with pigments was 0.218. A t-test statistical analyses with 95% confidence level was performed and showed significant differences for Samples F vs. D1 (P-value < 0.001).

### 4.3 Tear Strength

Initial testing involved Samples X1, C1, and D1 so that ten constant radius measurements could be tested. However, the results of initial tear strength testing were inconclusive as no readings were obtained. Despite using the heaviest pendulum (6400gf) available for the Elmendorf device, the pendulum was unable to swing freely to tear the specimen, as the mass of the pendulum was supported by the sample. In order to decrease the strength of the shingle and to obtain useable readings, this test method was repeated by modifying the procedure to produce thin laboratory shingles. The amount of coating was decreased from 36 to 20 grams, which was the thinnest specimen achievable using the procedures outlined in the experimental plan. Results showed that the average tear strength for both conventional and glass-modified shingles was substantially greater than the minimum shear strength of 1,700gf recommended by ASTM D3462, and results of a one-way ANOVA showed no significant difference between means at a level of significance of 0.0885. It is recommended to develop assembly methods to decrease the thickness of the coating layer of the laboratory samples and to pursue the use of industrial manufacturing processes in order to further evaluate the effects of glass fillers on actual production samples.

### 4.4 Economic Evaluation of Glass Modified Asphalt Shingles

To perform a cost analysis of glass modified asphalt roofing shingles compared to conventional shingles, material costs for conventional aggregates and glass cullet as top surface granules and as filler material were estimated. Ceramic coated black roofing granules were quoted at $145-185 per ton and approximately $100 per ton for the uncoated headlap granules by Specialty Granules Inc. (SGI) and 3M Industrial Mineral Division. Because shipping and freight costs are so varied, the prices were given as free on board (FOB) at the granule manufacturing plant, where the buyer pays for all transportation costs. High calcium limestone filler material was quoted between $17-40 per ton by Lhoist North America and Great Lakes Calcium. The estimated price for recycled glass was provided by Strategic Materials Inc. and Dlubak Glass, and roofing granules were approximately $131-135 per ton and $150 per ton for filler material. However, if the market demand increases, the price for glass roofing aggregates could eventually compete with container cullet pricing and 15.8mm minus plate glass recycling at $78-100 per ton. The cost of obtaining white pigment powder at a rate of 8% by weight of the surface granules was $3.00 per pound.

According to the United States Department of Energy (USDOE), although cool asphalt shingles currently sell for up to $0.50 per ft² more than conventional asphalt shingles (USDOE, 2013), the cost increase associated with implementing recycled glass granules with pigments is approximately $0.112 per ft². Conventional ceramic coated granules, which are utilized at a rate of 0.50 pounds per ft², can be replaced by glass granules without the use of pigment powder for a cost reduction of $0.008 per ft² in material cost alone. Glass filler material at a rate of 0.46 pounds per ft² can be utilized at a cost increase of $0.03 per ft² in place of limestone filler material. However, since filler material had no effect on reflectance or emittance, it was not included in the economic analysis. According to the Department of Energy Cool Roof Calculator, the estimated savings associated with changing reflectance to 0.30 from a black roof for residential homes in Baton Rouge, LA is $0.061 per ft² per year, resulting in $91.50 savings per year for a
typical 1500 ft² residence (USDOE, 2014). With the annual savings achieved from increasing reflectance, the payback period to offset the increased cost of glass granules with pigments is estimated at 1.8 years, which is a relatively short period of time as compared to the service life of a residential roof.

5 CONCLUSIONS

Results show that glass cullet received from source recycling plants are generally coarse grained aggregate and therefore must be ground or crushed in order to be applied into the manufacturing process of asphalt roof shingles. Typical asphalt shingles are characterized by low reflectance, and results show that reflectance values were influenced only by the type of top surface aggregate utilized, and the type of filler material had no effect on reflectance values. The results show that a typical black ceramic coated asphalt shingle produced reflectance values from of 0.036-0.040. Replacing the top surface granules with green glass produced reflectance values of 0.069 and clear glass from 0.086-0.090. In order to achieve cool roof attributes, the addition of a white pigment mixed together with the top surface granules increased reflectance to 0.263 for green glass and 0.254-0.275 for clear glass.

Glass modified shingles were tested for durability by measuring resistance to tearing. Conventional and glass modified shingles exceeded the minimum standard for tear strength of 1700 grams and showed no significant differences between the means. Compared to a conventional black shingles, initial costs analysis shows only a modest increase in material costs of $0.112 per ft² to produce glass modified asphalt shingles with pigments, but annual savings of $0.061 per ft² per year in building energy consumption can be achieved through the increased reflectance. Based on the results of this study, it is concluded that glass cullet can be successfully blended with conventional materials to produce a sustainable asphalt shingle that has a solar reflectance of greater than 25% without compromising performance.

6 ACKNOWLEDGEMENTS

The author would like to acknowledge Ghesquiere Plastic Testing Inc. for providing tear strength testing, Lhoist North America for providing limestone filler material, BlendTec for providing a mixer, Strategic Materials Inc. for providing glass cullet, 3M Industrial Mineral Products for ceramic coated roofing granules, and the Louisiana Transportation Research Center (LTRC) for granting us access to their laboratories.

Abstract: Reductions in electric power consumption at the University of Washington are an established sustainability performance target. In order to meet this target, Leadership in Energy & Environmental Design (LEED) certification of buildings on campus is part of a long term plan for the University. It has been assumed that LEED certification will result in less power usage by occupants while improving indoor environmental quality. However, the related indoor environmental quality for these certified buildings has not been evaluated in situ. The primary objective of our study was to investigate the indoor quality assessment, more specifically in this paper, we discuss the thermal comfort of a LEED Gold building through both in-situ measurements of temperature, humidity, and occupant comfort surveys. Three measurement stations have been implemented in a low-rise retrofitted Student Union Building starting April of 2014: two in a food court or commercial kitchen environment and the other in a small office. Surveys to assess the comfort levels of both populations have been undertaken. The resulting data set is rich in terms of providing technical and nontechnical feedback on the thermal comfort of a LEED certified building. Preliminary findings indicate that thermal comfort parameters employed for heating, ventilation and air-conditioning systems control were not optimum in practice.

1 INTRODUCTION AND BACKGROUND

In 2009, University of Washington (UW) President Mark A. Emmert stated his intent to establish a climate-neutral campus having no net greenhouse gas emissions (University of Washington Climate Action Plan Oversight Team 2009). As part of a plan to accomplish this goal, over 216 smart meters have been placed on buildings on the Seattle campus to monitor energy consumption through the related Pacific Northwest Smart Grid demonstration project. Another major strategy adopted by the university is to require high-performance building standards (University of Washington Climate Action Plan Oversight Team 2009). As a founding signatory of the American College and University Presidents’ Climate Commitment, UW uses the United States Green Building Council’s (USGBC’s) Leadership in Energy & Environmental Design (LEED) rating system for all buildings on the UW campus. According to UW’s Environmental Stewardship and Sustainability Office, the number of LEED-certified buildings has increased from 15 in 2011 to 27 in 2013.

The newly renovated UW Husky Union Building (HUB) (i.e., the Student Union Building) received a LEED Gold rating. To achieve these goals, dramatic changes were made to the building. New mechanical, electrical, lighting, and audiovisual systems were brought into the building to replace antiquated systems, although half of the building’s more than 60-year-old superstructure was preserved (Bussard & Chan 2012,
“The University of Washington opens newly renovated husky union building” (2012). In addition, a series of sustainable elements were incorporated into the new HUB. For example, the newly designed atrium, the large expanses of glass, and supporting mechanical systems created a naturally illuminated and ventilated building. As a result, in principal, the indoor environment can be improved while energy usage is reduced. This led to the research question of this study: does the LEED-certified Gold HUB perform according to protocols established by agencies such as the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE), the Charted Institute of Building Services Engineers, and USGBC in terms of thermal comfort?

Studies about occupant and indoor environmental quality (IEQ) in green buildings have focused mostly on occupant surveys without investigating the on-site physical measurements of the indoor environment (Abbaszadeh et al. 2006, Altomonte and Schiavon 2013, Asmar et al. 2014) and mostly for office buildings (Radwan et al. 2013). This study takes into consideration both the subjective (occupant surveys) and objective (physical measurements) aspects of indoor environment in a LEED-Gold certified building. In addition, IEQ measurements for commercial kitchen environment were undertaken.

2 RESEARCH OBJECTIVE

The predicted energy performance of a building is based upon several assumptions about the indoor environment quality such as the indoor temperature, relative humidity, CO₂ levels, lighting and acoustics. In this paper, we present one segment of preliminary findings of a long-term investigation focused on the development of a comprehensive framework to evaluate the effectiveness of sustainable practices used in new and existing green buildings. Specifically, we characterize the in situ IEQ for a naturally ventilated LEED Certified Gold building through physical measurements and occupant surveys. This paper presents the collected data on temperature, humidity, and occupant comfort surveys in both a small office and a commercial kitchen environment of a naturally ventilated LEED Gold building on UW campus in the year of 2014.

3 METHODOLOGY

3.1 Equipment Selection and Set-Up

After investigating the required measurement equipment, the research team mounted all the handheld devices on a moveable I.V. pole and delivered the three measurement stations to the office and the kitchen. The research team consulted multiple references (ASHRAE, USGBC, & CIBSE 2010, ASHRAE 2009, Haruyama et al. 2010, Simone et al. 2013, Stoops et al. 2012) to evaluate the necessary equipment for accessing the IEQ of the office area and commercial kitchen. Table 1 lists all the purchased equipment related to measurement of air temperature (Ta), globe temperature (TG), and relative humidity (RH) for the study to physically measure the thermal comfort parameters. Mounting heights were also extracted from existing sources (ASHRAE 2013a) and are summarized in Table 2.

3.2 Testing Location Selection

Three locations were used for data gathering. The selection of each location was based on how well it represented the surrounding area. Through consulting the kitchen and office staff, the research team decided that these locations were ideal in terms of keeping the impact of the data measurements on normal business operations to a minimum level. Within the kitchen environment there were two data-gathering
locations. The first location was near the restaurant’s cooking equipment. The second location was identified near the dishwashing machine. In the office, the unit was located in the general occupant seating/desk area.

3.3 Survey preparation

The International Organization for Standardization and ASHRAE have established indoor thermal environment standards. The Center for the Built Environment (CBE) of the University of California, Berkeley provided an occupant IEQ survey for researching building performance (Center for the Built Environment n.d.). The survey covers thermal comfort, indoor air quality, lighting/daylighting, and acoustics and served the purpose of this study. The CBE also has large databases of accumulated survey results. Therefore, the research team chose to use the CBE survey for occupants in the office inside the HUB.

The kitchen area is a different indoor environment from the office areas. The main activity in the HUB kitchen is cooking, which generates heat and effluents that must be captured and exhausted in order to control and guarantee thermal comfort and good air quality for the employees (ASHRAE 2009). Relatively little research has been conducted regarding thermal comfort in commercial kitchens. Therefore, a standardized survey for commercial kitchen employees could not be found. Haruyama (Haruyama et al. 2010) used questionnaire surveys to evaluate subjective thermal strain in different kitchen working environments in Japan. In the United States, ASHRAE-supported research (Simone et al. 2013, Stoops et al. 2012) investigated the thermal comfort in commercial kitchens of different types and locations in different climatic zones. A modified version of Stoops et al’s “Thermal Comfort in Commercial Kitchens Survey” was used in this research to collect subjective measurements. The modified survey contained 36 questions covering background information, personal comfort, personal control, work conditions, environmental sensitivity, and clothing.

Both the office and kitchen surveys were pre-tested with the HUB associate director. Based on the feedback, kitchen survey questions about building features including window blinds, roller shades, exterior shades, and security systems were deleted since they were not available or accessible to most kitchen staff. Questions in the office survey about exterior shades and the security system were also deleted given their limited installation.

4 PRELIMINARY RESULTS AND DISCUSSION

The preliminary results are provided for the thermal comfort measurement in the office and the kitchen. The results of the thermal comfort measurements include the indoor operative temperature, measured data as plotted in the graphic comfort zone, and the vertical temperature difference measured at 0.1, 1.1, and 1.7 m. The results for the office area were assessed separately for occupied hours for both summer months and autumn months. Summer months were from June through August. Autumn months were from October through November. Survey results were used to assess whether these objective data aligned with the occupants’ subjective assessment of the thermal comfort.

4.1 Measured Thermal Comfort Data

4.1.1 Office Area

Figures 1 and 2 contain representative time series plots comparing the daily average five-minute mean indoor operative temperature readings for the working hours for the summer and autumn, respectively. The indoor operative temperature (ASHRAE 2009) represents the temperature of a uniform environment that includes the effects of relative humidity. The globe temperature measurement is used as equivalent to the indoor operative temperature. Excursions of peak values above and below the 80 percent ASHRAE acceptability limits as defined in ASHRAE 55-2013 Section 5.4 occur occasionally, especially early in the morning during the summer months due to the free-cooling strategy, night ventilation. The 80 percent limits are a function of the outdoor temperature and vary as the weather changes. The statistical variance in the record is much smaller for the autumn readings.
Figure 1: Representative time series data for globe temperature TG (°C) in the office during working hours in the summer.

Figure 2: Representative time series data for globe temperature TG (°C) in the office during working hours in the autumn.

Figures 3 and 4 contain the measured data as plotted in the graphic comfort zone method for identifying the acceptable range of dry-bulb temperature and humidity as defined in Section 5.3 of ASHRAE Standard 55-2013 (ASHRAE 2013). For summer, the 0.5 clothing insulation zone is shown in Figure 3. Both the 0.5 clothing zone and the 1.0 clothing zone are shown in Figure 4 for autumn to reflect the clothing choices made by the office workers. The data often extended beyond the suggested comfort zones during the summer months. The plots illustrate the variability in the ranges of thermal comfort in the summer, with a wider, more acceptable range in the autumn.
Figure 3: Graphic Comfort Zone for working hours (8 am to 8 pm) in the office during the summer. The “boxed” area with dash line shows the 0.5 clothing zone.

Figure 4: Graphic Comfort Zone for working hours (8 am to 8 pm) in the office during the autumn. The two “boxed” areas represent the 0.5 (dash line) and 1.0 (solid line) clothing zone.

The vertical temperature difference in the office was also investigated but did not exceed the recommended ASHRAE limit of 3°C during the study. The ASHRAE limit of 3°C was occasionally violated during summer (1.81 percent of the time during summer months and 0.36 percent of the time during summer and autumn months). Most of the violations happened between 5 p.m. and 6 p.m.

4.1.2 Kitchen Area

Indoor temperatures at various vertical locations in the kitchen cooking area were notably different. ASHRAE Standard 55 recommends that the vertical air temperature difference between 0.1 and 1.7 m should not exceed 3°C. Figure 5 shows the five-minute average air temperature on a weekday at three heights as well as the spatial average. During the peak service hours, which are from 11:00 am to 1:30 pm, the spatial average ranged between 26 and 28 °C while the temperature at 1.7 m was above 27°C. The vertical air temperature difference was above the ASHRAE recommended limit 17 percent of the time for a particular day.
Figure 5: Five-minute average indoor air temperature in the cooking area on Wednesday July 2, 2014.

Figure 6 shows the five-minute average air temperature near the dish-washing machine on a weekday. Similar to the cooking area, the spatial average temperature ranged between 26 and 28°F during peak service hours. The vertical air temperature difference was also above the suggested standard limits 38 percent of time for that particular day.

In the cooking area, the difference in the vertical temperature gradually increased from 10 a.m. and peaked around 12:30, followed by a gradual decrease. The dishwashing area showed recurrent peaks and valleys, most likely due to the fact that heat was generated when the dishwashing equipment was in operation intermittently to clean the cooking utensils, dishes, cutlery, and other items. In the dishwashing area, the vertical temperature difference peaked around 14:30. This lag of about two hours was observed as the kitchen cooking activities peaked and started to decrease at about 12:30.

Figure 6: Representative five-minute average indoor air temperature near the dishwashing area on Thursday July 24th, 2014.

Figures 7 and 8 contain the measured data as plotted in the graphic comfort zone method for identifying the acceptable range of dry-bulb temperature and humidity as defined in Section 5.3 of ASHRAE Standard 55-2013 (ASHRAE 2013). For both the cooking and dish washing area, the “0.5 and 1.0 clothing insulation zone” is shown in Figures 7 and 8. The data repeatedly extended beyond the suggested comfort zones in both kitchen areas.
Figure 7: Graphic Comfort Zone for cooking area (6 am to 9 pm) in both summer and autumn. The solid “boxed” area shows the 1.0 clothing zone. The dashed “boxed” area shows the 0.5 clothing zone.

Figure 8: Graphic Comfort Zone for dishwashing area in both summer and autumn. The solid “boxed” area shows the 1.0 clothing zone. The dashed “boxed” area shows the 0.5 clothing zone.

### 4.2 Survey Results Regarding Occupants’ Thermal Comfort

#### 4.2.1 Office Area

The survey used seven-point ordered scale questions to evaluate the occupants’ satisfaction with the thermal comfort parameters. These seven-point order scales ranged from very dissatisfied (0) to very satisfied (7), with neutral being the midpoint (3). The initial invitation to participate in the survey was emailed to only those six office employees that were stationed in the space where the continuous measurements of the IEQ were being collected. However, recognizing that the building (HUB) serves 54 other permanent employees throughout the various office spaces, an identical survey was made available online to capture the responses from a greater number of occupants of the building. A total of 41 responses were collected out of 60 employees, which resulted in a 68.3 percent response rate. This also exceeded the ASHRAE Standard 55 (ASHRAE 2013) requirement for having at least 35 percent of occupants respond to the post-occupancy survey for evaluating the IEQ in a subjective manner.
Determining thermal comfort included asking questions about the indoor temperature in the workspace. On average, the respondents indicated feeling slightly above the neutral level at 3.5. However, about 40 percent of respondents were slightly to very dissatisfied (range from 0 to 2) with the indoor temperature. Of those people that were dissatisfied, 75 percent of them actually had a portable fan in their workspace, and 37 percent had access to window blinds or shades and/or operable windows. In conclusion, 94 percent of the occupants that expressed discomfort had means to individually control their environment with personally adjustable or controllable systems in place. None of the occupants indicated discomfort from the cooler morning temperatures.

4.2.2 Kitchen Area

The kitchen survey asked employees questions about air movement and discomfort. The employees of the kitchen area consist of regular staff and temporary student employees. Fifteen regular staff members worked in the kitchen at the time of assessment. The manager distributed 15 paper copies of surveys to the regular staff, and all 15 copies were answered and returned.

Over half of the employees (60 percent) did not feel adequate air movement normally during work. Those employees complained about excessive heat from ovens or woks, and suggested increasing air flow and installing air conditioning or fans. Seventy-three percent of the employees stated that they did not feel comfortable most of the time. Most of them felt warm at the front and back of their bodies. Regarding different environmental conditions in the kitchen that could cause discomfort, “too high temperature” and “sweating” bothered most of the employees. Complaints of other conditions such as “draft” or “smoky kitchen” were relatively low.

5 CONCLUSION

Occupants of the offices were mainly satisfied with the thermal comfort of the building. Nevertheless, slightly lower and higher room temperatures were observed during early mornings and late afternoons in the summer. The free-cooling strategy, night ventilation, was successful in reducing the indoor operable temperature to a comfortable level in the morning. Without a mechanical air-conditioning system in the office spaces, the rise in outdoor temperature during the summer afternoons, in combination with the higher occupancy rate, increased the temperature to exceed the 80 percent ASHRAE acceptability limits as defined in ASHRAE 55-2013 Section 5.4. The survey showed that occupants were not bothered by the lower temperature in the morning but were disturbed by the higher temperature in the afternoons. Interestingly, 94 percent of those that were dissatisfied with the temperature had means to control their environment with personally adjustable or controllable systems such as windows and fans.

Objective measurement of the two kitchen areas, cooking and dishwashing, showed frequent exceedance of 80 percent ASHRAE acceptability limits as defined in ASHRAE 55-2013 Section 5.4. Complaints did exist among most of the kitchen employees about the indoor operable temperature. Specifically, these included low air movement causing discomfort with high temperature and sweating. An overwhelming number of respondents, almost three-fourths, indicated that most of the time they felt uncomfortable working in the kitchen. They suggested adding additional mechanical cooling systems.

The results presented here are preliminary and data collection continues through 2015.

Acknowledgement

The authors would like to thank Yiming Liu, engineering technician; HUB Associate Director Paul Zuchowski; Carole A. Grayson, JD, director of student legal services; and Dale T. Askew, general manager of the Husky Den. We would also like to thank all the employees who filled out surveys and Michael Taborn II, who participated in collecting survey data as a summer graduate researcher. This research was also supported and funded by the University of Washington’s Green Seed Fund.

Abstract: Construction is one of the most high-risk industries in the world. The safety records of the construction sector report that, construction workers are approximately over three times more likely to be exposed to serious accidents comparing to other industries. In addition to these injuries and fatalities, work-related accidents also cause financial damage, conflictual cases and pecuniary penalties for the construction companies. Therefore, the significance of the safety management process has been increasing in the construction industry. However, since the majority of the construction activities are complex and require collaboration between the workers, the provision of the safety has become one of the challenging tasks. So, the behavior-based skills of the workers play a crucial role in the safety management. Traditional safety training methods have been merely focusing on information-based techniques such as lectures, videos, written materials, etc. On the other hand, previous research has indicated that adequate safety training should also involve behavioral modeling and hands-on training, together with traditional learning methods. Due to the nature of the construction projects, hands-on training in the construction field is not practicable. In this sense, using virtual environments is an effective method that enables a safe environment for the users without being exposed to adverse effects of the failed tasks. Thus, virtual environments allow visual simulation that is helpful for the improvement of the trainees’ behavior-based skills. Therefore, virtual environments provide an important opportunity to advance the level of safety training. The main aim of the study is to describe the developed virtual safety training environment called V-SAFE (Virtual Safety Analysis For Engineering applications), which involves methods to simulate, and visualize construction operation scenarios. V-SAFE is based on the Unreal game engine for the visualization of the environment, and USARSim is used for the high-fidelity simulation of the robot behavior and environment mapping. V-SAFE is projected to establish a base to identify construction-specific safety risks and to improve the behavior-based skills of the construction project participants. In brief, V-SAFE has high potential to improve the risk recognition capability, and situational awareness of the construction managers, workers, safety managers, field engineers. So, V-SAFE could be beneficial for the construction organizations aim to advance the effectiveness of the safety training.

1 INTRODUCTION

The number of fatal accidents in the construction industry indicates the risky environment of the construction projects. During a 10 year period between 2004 and 2013, 558 fatal accidents were recorded in Canadian construction industry which was accounted for the highest number of fatal occupational
accidents of any industry sector (Workplace Safety and Insurance Board, 2013). Quite similarly in the
United States, around 800 occupational fatal accidents occurred in the construction industry that
correspond to 11.8 per 100,000 full-time equivalent workers in 2013 (U.S. Bureau of Labor, 2014).
Moreover, the fatality rates did not differ in the European Union (EU) countries. Approximately 3,800 fatal
injuries occurred in 27 European countries in 2012 (Eurostat, 2013). Shortly, statistical results
demonstrate that construction workers are exposed to excessive on-site hazards that could result in injury
or even death. Therefore, we can conclude that occupational accidents in the construction industry are
still a major worldwide problem.

The occupational accident records clearly indicate inadequacies in the construction safety management
process (Waehrer et al., 2007). Coleman (1991) highlights that about 90% of the fatal construction
hazards could be avoided and 70% of these construction site accidents originate from the inadequate
safety management action. Similarly, Carter and Smith (2006) also show that hazard identification level in
the construction projects are not satisfactory, and 33% of the risks could not be precisely identified by the
workers. As a result of the insufficient hazard identification level in the construction field, accidents
inevitably occur on the construction site. One of the main reasons of the unforeseen hazards could be the
lack of adequate safety training for the workers in the construction industry (Helen and Rowlinson, 2005).
Several studies thus far have highlighted that efficient safety training could improve the hazard
identification and with this way the accidents could be prevented before they occur.

Moreover, previous studies (Hung et al., 2013; Aranda, 2000) have shown that, traditional training
methods might be able to improve the hazard identification level only to some extent that is not sufficient.
For instance, Hung et al. (2013) found that fall-protection training could be able to improve the
identification of some risk sources leading to the falls. Similarly, Aranda (2000) utilized the navigable
movies to set-up training program for the improvement of the hazard identification. However, all of these
training methods merely focus on the information transfer by using the materials such as lectures, 2D
drawings, photos, etc. Yet, previous research has indicated that adequate safety training should also
involve behavioral modeling and hands-on training, together with traditional learning methods (Burke et
al., 2006), but, the application of the highly engaging training in the construction field is not practical, it is
costly and even risky. Considering the need for an alternative safety training method, this paper
introduces a novel method using virtual reality that involves both behavioral modeling and hands-on
training in a risk-free environment.

2 LITERATURE REVIEW

The provision of the adequate safety training is one of the challenging tasks in the construction industry.
Therefore, in order to provide an effective safety training, identifying the critical issues for the
improvement of the safety training is important. Frese and Zapf (1994) state that, proactive training
methods are more efficient, comparing to passive techniques. In other words, Frese and Zapf (1994)
argue that conveying the safety information by practice plays a crucial part in the effectiveness of the
training. Similarly, Burke et al. (2006) extended the measurement of safety efficiency approach by
categorizing the training methods. Accordingly, Burke and colleagues identify three main safety training
methods; least engaging, moderately engaging and highly engaging (Burke et al., 2006). The least
engaging training methods are the information delivery systems such as videos, written information,
lectures, etc. The major limitation of the least engaging methods could be considered as only focusing on
the information delivery, rather than practical training. On the other hand, moderately engaging methods
also consist of quantitative feedback-based training methods such as questionnaires, interviews, etc.
Comparing with the least engaging methods, moderately engaging training methods also provide
feedback to the users. Finally, according to Burke et al. (2006) the most engaging active training methods
should cover the integration of the knowledge transfer and behavioral modeling. So, a precise safety
training should involve relevant information transfer, hands-on training, behavioral modeling, and
feedback mechanism (Burke et al., 2006). However, due to the nature of the construction projects, hands-
on training in the construction field is not practicable; it even increases the risk of accident.

In this sense, using virtual reality based training tools could be a suitable method for the trainees since
virtual training provides a safe work space for the users without being exposed to negative effects of the
failed tasks. Consistently, Sokolowski and Banks (2009) also state that the use of virtual simulation is useful when it is not possible to interrelate with the real system. So, the virtual system could be helpful to the users to apply the training recursively. Thus, they could learn from their mistakes and correct them. As a result, users could enhance their safety knowledge by modifying their safety attitudes and improving their cognitive abilities.

Similarly, virtual reality-based training systems have been used in several fields. Preliminary work on surgeon simulation was undertaken by Satava and Fried (2002) to describe the effects of using the virtual reality to advance the surgical simulation performance by the improvement of the relevant psychomotor skills. On their comparative experiment, results show that the use of the virtual training significantly improved the operation performance of the surgeons. Consistently, Lin et al. (2007) assessed the cognition capabilities of the drivers by quantifying the responses. The study shows that adequate virtual training could significantly improve the drivers' cognitive responses.

Similarly, virtual environments have been used in various fields in the construction industry as well, such as information management, geotechnical engineering, scheduling, structural design, etc. For instance, Arduino et al. (1997) developed an innovative virtual reality-based training platform for the trainees by using a geotechnical triaxial device. Study results show that virtual reality based training was helpful for the users to understand the soil behavior. In addition, a comparative study of Comu et al. (2011) measures the impact of the facilitation in a global project while the participants are geographically distant. Accordingly, results provide an insight into the role of the facilitation in the virtual project networks. Similarly, Wen et al. (2009) used the virtual reality for the training of the rigging operators. Results show that the trainees' operating skills were positively affected by the use of the virtual training.

The studies presented in different fields of the construction area point out that virtual reality has a great potential to improve the training level. Recent and growing body of literature has investigated the use of the virtual safety training tools in the construction industry. In a comparative analysis, Albert et al. (2014) aimed to improve the hazard recognition skills of the workers by using the virtual reality based safety training tool. As a result, a human-computer interactive augmented virtuality training platform was developed and cognitive mnemonics based on energy sources such as mechanical, electrical, etc. were presented. The results show that identifying hazards according to the energy-based cognitive mnemonics significantly improves the hazard identification level by the support of the systematic categorization. Similarly, a recent study by Guo et al. (2012) integrated serious gaming technologies into the construction safety management process to improve the training performance. The study reveals that the safety performance of the plant operatives and tower crane workers were significantly improved. Quite similarly, Le et al. (2014) developed a safety training tool for the safety education purposes. The system provides a role-playing platform for allowing the students for dialogic and experiential learning. Moreover, Park and Kim (2013) created a framework for the visualization of the novel safety management process by integrating building information modeling, location tracking, and augmented reality. Study results show that safety management visualization systems improve the hazard identification and the real-time communication between construction management team and workers. Taken together, these results indicate that the virtual safety training tools and visualization system improve the construction safety management by enhancing the effectiveness of the field safety risk identification, providing a better understanding for the workers about risk recognition, improving the real-time communication between construction manager and workers.

In the lights of these several studies (Albert et al., 2014; Guo et al., 2012; Le et al., 2014, Park and Kim, 2013) which contribute to the body of literature of construction safety management, we also aim to make a meaningful contribution. In this study, we analyzed the features, characteristics, and potential contributions of a virtual platform called V-SAFE (Virtual Safety Analysis For Engineering applications). In addition, the paper also discusses how the V-SAFE could be able to address the inadequacies in the construction safety training in a systematic manner by offering an enhanced and highly engaging training method. Hence, the study provides insights in a way that how virtual safety training could be applied in construction-specific training program. In addition, the study highlights that features of the virtual tools play an important role in the construction safety training.
3 RESEARCH METHODOLOGY

3.1 Overview of the Virtual Safety Analysis For Engineering applications (V-SAFE) Development

The main objective of this study is to develop a virtual reality based safety training tool for the construction industry. The tool simulates hypothetical construction activities in a three-dimensional (3D) virtual media. The main properties of the tool such as surrounding environment, reality integration, and collision detection, help to improve the hazard identification level of the users, and also advance their behavior-based skills. In other words, by using the V-SAFE, the trainees are exposed to real construction risks in a virtual simulation environment. Accordingly, users learn about the hazards they may face in their workplace and experience the potential consequences of their own mistakes or their colleagues' mistakes, in a safe virtual environment. In addition, this software also aims to enhance the performance of the operators since it provides repeatable training practice. In the virtual environment, workers are subjected to varied alternative incidents in putting up a brick wall. In this task, we defined two different roles as the crane operator and site workers that are assigned on-site duties. The task-based simulation consists of the major factors leading to hazards in the field, and trainees are asked to finish their task with appropriate safety behavior. Thus, the system aims to not only improving the hazard identification level of the workers, but also, enhancing the collaboration between different participants in the field.

V-SAFE is based on the utilization of the "Unreal Engine" by virtue of the "Unreal Software Development Kit". Unreal Engine (UE) is a cross-platform game engine written in C++ first released in 1998 by Epic Games, which is a popular game engine. The usage of the Unreal Game Engine is not limited to the games. NASA, U.S. Department of Transportation and Warner Bros are listed among the licensees of UE3 (Slashdot, 2006; Epic Games, 2011). Consequently, UE3 is also used in training, transportation and movie storyboard simulations.

Another component of the V-SAFE is USARSim (Unified System for Automation and Robot Simulation). USARSim is a robot simulation environment built using UE3. USAR enables combining the use of engineering and scientific application in the adequate virtual environment (Balakirsky et al., 2006). Recently, researchers have shown an increased interest in the use of USARSim, due to its broad range of expertise such as advanced locomotion systems, sensor fusion, cooperative multi-agent planning, human-robot interfaces and more. USARSim, an open-source project is funded by National Science Foundation, supervised by National Institute of Standards and Technology and used in rescue virtual robot competition league of RoboCup (Balakirsky et al., 2006). USARSim is designed to simulate disaster scenarios in which virtual robots perform rescue missions (Balakirsky et al., 2006). For this purpose, many robots and sensors are implemented in UE3. In the V-SAFE, USARSim is used to control autonomous agents in the simulation environments and observe the environment using sensors.

The general structure of the V-SAFE involves four major stages. In the first phase, users create their accounts and avatars. Hence, they could share their personal information through the media with the other users. Secondly, users select their simulation preferences using the Lobby Web Server interface via their web browsers. Thirdly, when all users are ready, the web browser starts the USARSim and Unreal Simulator with the given parameters. Finally, during the simulation, the USARSim, and Unreal Simulator communicate with the simulation coordinator running on the V-SAFE server. Simulation Coordinator tracks the state of the simulation on all users' accounts and synchronizes the simulation events when necessary. The structure of the V-SAFE training system that involves the data tracking and visualization is shown in Fig. 1.
As we mentioned, the V-SAFE is powered by Unreal Game Engine and Unreal Software Development Kit. So, all the components, functions, and digital tools were all developed through the Unreal Development Kit and USARSIm editors and the kits in the game engine. First of all, terrain editor function primarily aims the integration of the virtual terrain to the virtual scene (Mooney, 2012). The general virtual terrains are supported by the dynamic multiple layers of the deformable blended materials. Thus, virtual terrains such as grass, concrete, etc. could have been integrated into the virtual environment. Secondly, object modeling is also another important feature of the environment. In our study, we defined static and dynamic 3D objects related to the construction tasks such as the crane, building, electrical equipment, scaffold, machinery, etc. In the modeling process, object editor provided to input the geometric properties of the materials inside the virtual environment, accordingly the quality of the simulation is significantly enhanced. The third important feature of the engine is the collision detection system. This feature allows the users to move around and inspect the elements of the virtual environment. So, collision detection development advances the realistic effects of the virtual media (Mooney, 2012). By using these functions, all the simulation related elements were embedded into the virtual environment.

3.2 V-SAFE Training Procedure

The training procedure of the V-SAFE was based on three steps. In the first step, we identified all the possible hazards that could have occurred during the building up a brick wall task based on previous construction projects. In addition, we also considered the number of the identified hazards; precursors lead to these hazards, and their potential impacts. In other words, we defined which accidents are more likely to occur, how these hazards could be prevented and what are the possible effects of these hazards. By this systematic analysis of the hazards, we identified the most critical hazards for the simulated construction activities. In the second part, we defined these hazards into the virtual environment of the V-SAFE together with their probability of occurrence. During the identification of these hazards, we assigned three principal reasons of the hazard occurrence as material-based, safety knowledge-based and behavior-based. Thirdly, we associated these hazards with the objects and activities in the virtual environment. After the completion of three stages, we developed the main scenario. Thus, we finalized the V-SAFE virtual environment for the user interaction.

After the completion of the V-SAFE virtual environment, we conducted an alpha test in order to validate the functionality of the V-SAFE. The Alpha test was aimed to gather information about the strengths and limitations of the V-SAFE and to evaluate the fundamental functions of the virtual tool. So, the preliminary analysis of the V-SAFE could be conducted, and the tool could be upgraded considering the feedback provided by the trainees. During the preliminary analysis, firstly the trainees were assigned two different
roles that are the crane operator and the site worker. For instance, when building up a brick wall, the crane operator moves the necessary materials and equipment to the designated work area on the second floor. In the virtual environment, even though users attempt to fulfill their assigned duties individually, at the same time they closely collaborate in the environment. According to their behavior in the virtual environment, trainees could be possibly become subjected to different types of exposures such as falls, struck by the objects, electric shock, etc. Consequently, during the alpha testing, participants were asked to monitor and use the V-SAFE environment and models to evaluate the system competence for the user interaction.

During the interaction, trainees use the standard computer hardware such as keyboard, mouse and monitor. The viewpoint is based on the first person view of the avatar, and the users could move their avatar by using the keyboard and mouse (Fig. 2.).

Mouse provides the orientation of the character in z-axis while the keyboard provides the movement in x and y axes. During the virtual tour, the users could walk on the virtual terrain and interact with the static and dynamic 3D objects and other users by their avatars (Fig. 3.). So, the users can interactively take place within the simulation, and they can repeat the virtual training till the desired performance level is achieved.

4 DISCUSSION

In this research, we aimed to develop a highly engaging safety training tool, the V-SAFE, which involves necessary information transfer, hands-on training, behavioral modeling, and feedback mechanism. As mentioned in the literature, there are potential benefits of using the virtual reality based construction
safety training tools. In traditional hazard identification, the identification process is satisfied with the examination of the 2D materials such as drawings, structural and architectural designs, photographs and videos. However, this approach does not improve the spatial awareness and decision-making capabilities of the trainees. As a result, the cognition and vision of the users are extremely limited, and several potential hazard sources could be easily neglected, due to the lack of the third dimension consideration. However, the virtual environment could improve the spatial awareness by establishing a base for manipulating with the objects and navigating in the virtual environment. Thus, the hazards could be identified more effectively since 3D environment supports the correct safety information processing and enables collaboration among the users.

All previous studies (Albert et al., 2014; Le et al., 2014; Park and Kim, 2013) show that virtual construction safety training methods improve the hazard identification level, even though the methods used vary significantly. For example, Park and Kim (2013) aimed to integrate a question and answer procedure into the relevant hazard sources. Thus, the related safety questions about the risk sources could be directed to the trainees while the users encounter with the hazard source in the virtual environment. In that case, the virtual environment could be considered as a moderately engaging training method according the definition by Burke et al. (2006), since this technique focused only on the transfer and evaluation of the safety information. On the other hand, this method did not address behavioral modeling and safety attitudes of the users. Similarly, Le et al. (2014) developed a safety training tool based on the inspection of the virtual media. During the investigation of the different construction tasks, users can monitor potential hazards in the custom scenarios. However, this method still fails to evaluate the users’ safety behavior. In the same vein, Albert et al. (2014) developed a human-computer interactive augmented virtuality and cognitive mnemonics based on construction hazards and on-site energy sources. With this approach, the safety memories of the users were significantly improved, yet the study was not aimed to improve the behavioral safety approach. So, the common characteristic of all of these existing approaches could be considered as the usage of virtual training tools as the enhancement of the traditional methods while they are still at the moderately engaging level.

With the V-SAFE, we aimed to fill this gap in the literature by developing a tool that provides highly engaging safety training unique to the construction industry. First of all, we formed up an experiential learning method, for not only improving the hazard identification level, but also improving the users’ behavior-based safety skills at the same time. The term experiential learning refers to the process of learning directly from the experience (Gentry, 1990). However, processing the safety information through experience on the construction sites is not practical. In this sense, the V-SAFE tool provides a safe platform for hands-on training. With this way, users could accumulate their safety knowledge and improve their behavior. During the alpha test, each trainee was given a different role in the simulation. For instance, one of the users was responsible for the crane operation, which requires both the use of safety information and correct decision-making process. As a result of this interaction between the users and the surrounding virtual media, trainees oriented to improve their safety behavior and gain practical experience.

Another significant feature of the virtual construction safety training is the provision of the individual and interpersonal learning (Wen et al., 2009). In the learning process, self-learning is an important part of the safety training especially for the workers with insufficient safety knowledge. In the construction projects, falls are among the most common causes of occupational accidents. For instance, during the virtual training, the inadequate behavior of a user such as not wearing a full-body harness could lead to the falls. By realizing the consequence of such an action in the virtual environment, users could modify their safety behavior in the real workplace. As a result, trainees could learn about the construction hazards in the virtual environment and do not repeat the same hazardous actions on job-site. Just like self-learning, interpersonal learning is also another major part of the virtual safety training (Wen et al., 2009). The V-SAFE establishes a platform for the trainees that interact with other users and with this way learn from each other. For instance, when a user violates a safety rule in the virtual environment, other users could warn him to modify his action. Similarly, trainees can also observe the safety violations and take lessons from others’ mistakes. Therefore, utilizing the V-SAFE has a great potential to fulfill two primary learning models by providing collaborative tasks and multiuser environment.
One of the most important features of the simulated environments is providing the sense of reality (Park and Kim, 2013; Albert et al., 2014; Cheng and Teizer, 2013). In other words, the users interact with the surrounding environment and other participants as if it is in a real workplace. In the virtual environments, the sense of reality is also supported by spatial awareness of the users. Accordingly, by interacting with the 3D environment, the users can improve their hazard identification understanding. In order to provide a better hazard identification process, the sense of reality and the visualization quality of the virtual tool are extremely significant. In this sense, visual features, object modeling, etc. of the virtual environment should be realistic and visually effective. In the V-SAFE tool, UE3 supports several image quality functions such as rendering, auto adjusting, etc., which provides high-quality images and object modeling. As a result, users could be able to monitor the virtual environment and the objects in the high quality and full HD resolution. Briefly, more effective visualization by the V-SAFE has a high potential to improve the sense of reality and spatial awareness of the users.

This study demonstrates the features and potential benefits of the V-SAFE training tool based on the alpha test results. The results of the alpha test show that the main functions of the tool such as collision detection, terrain generation, static and dynamic models run without having a major problem. Moreover, we noticed that the multiuser environment of the V-SAFE successfully enabled both the user-to-user and the user-to-virtual object interaction. On the other hand, there are several limitations in this study. First of all, because the V-SAFE is at the alpha testing stage, the number of the scenarios, objects and assigned roles to the trainees were considerably limited. As mentioned, we defined only two major roles that are the crane operator and site workers. Also a single construction scenario, building up a brick wall on the second floor, was implemented. At this stage of our research, we only focused on developing the V-SAFE and identifying the work logic, methods and training procedure. In the following versions of the tool, we plan to simulate more construction process tasks among more roles. Consequently, we will conduct a pilot test of an upgraded version of the V-SAFE. Hence, we will be able to evaluate the training effectiveness of the V-SAFE more accurately.

5 CONCLUSION

The safety management of construction projects is extremely challenging due to projects’ dynamic and complex nature. Providing adequate training could be considered as an important element of the safety management process. Traditional safety training methods have been merely focused on information transfer techniques. The recent developed virtual safety training tools convey the safety information through a 3D supported environment that improves the hazard identification level of the users. Yet, the safety behavior of the users has not been taken into account. This study fills an important gap in the literature by recommending a highly engaging training method for the construction projects. In this study, we introduce the V-SAFE that is a virtual reality based safety training tool and also evaluate the potential benefits of using it in order to achieve a better safety performance level. We also showed that this tool can improve the risk recognition capability and the spatial awareness of the users. Consequently, the V-SAFE contributes not only to the literature on construction management but this novel method could be beneficial for the construction organizations that aim to advance the effectiveness of the safety training and hazard identification level.

SOCIAL CAPITAL IN CONSTRUCTION PROJECTS: AN EXPLORATION

Tas Yong Koh¹,³, Steve Rowlinson¹ and Martin M. Tuuli²

Abstract: The concept and phenomenon of social capital has been identified as an organizing logic that can add value to project organizations. In this respect, social capital is conceptualized as both personal and impersonal linkages between individuals in project organization, the quality of these linkages, and the shared representations embedded within these linkages. Social capital provides a means of coordination and collaboration among project participants. However, given the novelty of the concept in construction settings and peculiarities of construction projects, key questions arise as to what represents and are the forms of social capital in project settings? We adopt a mixed methods approach to answer these questions. Data from a survey of 376 respondents and a case project converge into forming a coherent conceptualization of social capital in construction projects. The findings confirm the multi-faceted nature of social capital and reveal the mechanisms by which social capital facilitates project organizing. Social capital appears to be more acutely needed in construction projects. While structural capital provides the platform for information and influence transfer, relational capital provides psychological safety upon which cognitive capital is translated into task performance. We conclude by discussing both the theoretical and practical contributions of the study to the relational governance discourse in project management.

1 INTRODUCTION

There is an increased recognition of the importance of social context and relationships among participants in the management of construction projects (e.g. Anvuur et al. 2011; Bresnen 2009; Cheung et al. 2006; Fong and Lung 2007; Smyth and Pryke 2008). In the relational paradigm discourse, the learnt wisdom implies that relational issues are often the causes of breakdown in teams rather than the technical complexity of the project (Fong and Lung 2007). Under this backdrop, because construction projects are organized around a network of firms and individuals that are economically independent but technically interdependent (Rooke et al. 2003), and project participants relationships are embedded in those networks that are intertwined through social interactions, those relationships are important as they affect the level of cooperation among the participants. In this respect, the concept and phenomenon of social capital has been identified as a concept that can add value to the study of network-based organizations such as construction projects as it can be used to facilitate actions (Koh and Rowlinson 2012). However, given construction peculiarities, a key question that remains relatively unexplored is, what represents social capital and what the forms of social capital are in project settings? Adopting Nahapiet and Ghoshal’s (1998) conception of social capital, another key question posed in this paper is, what are the manifestations and effects of structural, cognitive, and relational dimensions of social capital in project settings? We employed a mixed methods approach to answer these research questions.
2 PROJECT SOCIAL CAPITAL

2.1 Relevance of Social Capital in Construction Projects

For the purpose of our study, project social capital is defined as the sum of the actual and potential resources embedded within, available through, and derived from the network of relationships possessed by an individual or a cluster of individuals that can be used to achieve the goals of a project (Brookes et al. 2006; Nahapiet and Ghoshal 1998).

A project organization is characterized by factors that are germane to the application of social capital. These factors include interdependence, intensive social interactions, and closure. While providing a condition for project operations, the high level of mutual interdependence also promotes social capital by increasing the opportunity of participants’ interactions (Nahapiet and Ghoshal 1998). In this respect, project organization provides a community, a space to bring together project participants for the performance of tasks in terms of supervision, coordination, and mutual adjustment (Mintzberg 1979). The project operational features also render a need for social capital. Because a project organization is established for a specific purpose to be realized in a definite time, the intensity and dynamics of social interactions in project organization are much higher if compared with those in permanent organizations. As network type of organizations often lack a central authority (Poldony and Page 1998), the coalition formed by project participants requires social mechanisms such as trust and reciprocity to function effectively (Jones et al. 1997; Powell 1991). In terms of closure, although permeable to some extent, a project organization nevertheless has a social boundary that separates members from non-members (cf. Bourdieu 1986). This closure is conducive to the development of norms, identity, or even trust among participants. It is this feature of closure that leads especially to the development of cognitive and relational type of social capital (Coleman 1990; Nahapiet and Ghoshal 1998).

2.2 The Three Dimensions of Social Capital

The three dimensional conception of social capital propounded by Nahapiet and Ghoshal (1998) comprises the structural, cognitive and relational aspects. The structural dimension refers to the impersonal configuration of linkages between persons or social units. The main facets under this dimension are network ties among project participants and the existence of approvable organization that is created for one purpose but can nevertheless be used for other purposes (Coleman 1988; Nahapiet and Ghoshal 1998). The cognitive dimension refers to those aspects that provide shared representations, interpretation, and system of meaning among group members (Nahapiet and Ghoshal 1998). It reflects the condition whereby project team members share a common understanding (Bolino et al. 2002) and the extent to which they have developed a shared cognitive scheme among themselves (Maurer and Ebers 2006). The relational dimension is characterized by the personal relationships actors develop among themselves through the history of interaction (no less in the construction project settings) (Granovetter 1992). Relational dimension involves emotional closeness and reciprocal services among actors (Granovetter 1973). This dimension concerns interpersonal connections that are affective in nature (Krackhardt 1992). It focuses on the quality of the relationships in terms of trust, intimacy, obligations, expectations, etc. (Bolino et al. 2002). The importance of relational dimension lies (with the cognitive dimension) in its ability to facilitate control on project participants.

3 METHODS

The research questions of the present study concerns the exploration of social capital in construction project settings. There is a need to employ both quantitative and qualitative approaches – triangulation (Jick 1979). With the use of the two approaches, we seek to complement the results obtained from one method with those from the other and, in some instances, expand the breadth and range of our inquiry on the phenomenon of social capital in projects (Greene et al. 1989). Questionnaire survey and case study were chosen as the research methods for the study. We employed mixed methods sampling which incorporated both probability (survey) and purposive (case study) samplings (Teddlie and Yu 2007). For the questionnaire survey, responses were solicited from industry practitioners who were either working on on-going construction projects or participated in recently completed projects. We targeted project
managers, site agents, architects, engineers, quantity surveyors, and supervisors/foremen in various capacities as respondents. Their names and contact details were randomly drawn from the membership of professional institutions, trade associations, and governmental departments. In all, 2,186 practitioners were identified and invited to participate in the survey. We received a total of 376 valid responses (17.2% response rate). Of the respondents, 90.2% are male. On the age bracket, 86.3% of the respondents are between 31-60-year old within which 41.7% of them are between 41-50 years old. More than 90% of them have at least 5 years of project experience. Slightly over half of the respondents (50.8%) worked on building projects. The remaining worked on civil engineering (47.6%) and process plant projects. We operationalized the structural dimension with network ties (NW) and informal grouping (IF), the cognitive dimension with shared understandings (SU), and the relational dimension with trust (TR) among project participants (see Fig. 1 for the scales). For the case study, we selected a building construction project known as Project Eastern for the study. Based on our preliminary observations, this project’s procurement system, partnering arrangement, and organizational structure provide relevant settings for us to both investigate and illustrate the phenomenon of social capital. Table 1 provides further descriptions of the case project together with the informants selected for the case study.

4 QUANTITATIVE DATA ANALYSES

We used confirmatory factor analysis (CFA) to examine the dimensional structure of social capital (SC) and to test the convergent and discriminant validity through a measurement model using the proposed constructs of NW, IF, SU and TR. Preliminary model exploration suggests that IF is represented with only one item. The final measurement model indicated that all items have loading in excess of the minimum 0.5 (Hair et al. 2006: 777) at p<0.001. The model has also yielded adequate goodness of fit (chi-square = 274.14, degree-of-freedom = 163, p-value = 0.00, TLI = 0.96, CFI = 0.97, RMSEA = 0.04). Table 2 shows the validity measures, descriptive statistics, and the reliability measures. From Table 2, while most of the variance extracted (VE) for constructs are greater than the required 0.5, the VE for IF is lower at 0.30. Although the value is less than 0.5, but because informal grouping is an important facet of the structural
dimension of social capital, we decided to keep the construct in the model (cf. Hair et al. 2006). For discriminant validity, the VE for each construct is greater than the squared correlation between the focal construct and other construct in comparison. These results imply that, with the exception of IF, the requirements for both convergent and discriminant validity of the constructs are generally met.

We construct the higher level SC model from the measurement model by introducing the higher lever SC construct that link lower constructs of NW, IF, SU, and TR. The final SC model is shown in Fig. 1.

![SC Model Diagram](image)

The scales used (SPE in bracket):

- **Network ties, NW** (Hatata 2006)
  - H1: Number of persons provide help at work (0.56)
  - H2: Number of persons provide social support at work (0.99)

- **Informal grouping, IF** (Nahapet and Ghoshal 1998)
  - H3: Usefulness of informal grouping (0.49)

- **Shared understanding, SU** (Pinto et al. 1993; Sarker et al. 1998; Tsai and Ghoshal 1998)
  - C1: Shared vision (0.65)
  - C2: Collective goals (0.70)
  - C3: Collective rules (0.70)
  - C4: Shared understanding of project requirements (0.76)
  - C5: Shared culture (0.83)
  - C6: Shared understanding of others’ requirements (0.73)
  - C7: Common understanding emerged (0.71)
  - C8: Shared technical knowledge (0.66)
  - C9: Common thinking emerged (0.82)

- **Trust, TR** (Chen and Huang 2007; Cummings and Bromilow 1996; Nyhan and Marlowe 1997)
  - E9: Meet obligations (0.74)
  - E7: Confident of abilities to perform (0.74)
  - E13: Well thought out decision (0.74)
  - E16: Members are reliable (0.86)
  - E6: Fair treatment (0.61)
  - E8: Tell truth in negotiations (0.70)
  - E12: Not misleading (0.65)
  - E15: Negotiate expectations fairly (0.74)

Figure 1: Second-order social capital (SC) model with standardized parameters estimates (SPE)

In the SC model shown in Fig. 1, although all the estimates are statistically significant, the two constructs that represent structural dimension yielded estimates that are lower than 0.5 – 0.22 for the path SC-NW, and 0.49 for SC-H3. While the slightly lower 0.49 path H3 is acceptable, the 0.22 NW path is less desirable. However, Hair et al.’s (2006: 798) have cautioned, because NW (and IF) represents the mainstay of structural dimension of SC, and that it demonstrates adequate internal consistency and convergent validity (0.71 and 0.55, respectively, see Table 2), NW and IF are retained in the model.

5 QUALITATIVE DATA ANALYSES

We used interview data as the main source of information complemented other data types. We used broad-base questioning topic guide to solicit project informants’ views on the manifestation and formation of social capital, and its impacts on team interactions. We performed thematic analysis for the data.
collected. In Project Eastern, the client team assumed dual role of project manager and designer. They were responsible for design-related issues - design management and getting approval - and contract administration. With the novel modified guaranteed maximum price (MGMP) system which incorporated the contractor’s design, there was a need for full compliance of Independent Checking Unit’s (ICU) requirements. Contractor’s designs must be approved by the more stringent ICU prior to site works. The contractor’s design had to be submitted through the client’s structural engineering division. Handling the ICU submissions and approvals had become significant affairs. To manage design-related issues, the project architect (PA) had convened frequent design meetings dubbed “working sessions.”

5.1 Manifestation of Structural Dimension and Position

Structural dimension serves both explicit and implicit functions. The positions of participants and bridging are the explicit function. The internal network interweaved both the client and contractor project personnel into the core team for the project. Multi-connections were present forming a closed network that facilitated information transfer both laterally and vertically across hierarchies. Bridging involved connecting the actor’s team to other networks that were related to the activities of the focal team. In the project the SAgt had attempted to match and link his own contractor's key staffs to those from the client organization. This network was established with reference to the communication matrix set up during partnering sessions. Both the client’s and contractor’s key staff were encouraged to communicate directly among themselves with reference to their positions and areas of responsibilities in the matrix thereby enabling faster, timely, and more accurate communication through the re-configured network.

Implicit functions are associated with the indirect effects that can be derived from an actors’ position in the network. In Project Eastern, the project clerk-of-work (PCOW) had demonstrated leadership to his frontline junior COWs. The latter were initially insistent on the contractor to deliver highest quality standard of works resulting in slow work progress. Sensing the issue and in the bid to improve progress, the PCOW attempted to convince his subordinates to adopt a more practical stance. With his “imposed” leadership and the contractor’s improved work quality, progress slowly picked up. Here, leadership leverage to improve outcome was effected through and contingent upon personnel occupying strategic positions in the projects. Another implicit function is that of legitimacy. In the project, when some of the contractor’s designs of the MGMP packages were disapproved by the ICU, the client team led by the PA helped the contractor to convince the ICU of the adequacy of the designs.

An intriguing effect of structural dimension is the existence and effects of informal grouping and ties. In Project Eastern, the emergent grouping comprised the client and contractor teams, and the subcontractors. As numerous discussions were needed for the design, frequent and intensive design meetings – “working sessions” - were organized among a wide range of participants occupying different hierarchical levels in the project. This resulted in speedier issues resolution as the arrangement “helps to reduce unnecessary corresponding work” (PA). The intensity of the interactions of all parties also helped foster group cohesion and trust building. The PA proclaimed: “We sit down together once a week or twice a month to resolve design issues, and by doing that, actually we build up trust very efficiently.”

5.2 Manifestation of Cognitive Dimension and Shared Understanding

The first kind of shared understanding is the common goals for all parties. Generally, for Project Eastern the common goals for the core teams were timely completion and meeting project budget. Because of the need to achieve common goals, coupled with the need to face the uncertainty and increased workloads for all parties inherent in the string of new initiatives, a sense of solidarity within the core team emerged (more on solidarity later). The PCOW expressed it this way: “The shared goal is just the same... Actually we are the same, we are on the same boat.” This atmosphere instilled a sense of team cohesion and willingness to share responsibilities among team members in the project. Relatedly, the understanding and appreciation of each other’s constraints among the participants are other kinds of shared understanding. This phenomenon is illustrated by the late issuance of structural drawings from the client’s organization resulting from the sudden surge in the number of projects and a shortage of design personnel at the beginning stage of the project. The late issuance affected the contractor’s work planning. The client’s structural design team admitted their inability to produce the drawings on time. They hence
entertained the contractor’s requests for design-related information on urgent basis to mitigate further delay in the contractor’s program. By appreciating and accommodating other’s difficulties, the core team became more cooperative. These shared understandings of technical and contractual requirements among the parties minimized the number of disputes while improving operational efficiency of the project.

5.3 Manifestation of Relational Dimension and Trust

The forms of relational social capital include team spirit, solidarity, commitment, and trust among the core team members. Collegial team spirit was highly evident in Project Eastern. In the project, one form of project governance was the business-as-usual approach. The traditional contract-based interactions among members characterized this approach. However, alongside this mechanistic arrangement was a more humanistic approach. This phenomenon evolved from the initial socialization period of the core team members. After experiencing intensive interactions for some time, a less contractual approach emerged. The client SA recalled: “For a certain period of time, they [referring to the core team] still get some kind of human relationships, and this is important and, under normal situations, we welcome this sort of arrangement because you are not only client-contractor relationships.” It is this emergent relationship that laid the foundation for further collaboration among parties in the project. In addition, solidarity resulted from the need to deal with uncertainty and the increased workloads in relation to the novel procurement system and the string of new initiatives. A catalyst for the formation of a common rapport was the various episodes of contractor’s submissions of design packages to the ICU which had become common target for both teams. Both sides recognized the need to work together for timely ICU’s approval. Within the atmosphere of solidarity both sides showed increased commitment.

The level of trust – a sense of generalized trust - among Project Eastern core team members appeared to be high. The team worked on “a trust system” (PA). This sentiment was echoed by the contractor’s SPM. The manifestation of the trust system in the project lied in large part on the prevalence of the informal arrangement in project organizing. Often, based on the trust among the team members, design amendments that had been agreed upon in design meetings would be acted upon without the need to wait for written (formal) instruction. On the part of the contractor, in the context of ICU’s submission and approval, the impression was that the client team was always willing to assist in their submission. The next type is contractual trust. As contract administrator, contractual trust was more emphasized by the client’s team. In discharging their contractual obligations the client and contractor reciprocated to each other informal agreements to foster contractual trust. This reciprocity facilitated quicker processes as site works were conducted in parallel with the issuance of formal instructions.

5.4 Manifestation of Personal Dimension

The personal dimension is an emergent theme from the analyses. The project informants converged on their views on the importance of individual’s personality and positive characters in project organizing. Willingness to be consultative is one manifestation of personality as evident from the project. The PCOW adopted a more collaborative approach when dealing with the contractor instead of the traditional “command and control” approach. When a problem was encountered, the PCOW discussed and worked with contractor team on the possible solutions instead of issuing a site direction. This approach helped in bringing the two sides closer. The contractor’s QCM affirmed that this approach “helped build the relationship among the two teams.” The second manifestation of positive personality is the project participants’ willingness to exercise flexibility. The manifestation of this intention was most evident in the dealing of the new initiatives. The PA acknowledged the existence of some “tough grey areas” with the trials of those initiatives. Notwithstanding the need to comply with contract and specification, the client’s team was willing to be flexible to “allow some room for them to “maneuver” (PA).

6 DISCUSSIONS

6.1 Structural Dimension

In the quantitative approach of the study, structural dimension was conceptualized as getting one’s works done with the help of network members and getting social support. Although the quantitative evidence
shows support to these two measures, their formations are not strong. It appears project participants generally do not consider obtaining work-related help and social support as constituting social capital. These phenomena suggest that project participants rely on the project organizational control and role-based coordination for task performance, and the reliance on social support is trivial. The qualitative aspect points to the phenomena of bridging and bonding. In the project, bridging had been effectuated among the contractor’s team through the SAgt. And, bonding social capital was highly evident in the project in that the project core team had demonstrated a spirit of camaraderie. This team cohesion improved the team resilience and ability to absorb the shocks related to the uncertainty and complexity brought about by the new initiatives in the project. Due to the high emotional content and psychological closeness in the relationships (Walker et al. 1997), high bonding team confers flexibility and member supportiveness in the management of group affairs. In a highly dynamic environment as in the project, flexibility is highly instrumental in coping with the flow of opportunities that are typically more complex, ambiguous, and less predictable (Davis et al. 2009; Eisenhardt and Martin 2000).

However, the structural features observed in the project had facilitated project organizing. In the project “working sessions” the core team members were also the central figures in their respective extended individual networks (e.g. SAgt with his subcontractor teams). These core team members not only occupied positions of high centrality in the project organization’s technical advice network, they also occupied central positions in the project formal structure performing the technical coordinating functions. The consistency among the personnel’s roles, responsibilities, behaviors and their formal and prescribed roles had led to structural stability and, to some extent, predictability of the project organizational affairs.

6.2 Cognitive Dimension

The quantitative analyses indicate that shared understanding of project requirement, other’s requirements, technical knowledge, shared culture, common thinking, and collective goals represent the cognitive dimension. These items are similar with those derived from the qualitative analyses. Shared understanding of project and technical requirements provide the basic knowledge domain of works and project organizing among participants. Because these aspects mainly concern the physical construction and contractual provisions of the project, they facilitate the discussion and exploration of alternatives and trouble-shooting. Shared understanding on other’s difficulties and constraints help improves relationships among parties. As participants developed fine-grained knowledge of each other’s processes and operational needs, resources, and abilities, such knowledge improves the appreciation of other’s behaviors and needs (Ritter and Gemunden 2003) that results in adaptation of parties’ work processes.

Shared culture and common thinking convey a sense of identity for the members of a collectivity, enhance the social system stability, and serve as a sense-making device that guide and shape members’ behaviors (Smircich 1983). Within the core teams of the case project, the network of cognition that is characterized and represented by the various type of shared understanding intertwined with the structural features of the project organization. To the extent that network members’ expectations affect their perceptions, the reciprocity and transitivity (Kilduff and Brass 2010) of the cognitive perceptions percolated throughout the core team networks. That is, network ties provide informational indications of the general approach of handling the group affairs (cf. Borgatti and Halgin 2011).

6.3 Relational Dimension

The quantitative data reveals that trust is characterized as parties meeting their obligations, the confidence and obligations to perform, the ability of members to make well thought out decisions, the reliability of members, and the expectations that members negotiate project affairs in a fair manner. The qualitative analyses reveal a more varied and dynamic nature of relational dimension. In the project, the time of interactions was short but crucial, and the interactions were intensive, the teams relied on the development of swift trust of the competent and contractual nature in project organizing. Swift trust entails the reliance of judgment on the other project participant’s professionalism, and it depends on doing rather than relating (Meyerson et al. 1996). In the project, trust was formed through the trustee’s performance of specific tasks to the expected standard. Project informants also stressed the importance of reciprocity in the course of relationships development. In the developmental view, the use of contractual trust was
relatively more prevalent than trust with relational content in the beginning. However, over time, with both competent and contractual trusts slowly institutionalized, coupled with performance and reciprocity, a trust with relational content started to emerge. This observation is in line with the view that control mechanisms embodied in contract and its administration can actually serve as a springboard for the inducement of trust (Rousseau et al. 1998). If trust is taken in a wide sense that includes trust that is based on the contract, then trust and contract go together (Woolthuis et al. 2005).

Team spirit and solidarity are other aspects of relational dimension. These also facilitates the recognition that task completion leads to collective good rather than self-interest (Smith 2009). More importantly, it enables a broader set of values to be instilled among group members. This higher level values enable the group to shift size and focus rather easily. As such, solidarity tends to confer the flexibility in both structural form and cognitive framework of reference of the group thereby adaptation among group members. This increased capacity had enabled speedier decision making among the group members.

6.4 Personal Dimension

In project organization, participants constantly operate in the environments that are fluid, fast pace, emergent, and ever changing where each is vying for favorable position. Consequently, involvement in project can be stressful (Bryman et al. 1987). In this environment, it is essential to maintain relationships that are characterized by vitality, mutuality, and positive regards. This can only be achieved by project participants having positive attitudes and personality as observed in the project. The working relationships that stem from individual characteristics which in turn extend to multi-party interactions, together with their cognitive and relational embeddedness, lead to high quality connections among them. In this respect, personal dimension is an important addition of individual attributes in the discourse of social capital in project settings (cf. Kilduff and Brass 2010) and this is a key finding of our study.

Table 3 presents the integrative results of the two approaches. The analyses facilitate the convergence and corroboration of results on social capital in project settings. The analyses confirm and extend the dimensionality, provides the processual aspects and dynamic scheme of social capital. In this respect, the mixed methods approach provide greater confidence in improving our understanding of the phenomenon of social capital. While contributing to the understanding of relational governance in project management in general, our study and research approach also contributes to team effectiveness in temporary (project) settings in that our study has provided a more nuanced and detailed understanding of the combined effects of team processes, motivational, and cognitive effects (Mathieu et al. 2008) on team working. Further, our key finding of the new personal dimension has added to the recent recognition of individual attributes in the network discourse. Because actor’s properties matter for a group to extract network values, our identification of this new dimension has contributed to the social capital literature (c.f. Kilduff and Brass 2010).

7 CONCLUSION

In this study, we set out to explore the manifestations and effects of social capital in construction project organizations by employing a mixed methods approach. Both research approaches show the dimensional correlation nature of social capital and the identification of a new dimension. In project settings, the simultaneous congregation of the members with both strong and weak ties, positive personalities, the creation of common understanding among members, and the closely knitted relations that emerge in the course of interactions all interact in flux to sustain the social capital in project teams. Through facilitating information, communication, and transfer of influence, the structural dimension provides a forum through
which project members can evaluate the trustworthiness, reputations, quality, and affiliation of other members. While this dimension provides a platform for interactions, relational dimension provides a normative structure that helps generate a common set of convention, climate, rules and routines (Granovetter 1992) in project organizations. Relational dimension provides underlying psychological security among members through trust, commitment, and reciprocity. These two dimensions, in turn, constitute a means by which cognitive dimension is translated into members' task performance by facilitating the alignment of disparate project parties. Viewed this way, social capital, as a means of relational governance, is more pertinent to project operation if compared with other more permanent organization. For these reasons, it is important for project organizers to promote socialization among project participants and devise mutually supporting network structures that allow consistent application of roles, responsibilities, and authorities of those participants.

BEST VALUE PROCUREMENT FOR HIGHWAY DESIGN-BID-BUILD PROJECTS

Bharath R. Kolli¹, ² and Daniel Tran¹
¹ Dept. of Civil, Environmental, and Architectural Engineering, University of Kansas, USA.
² bharathkolli@ku.edu

Abstract: Best value procurement is the process in which factors additional to price are considered in the selection of a contractor. Time, operation and maintenance, technical and managerial merit, and past performance are the other key factors considered along with price in best value projects. Compared to the low-bid procurement, best value procurement offers several advantages, including opportunities to improve project quality, promote innovation, and enhance project performance. Best value procurement, while commonplace in highway design-build (D-B) projects, is limited in use for design-bid-build (D-B-B) projects. This paper explores the procedure and existing practices of D-B-B best value contracts for highway projects. Data was collected from a survey questionnaire, structured interviews, and case studies. The survey questionnaire was nationwide distributed to 52 state Departments of Transportation (DOTs) to identify the practices of using best value procurement in transportation projects. The seven structured interviews and four case studies were conducted in detail to investigate the opportunities and challenges of evaluation criteria, selection methodologies, and evaluation committee structure in D-B-B best value projects. The results indicate that evaluation criteria and selection methods are established on a project-by-project basis. The owner agency should develop selection criteria and establish evaluation committees that are most beneficial to a given project. This paper provides some guidance for state DOTs to use best value procurement for their D-B-B projects.

1 INTRODUCTION

State departments of transportation (DOTs) have historically used a low bid approach to procure construction services. Under the low bid approach, price is a sole competitive factor. Non-price factors such as qualifications, experience, technical approaches, and innovative solutions are not considered. Typically, DOT awards the contract based on the lowest responsive bid. The best-performing contractors who will deliver high quality projects are less likely to be awarded the contracts in low bid contracting (Elyamany and Abdelrahman 2010). Researchers have identified several benefits of using low bid procurement including potential for monetary savings (Palaneeswaran et al. 2003), easy and simple implementation, reduced protests and disputes (Gransberg and Senadheera 1999), a long-standing legal precedence, and enhanced competition (Scott et al. 2006). While the low bid approach offers several advantages and is inherently transparent, it does not always offer the best performance during and after
construction. To improve project quality and performance, a number of DOTs are increasingly using best value procurement to deliver their transportation projects.

A review of literature indicated that a number of studies have investigated best value procurement for highway projects. However, most of them have focused on highway design-build (D-B) projects. Limited studies, if any, have explored the use of best value procurement for traditional design-bid-build (D-B-B) projects. Building upon the relevant literature, the objective of this study is to examine how to employ best value procurement in the D-B-B delivery method for highway projects.

2 BACKGROUND

Best value is defined broadly in the literature. Even in the highway industry, the best value definition may vary by state. This study uses the best value definition based on the National Cooperative Highway Research Program (NCHRP) Report 561 as follows: best-value procurement is “a procurement process where price and other key factors are considered in the evaluation and selection process to minimize impacts and enhance the long-term performance and value of construction” (Scott et al. 2006). The report also indicated that best value procurement allows both objective and subjective elements to be considered in the selection process. The objective elements may include contractor experience, timeliness and accuracy of submittals, record of safety, or compliance with material and workmanship requirements. The subjective elements may include effective management, proactive measures to mitigate risk, training programs, customer satisfaction, and client relation.

Best value procurement is one of many procurement options. It is not ideal for every project, but it can provide benefits on appropriate projects. Project goals and project characteristics can determine if the use of best value will be advantageous. Goals that align well with best value procurement include shortening of the project duration, creating opportunities for innovation, and selecting the most qualified team. Appropriate project characteristics include opportunities for innovation, the amount of design required to develop a competitive industry proposal, agency experience with the process, and market capability. For example, researchers show that the best value method more often delivers projects that meet owner expectations (El Wardani et al. 2006). Projects delivered using best value usually stay close to the original budget and schedule (Molenaar and Johnson 2003). Best value procurement is useful on those projects with unique objectives or challenges that may be difficult to meet using traditional low-bid procurement (MnDOT 2013).

State DOTs are increasingly using best value procurement for delivering their transportation projects. The 1996 version of the Federal Acquisitions Regulations (FAR) stated that best-value procurement should be selected when the project needs innovation and new technology or when a specific type of experience is required to obtain the desired outcome (FAR 1996). Considerations for best value procurements can include price, schedule, technical and managerial merit, financial health and past performance (Scott et al. 2006). Because the system provides a balance between price and qualitative considerations, it can optimize the benefits of fixed-price sealed bidding and sole source selection. The inclusion of key factors in evaluation criteria that match the specific needs of a particular project can raise the likelihood of meeting project performance goals (Abdelrahman et al. 2008). In fact, public clients use best value procurement when they aim to achieve the maximum outcome for their projects as opposed to the lowest price (Zhang 2006).

As mentioned above, although various studies have focused on the use of best value procurement on D-B highway projects, a little research explores how best value procurement can be used for highway D-B-B projects. This paper attempts to fill this knowledge gap by conducting four case studies with state DOTs.
that have experience using best value procurement on their D-B-B projects. The following sections present briefly how these four case studies were selected.

3 RESEARCH METHODOLOGY

The research methods employed in this study include three main steps: (1) a national survey, (2) structured interviews, and (3) case studies. The objective of step 1 is to preliminarily determine and identify the current state of practice on using best value with D-B-B projects. Based on the results of Step 1, the authors conducted interviews with seven state DOTs who have the most experience with best value procurement. Finally, step 3 involved conducting four in depth case studies to explore how best value procurement can be applied to these four D-B-B projects.

3.1 Survey

Because of the lack of information about the best value D-B-B contracts, the authors developed a nationwide survey to preliminary collect data. The survey consisted of 18 questions related to the topic such as: project delivery methods using the best value, experience of the agency, evaluation criteria, selection methods, evaluation committee, debriefing, legal, and protest information. The survey was sent to all 50 DOTs across the United States including the District of Columbia, and Puerto Rico. After two follow-up requests, the authors received responses from 46 state DOTs. It is noted that the survey questionnaire asked the participants to describe not only their state of practice related to the best value D-B-B approach, but their perception regarding the use of best value procurement for D-B projects. The survey results indicated that 19 state DOTs are using or considering the use of best value procurement in their D-B-B projects. Based on these responses, the authors searched for relevant information on these state’s D-B-B best value projects in their websites. Much information from state DOT websites could not be found about the use of best value procurement with design bid build apart from the agencies like New York, Michigan, Minnesota, and Oregon.

3.2 Interviews

The responses from the survey were analyzed to determine which state DOTs have the most experience on best value projects. As a result, seven state DOTs were selected for interviews to further investigate the use of best value procurement with the D-B-B delivery method. The interview questions were divided into four sections, including 1) proposal evaluation criteria, 2) selection methodologies, 3) evaluation committee, and 4) debriefing procedures. The authors invited the DOT officials to participate in an interview by phone and email. The interview questions were sent in advance to the officials who had agreed to provide information on their best value projects. After the interviews, the author sent a request for potential case studies on best value D-B-B projects. In addition, the interviewees were requested to provide the documents most relevant to their best value procedures.

3.3 Case studies

Due to the lack of data collected in the survey, and interviews about the use of best value procurement on design bid build delivery method, the case study is a main research tool for this study. In this step, the authors analyzed documents collected from the survey and potential case studies provided by state DOTs in the interview process. As a result, four case studies were selected to conduct a detailed analysis. These four case studies were selected because of the completeness of the documented best value process. In each case study, the authors followed a rigorous case study protocol that included the following four primary criteria: (1) evaluation criteria; (2) selection methodology; (3) evaluation committee; and (4) debriefings. The following sections present the results of these four case projects.
## 4 RESULTS AND ANALYSIS

Table 1 summarizes the key findings from evaluation criteria, best value award algorithm, and evaluation committee of the four case projects.

2. Specific tunnel experience (24 points)  
3. Traffic control and safety plan (16 points) | Price: 50%  
Technical qualifications: 40%  
Technical Approach: 10%  
Proposal with highest score is awarded the project | Experts from ODOT bridge engineering section, region 1 technical center, project Manager, and representative from FHWA |
| 4  | Oregon DOT  | I-84: Sandy River-Jordan Road, Bundle 210 project, Multnomah County | 1. Qualifications and Experience (18 points)  
2. Project Understanding and approach (21 points)  
3. Key personnel (21 points)  
4. In water work approach (16 points)  
5. Steel Box girder approach (8 points)  
6. Diversity (16 points) | Price: 70%  
Technical and qualification factor: 30%  
Proposal with highest score is awarded the project | Individuals from ODOT, non-scoring members from outside ODOT |
One can observe from Table 1 that the price component is an important factor in selecting the contractor for the D-B-B best value projects. For example, in the case study with NYDOT, it was observed that the contractor was selected based on the lowest responsible bid. The case studies with Oregon DOT revealed that the price factor accounted for 50% and 70% associated with Dennis Edwards Tunnel and I-84 Sandy River Jordan Road projects, respectively. However, the technical factors considered in the evaluation process were varied depending on the project type and characteristics. For example, Oregon DOT asked the proposers about their specific tunnel experience with regards to the Dennis L. Edwards tunnel project. Michigan DOT specified a list of detailed technical criteria such as air quality, noise restriction, safety and mobility on their M-39 Southfield project. New York DOT used standard evaluation criteria that are similar to D-B best value projects on their best value D-B-B Patroon Island Rehabilitation Project. These evaluation criteria include responsiveness to request for qualifications (RFQ), legal, financial requirements, experience, and past performance. The following sections discuss each case study in detail.

4.1 Michigan DOT case study: M-39 South Field Freeway Project

M-39 Southfield freeway project involved the reconstruction of roadway from McNichols to M-10, roadway rehabilitation of 28 bridges, freeway lighting and signing, sanitary sewer and screen wall replacement. Michigan DOT (MDOT) does not have a standard procedure for their best value projects. The selection process and evaluation criteria were determined depending on the type and location of the project. The eight evaluation criteria for this project include: 1) air quality, 2) noise restriction, 3) managing utilities to homes, 4) construction traffic, 5) avoiding damage to adjacent property due to vibration, 6) local contractor and workforce participation concerns, 7) safety and mobility, and 8) schedule concern. The maximum point available for each factor is shown in Table 1. The maximum points available for the technical proposal are 500. The composite score of the proposals is calculated by dividing the bid price of the proposal by technical score. The proposal with the lowest composite score was awarded the contract.

The technical evaluation committee was comprised of the Detroit transportation service center (TSC) manager, development manager, delivery engineer, region engineer, region planning specialist, and director of MDOT office of small business development. The committee started with a baseline score and added points for innovative ideas. The final technical score of the proposals was the consensus rating of all the committee members. Price proposals were opened by the committee after evaluating the technical proposals. Finally, the project manager conducted debriefings to unsuccessful proposers after their request. Detailed comments about the strengths and weakness of the proposals were discussed in that meeting.

4.2 New York DOT case study: Patroon Island Rehabilitation Project

The Patroon Island bridge project involved the construction of ramps connecting the I-90 interchange with I-787, repairing the bridge decks and bearings, and painting the bridges. The project manager worked with the chief engineer to determine the evaluation criteria for the project. The evaluation factors for this project are responsiveness to RFQ, legal and financial information, experience, and past performance of the proposers. These evaluation criteria for D-B-B projects are similar to that of D-B projects. The proposals were evaluated against these factors by the evaluation committee on the pass or fail basis. After evaluating technical criteria, the evaluation committee evaluated the cost proposals. The proposer with the lowest cost bid was awarded the contract.

The evaluation committee, which included officials from the New York DOT, was responsible for the evaluation of the proposals and the selection of the best value contractor. The evaluation committee was prevented from seeing the cost proposals to avoid any potential bias during the evaluation process. The
agency conducted debriefing to the unsuccessful proposers. A debriefing was conducted by a procurement official who is familiar with the selection and contract award process. Strengths and weaknesses of their proposals were explained to the proposers.

4.3 Oregon DOT case studies

Oregon DOT has employed best value procurement for several D-B-B projects. To identify the differences of using the best value approach with different type of projects, the authors conducted two case studies in Oregon DOT.

4.3.1 Dennis L. Edwards Tunnel Project

This project involved removing and replacing the existing lining, improving the wall drainage, and improving the lighting system of the tunnel along with the installation of a bike warning system. Oregon DOT (ODOT) used price plus technical qualifications plus technical approach best value process to select the contractor. The price factor accounted for 50% of the weight in evaluation process while the technical qualification and approach accounted for 40% and 10%, respectively.

The three evaluation criteria for this project included (1) construction and general tunnel experience, (2) specific tunnel experience, and (3) traffic control and safety plan. The evaluation committee was comprised of two technical experts (one from ODOT bridge engineering section and the other from regional technical center), the project manager, a representative from the Federal Highway Administration (FHWA), and the engineering consultants who acted as facilitators and observers during evaluation process. The proposals were evaluated and scored separately by the members and the average of all the scores was the final technical score of the proposers. The project was awarded to the proposer whose combined score is the highest among all the proposers.

4.3.2 I-84 Sandy River – Jordan Road, Bundle 210 project

This project was a typical highway project that involved replacing and repairing the bridge. Different from the Dennis L. Edwards Tunnel project mentioned above, the price factor accounted for 70% of the weight in the selection process and the technical qualifications and approach factors accounted for 30%. The main reason for this is that this project was a typical highway project while the tunnel project was more complex. As a result, the technical factors of the tunnel project accounted for more weight in the evaluation process. In the tunnel project, the agency used a specific tunnel experience factor to select the proposer who have more experience and offers the best value for the particular type of work involved. On the other hand, for the I-84 Sandy River project, which is a typical highway project, the agency preferred setting more weight on the price factor for their D-B-B projects. In addition, the evaluation committee of this project was simpler than that of the tunnel project. Technical experts, a member from FHWA, and a consultant were not required for this project. Only officials from ODOT and a non-scoring member from outside ODOT were included in the evaluation committee.

5 DISCUSSIONS

The case studies presented above illustrate the use of best value procurement in D-B-B projects. It is observed that Michigan and Oregon DOTs develop the evaluation criteria depending on the nature of the project. New York DOT has employed a similar best value D-B project procedure for their best value D-B-B projects. In general, price accounts for the greatest weight in the best value evaluation process for D-B-B projects. Specifically, New York awards the project to the lowest bidder from the list of prequalified bidders while Michigan and Oregon assign more weight to the price while calculating the best value
scores. Michigan selects the best value contract based on the least composite score, which is calculated by dividing the price over the technical score. Oregon selects the best value contractor for their D-B-B projects based on the highest score that is combined between price and technical factors. Recently, Minnesota DOT has published a manual for the best value procurement on D-B-B projects. This manual introduces a streamlined approach to best value procurement that can be applied to a variety of projects. The approach, which is intended for projects that requires advance design, suggests that the agency should develop pass-fail criteria to reflect the benefits of the project and select the low bid from the proposals meeting the criteria (MnDOT 2013).

Based on the four case studies, one can observe that the evaluation committees are often comprised of officials from state DOTs. In some cases officials from outside the agency (i.e., consultants, a representative from FHWA, or a non-scoring member) may also be included in the evaluation committee. Typically, after awarding the best value contract, state DOTs conduct debriefing sessions for the unsuccessful proposers. In these meetings, a member in the evaluation committee often explains the strengths and weaknesses of their proposals.

6 CONCLUSIONS

Transportation agencies are increasingly using best value selection procedures to deliver transportation projects. While low bid procurement processes are simple and transparent, they do not allow agencies to evaluate additional factors that may add value to the agencies and stakeholders. Best value procurement is often used for D-B highway projects. This paper shows that best value approach can be applied to the traditional D-B-B projects. The case studies presented in this paper explained about the methods adopted by the state highway agencies the selection process of a best value contractor. The findings from this paper suggest that the use of best value for D-B-B projects in several state DOTs brings significant benefits to their agencies. Non-complex projects, in particular, have the potential for using streamlined best value processes. The evaluation criteria and award algorithms need not be as complex as those found on large D-B projects. In addition, the owner agency should develop the evaluation criteria and establish the selection committee based on a project-by-project basis.

Although the findings from this paper encourage the use of effective best value procurement on D-B-B delivery, the paper has several limitations. First, due to the lack of best value D-B-B project data, it is challenging to compare the project performance between best value and low bid procurement on D-B-B projects. Second, the sample size for this research is small. This study has not focused on some important factors like industry outreach, stipends, and training to evaluation committee which plays an important role in the selection of the best value contractor. A more substantial study with consideration of other factors and a large sample size should be performed to identify the best practices of using best value procurement on D-B-B delivery method. In addition, future research could determine how to streamline best value procurement, allocate the risks equitably for the agency and contractors, and quantify the project performance between D-B-B low bid and best value projects.

USING SIMULATIONS TO BETTER TRAIN FUTURE AND EXISTING
CONSTRUCTION MANAGEMENT PERSONNEL

Thomas M. Korman¹, Martin Čásenský² and Hal Johnston³

³ California Polytechnic State University, San Luis Obispo, CA, U.S.A.

Abstract: In the construction industry, there is a continued need for training current employees as well as
future employees. Such training opportunities that exist include safety, technical, and project
management. Historically training has included lectures from subject matter experts by those considered
to be experts in a particular subject or field. However, this has required removing personnel from projects
to allow time for training or by requiring employees to invest time outside the normal working hours for
training. With the advent of the internet, on-site lectures have been replaced with webinars and/or telecast
to allow personnel to remain in one location and receiving training; however, many educators cite that
student engagement is often limited and learning is not as in-depth when compared to in-person training
sessions. One new training technology that is developing is the use of virtual simulations that are
designed to allow for specialized training while engaging them in the educational process. One such
simulation, the COnstruction INdustry Simulation (COINS), has been developed to train students in the
management of a construction company managing multiple projects simultaneously and is
slowly moving to advance company trainee. COINS engages
students in the decision making of heavy civil construction and commercial building sector. This
simulation has been used in the classroom and now is just available to construction firms to use with
personnel. This paper describes the development and use of COINS simulation designed and developed
to educate future and existing construction management personnel. It is currently used at a number of
different universities including the Czech Technical University in Prague.

1 INTRODUCTION

If one were to survey construction educators and construction trainers, we would fine a small number
using large scale complex simulations. Most university faculty opt for traditional lectures using
powerpoints and a number use case studies, and a few use management games. The question is why
don't we use simulations? The definition of a simulation is the imitation of the operation of a real-world
process or system over time. This definition begs the question even more, why don't we use simulations?
Fear of technology, availability, overly complexity, etc. One such simulation, the COOnstruction INdustry Simulation – COINS (Korman, Johnston, Duckworth), has been developed to train
students in the management of a construction company managing multiple projects simultaneously and is
slowly moving to advance company trainee. COINS engages students in the decision making of heavy
civil construction and commercial building sector. This simulation has been used in the classroom and
now is just available to construction firms to use with their personnel.
2 LITERATURE REVIEW

While multidisciplinary project-based learning has been advocated in engineering for a number of years, the initiation of the Accreditation Board for Engineering and Technology, Engineering Criteria 2000 (ABET 2000), and its call for a required multidisciplinary experience stimulated increased interest in developing courses in this area. Still more recently, an increased number of papers advocating multidisciplinary project-based curricula have appeared at conferences and in journals. It has become clear that project-based learning is addressing a need in the preparation of engineers that was not previously satisfied by standard curricula (Mergendoller, Strobel).

Dialogue with the construction management Industry Advisory Board (IAB) revealed the following important issues and obstacles our students experience upon entering industry. First, students often have not encountered large-scale team design projects and, therefore, have to learn how to work in such an environment. Thus, on the job, they must gain experience in the process, develop a technical specialization to support their project role, and build their ability to collaborate on and contribute to multidisciplinary projects. Secondly, we discovered that our students were not prepared to apply design and construction engineering fundamentals to real world complex projects, specifically utilizing project controls to monitor and evaluate an active project.

In addition to the educational deficiencies noted in our curriculum, CCE curricula generally do not present an integrated approach to engineering education that includes practical applications of theoretical knowledge incorporating constructability issues. Students often master the course and laboratory work associated with courses in the curriculum, but they do not gain a comprehensive engineering experience that requires them to synthesize what they have learned in their curriculum and extend their knowledge through independent learning that reaches outside their field of study, specifically in the topics of constructability. This is further observed at community colleges where students do not have the opportunity of being immersed in a large-scale engineering academic environment of a four-year institution and frequently lose interest in pursuing further education or an engineering career (Terenzini, Cabrera).

This educational gap is systematic among engineering universities. Design engineers frequently receive limited feedback regarding the constructability of their design once a project has entered the construction phase and how construction engineers receive limited feedback regarding the progress of their project. This stems from the educational gap that exists between design and construction engineering curricula, which fail to address constructability issues and lack educational tools and methods for students to test and validate project control theory (Kilgore, Atman, Yasuhara, Barker, Morozov).

Traditionally, students have not acquired these skills at CPSLO. In fact, our experience and research indicates that while many universities and community colleges offer lower division courses that teach students about project control theory, they are not able to provide an educational experience where students can practice these skills. Therefore, in an effort to produce a project-based learning experience, the CPSLO faculty have been developing COINS—Construction Industry Simulation—to reinforce several key learning objectives and to provide a valuable experience for students to work on projects that require the application and synthesis of project controls and monitoring knowledge. Through the use of COINS, students will be placed in a virtual environment to replicate, as nearly as possible, the working environment they will encounter after graduation. Students will be exposed to exercises that are significantly different from typical homework assignments in conventional courses. COINS requires students to work collaboratively and use effective communication skills. Based on our review of the literature, we expect that COINS will engage students unlike any other teaching intervention as there are currently no Project Based Learning (PBL) solutions using simulations to enable students to conceptualize the demands of scheduling multiple projects with multiple resources. Other engineering simulations, such as Messner's Virtual Construction Simulator, simulate building a specific project, focusing on very specific job areas (Nikolic). COINS, on the other hand, is conceptual in nature, actively involving students in the scheduling of multiple projects and allocating multiple resources concurrently while enabling them to see the relevance in the real world of what they are learning. Finally, we anticipate that COINS will become a model for other civil and construction engineering programs who
wish to enhance their compliance with the ABET 2000 requirements and foster the success of a greater number of students Vogel, Bowers, Bradshaw).

3 CONSTRUCTION INDUSTRY SIMULATION (COINS)

Construction Industry Simulation (COINS) is a computer simulation built to simulate the business environment for a construction company. The players, participants, play the role of contractors, competing in a market with variable demand for construction work. The simulation immerses trainees into the day-to-day operations of a construction company, requiring them to manage specific aspects of the company with the goal of procuring and managing construction work in terms of its planning, scheduling, and resource allocation. Student trainees have a choice between commercial construction company, a heavy construction company, or a company that does both. Players are required to set up a complete business strategy including the following tasks:

- examine available information
- determine the best portfolio of jobs to bid on
- create strategies to improve bonding limits
- set strategies to create negotiated work
- develop bid prices for desired jobs
- monitor their financial position as work progresses
- monitor and create strategies to improve company’s appraisal metrics
- choose and modify their construction methods to meet due dates and reduce costs
- interpret their competitors’ strategies
- respond to changing conditions and situations proposed to the company and driven by the decisions and actions of the company

3.1 Projects and Activities

Each period the simulation generates a list of projects available for the teams to estimate, schedule and propose on. The types of projects include the following: highways, bridges, site development, mass excavation, and underground utilities on the heavy civil side, and multi-family housing, educational facilities, hospitals and medical office buildings, commercial office buildings, and industrial manufacturing facilities on the commercial side.

All projects have nine (9) activities that the teams need to schedule, generate and cost estimate. The activities that must be scheduled and estimated include the following: clear and grub, rough grading, excavation, underground piping, concrete forming and placing, backfill and compaction, placement of aggregate base, asphalt-concrete paving, and finish grading. On the commercial side, the activities include the following: excavation, foundation, basement, framing, closure, roofing, siding, finishing, mechanical, electrical, and plumbing.

In addition the simulation creates an Estimated Time and Cost Report for each job. Using this information, each company must decide which jobs to bid on, the bid price, and which of the five methods to use for each of the activities.

Every activity has five (5) different construction methods that vary in time and cost. The Estimated Time and Cost Report gives labor and material costs and the amount of time required for every activity using each of the five methods. Heavy construction bids are generally unit price bids while commercial bids are lump sum.

3.2 Use of the COINS Simulations

COINS has been used in several courses including: Professional Practice, Construction Estimating, Construction Accounting, Management of the Construction Firm, and Business Practices
During the 2005/2006 academic year, the simulation was used for regional competition between multiple universities in the Associated Schools of Construction Regional 6 and 7 Student Competition.

Most recently, in November 2009, universities from the Czech Technical University (CTU) - Prague, Czech Republic, Auburn University - Alabama, California State University, Fresno - California, Illinois State University - Illinois, Boise State University - Idaho, Western Carolina University - North Carolina, and Washington State University – Washington, participated in an international competition. Competition Results were evaluated in five categories: Highest Retained Earning - received the highest profit, Highest Appraisal Metrics - the best valuation metrics and third, Most Awarded Projects - the company with the most awarded projects.

4 GAME PLAY SIMULATION

During the simulation, student trainees experience three distinct phases playing through the simulation. These are:

4.1 Phase I – Project Planning and Design

Students begin the simulation in Phase 1 by being presented with a list of potential projects to review. Considering market conditions, student teams proceed by selecting a project to plan and then designing a project control system for the project. This is accomplished by selecting methods for each project activity and balancing the schedule and cost considerations. In Phase 1, students compete against their peers as well as the simulation's virtual companies for award of the project. Award of projects is based on the team's accuracy and proximity to the simulation's internal estimate. Teams that are not initially awarded a project for their efforts must continue with the simulation, refining their plans, until their plans are awarded a project. Thus, the COINS simulation enables student trainees to learn from their mistakes.

4.2 Phase 2 – Construction Engineering

When a student team is awarded a project, they enter Phase 2. In Phase 2 student teams must manage their project by monitoring and controlling the project activities, analyzing the schedule and costs in reference to the methods to the activities they selected for each activity. Throughout the duration of their project, students are presented with real-life scenarios which they must respond to, thus measuring, testing, and validating the design of the project control system. Therefore, students are able to utilize their knowledge and hone their skills at controlling the process through modifying their project control system. The simulation provides feedback to the students which they then can use to continuously improve their model throughout the duration of the simulation.

4.3 Phase 3 – Project Closeout

Phase 3 begins after students have completed each activity for their virtual project. They have the opportunity to evaluate their performance using several predefined metrics, including Schedule Variance, Cost Variance, Cost Performance Index, and Schedule Performance Index.

5 STUDENT TRAINEE LEARNING PROCESS

As mention above, one of the first activities for the student trainees is to determine what positions will make up their main office overhead. This is reevaluated each period, and hire/fire activity is performed by the team. A report is given to the company telling them how they are handling their personnel and it's requirements. Work scheduling is very important in the selection of the methods so projects can be completed by the contractual deadlines, and the costs reduced as much as possible. Each bid price submitted should cover all the firm's direct and indirect job expenses, its main office overhead costs, and the desired profit. At the end of each period the simulation will determine which company is awarded each available project. The lowest bid will not necessarily win since the computer takes into account several other factors:
• Is the firm’s cash-on-hand adequate to provide enough liquidity with regard to the bid price?
• Is the bid price below a minimum amount, computed by the program? If so, then the bid will be
disregarded as irresponsible and be rejected.
• Is the bid price higher than the unknown contractors, the presence of this simulated company assures
a competitive, uncertain environment with realistic bid prices.
• Is the firm within its bond limits?

At the end of each period, teams receive a progress report for the previous two month period, giving a
statement of the firm’s work progress on each of its jobs during that time. It shows the amount of work
completed as well as the expenses incurred for each activity in every one of the company’s projects. The
amount of work completed during a period depends not only on the methods selected for the various
activities, but also on uncertainty factors during that time such as the weather conditions, labor
availability, and the fluctuating cost of materials.

An end-of-period financial report is also provided to the participants showing the expenses incurred
during that period. It lists amounts spent on direct construction services, bidding costs, delay fines, taxes
incurred, and interest on borrowed money. It also shows payments to the contractor by the owner
according to the payment requests and gives total cash-on-hand at the end of the period. Each firm may
at any time apply for a loan to improve its financial situation. Loans granted are amortized over a one year
time period. Changes in company ratios are also logged along with changes to the company’s appraisal
metrics:

• Is the firm within its bond limits?
• Financial Liquidity
• Financial Success
• Responsibility
• Pace
• Ethics
• Name Recognition

At the end of a period, the firms can examine their Progress Reports and decide on the effectiveness of
the methods chosen for the various work activities. If they wish, they may change them and specify
different methods for the following periods. The choice of methods allows companies to utilize slower but
cheaper methods if they fear budget overruns, or faster but more expensive methods if meeting
contractual deadlines is the main concern. In addition, overtime may be used to speed up certain
activities, greatly increasing the labor costs. Firm must be concerned with the amount of liquidated
damages on each project as they vary from project to project.

At the conclusion of the simulation, the program provides each participating company with a final report,
forecasting the expected results of any on-going projects or their position at that point in time. It also
shows the final total worth of the firm. Teams should consider maximization of profit as one of their main
objective, and one of the primary criteria used to evaluate each firm’s performance. As the simulation
progresses, evaluations of company ratio, and appraisal metrics can be used to determine successful
completion of the simulation.

6 LEARNING OBJECTIVES

The phases described in the previous sections were designed with specific learning objectives to ensure
that identified curriculum deficiencies were addressed, integrating knowledge from project planning,
project procurement, schedule control, and cost control bodies of knowledge. Tables 1, 2, and 3 provide
a list of the learning objectives and mechanism COINS uses to assess student learning.

</tr>
</tbody>
</table>

Table 3: Project Closeout Learning Objectives.

7 ASSESSMENT OF STUDENT TRAINEE LEARNING

The simulation has a built-in grading module that can be used to obtain statistic on the various companies for comparison or to use in the classroom for grading the simulation. Each faculty can have their own method of grading. The following criteria can be used by faculty for assessing participation and student learning:
Is the firm within it bond limits?
Number of jobs bid
Minus the jobs rejected (i.e., not enough bonding capacity, substantially low cost estimate, etc.)
Number of times the number jobs you are the lowest cost
Number of times the company retained earnings
Company’s appraisal metrics

8 DISCUSSION AND RECOMMENDATIONS FOR FUTURE IMPLEMENTATIONS

Many new hires will come from academic areas other than Construction management. A need for these employees to understand an overall picture of the industry is important. Another group of employees are in accounting area and they too can benefit from a “capstone” look at their companies. To assist in the development of COINS, the developers have developed an Industry Advisory Board (IAB) from the construction industry as well as a working group of educators to continue the development and ideas for changes. Because of the idea of module development COINS can turn on and off some of its modules, making it a better fit in different classes. For example, estimating can be turned to an automatic mode which in a construction accounting class helps the student focus on accounting and not on the estimating itself which can be very time consuming and complex. Periods can move much quicker giving the students more accounting to analyze and in a shorter time in which they can see the changes that occur within a company without being bogged down in the estimating/procurement of work. Billing can be turned on to auto mode and additional projects can be added to each team to create additional project or backlog. The game play between commercial and heavy/civil construction is also modulized so a faculty can play only commercial, heavy/civil or both can be played in one game. Future additions are also planned as modules, i.e. personnel additions, case studies, and wide use of equipment management.

\textsuperscript{3} hetak@uw.edu

Abstract: The University of Washington (UW) is aiming to reduce the overall electricity consumption on campus as part of its Climate Action Plan launched in 2009. To achieve this goal, UW installed 216 smart grid meters and automatic heating, ventilation, and cooling control systems across the entire campus and acquired over 200 sets of plug-load monitoring equipment. The university used the smart grid data and the monitored plug-load data to test how occupants in selected residence halls responded to receiving detailed information about their energy usage patterns, its environmental impacts, and associated costs. The experiment demonstrated that in residence halls, plug-load monitoring did not have any significant impact on the occupants' electricity consumption. Hence, there is still a need to further assess which strategies are effective in achieving long-term electricity reduction goals for the university. The goal of this study was to conduct a comparative analysis by replicating the plug-load analysis conducted in residence halls in a faculty/staff office setting. The study entailed interviewing university administrators that were involved in the residence hall plug-load study. Interviewees were asked questions about the findings, shortcomings, and recommendations for future studies. Also, this study characterized the load profiles of the faculty/staff offices by monitoring the plug-load consumption in four offices for nine weeks and explored plug-load reduction interventions applicable to office settings. The study found that the unreliable network connection caused frequent disruptions in data collection and strong bias in the individual electricity consumption data. The inventory of electronic appliances in the monitored offices revealed a high variability in the number of devices which lead to variations in base consumption and peak plug loads between faculty offices, and lack of occupant engagement was found to be the main challenge in the implementation of plug load monitoring campaigns. The results provide universities around the country with valuable information and insights on how to design and implement an on campus plug-load reduction intervention with quantifiable energy-saving potential.

1 BACKGROUND

Worldwide reductions in greenhouse gas emissions are needed to mitigate the most severe impacts of climate change. Commercial buildings account for roughly 18 percent of the total annual energy use in the United States (US DOE 2014). Therefore, sustainability initiatives at workplaces offer a substantial opportunity to reduce the harmful effects on the environment.

The University of Washington (UW) is aiming to reduce the overall electricity consumption on campus as part of its Climate Action Plan launched in 2009. Currently, miscellaneous electricity loads (e.g., computers and office equipment) from offices account for approximately 12 percent of the total electricity
used in the UW, which means that an average of 36 million kilowatt hours of electricity is used annually on plug loads (University of Washington 2012). According to the results presented in recent literature, a well-designed energy intervention in the UW offices has the potential to save up to $360,000 of UW's annual electricity costs. Furthermore, reducing plug loads would not only help the university to reach its carbon neutrality goal but would also improve the power quality on the local grid and moderate peak electrical demand in the Seattle area.

Traditionally, energy-conservation efforts in office environments have been implemented through technological or operational modifications (Starik & Marcus 2000). However, humans are the main operators of technology, and a failure of the human component can fail the entire energy-efficiency initiative. Thus, instead of focusing solely on technological solutions, recent research has shifted to investigate the effects of occupant behavior on building energy use (Fischer 2008, Azar & Menassa 2010, Masoso & Grobler 2010, Schweiker & Shukuya 2010, Kamilaris et al. 2014). The results of these studies have shown that the energy-saving potential of behavioral change is comparable to, and even higher than, that of technological solutions (Masoso & Grobler 2010, Schweiker & Shukuya 2010). Some estimates even suggest that the occupants control or impact up to 50 percent of a building’s energy use and that changing occupant behavior patterns gives the most effective reductions in energy use (Kamilaris et al. 2014).

Changing occupant behavior in offices and other commercial buildings is not without its challenges. A wide variety of studies have looked into the different types of interventions that could most effectively result in electricity savings. One of the most applied measures of impacting and controlling occupant energy use is giving occupants regular feedback on their energy usage patterns (Jain et al. 2012, Jeong et al. 2014, Gulbinas et al. 2014, Hargreaves et al. 2010, Hargreaves et al. 2013, Pereira et al. 2013, Froehlich et al. 2010, Vine et al. 2013). Because feedback frequency and accessibility have been found to correlate positively with the impact on energy reductions (Abrahamse & Steg 2011), most of the recent research on occupant behavior has used real-time monitoring solutions (Jain et al. 2012, Gulbinas et al. 2014, Jain et al. 2013a, Jain et al. 2013b, Ueno et al. 2006). Various studies have shown that frequent feedback is generally effective and correlates negatively with the energy consumption rate (Faruqui et al. 2010, Siero et al. 1996, Vassileva et al. 2012, Murtagh et al. 2013). However, its effects are often temporary, as the engagement of the participants has been repeatedly observed to reduce over time (Hargreaves et al. 2010, Ueno et al. 2006, Murtagh et al. 2013). Furthermore, not everyone is interested in receiving feedback on their electricity consumption: In their study, Murtagh et al. found out that 41% of the participants did not access their individualized feedback even once. These results indicate that in order to design effective electricity interventions with consumption feedback, the focus should be in long-term participant engagement. When implemented successfully, high-frequency electricity feedback can result in total electricity savings of about 20 percent (Murtagh et al. 2013, Acker et al. 2012, Ecova 2011).

UW has already installed 216 smart grid meters and automatic heating, ventilation, and cooling control systems across the entire campus and acquired over 200 sets of plug-load monitoring equipment. In 2013, the university used the smart grid data and the monitored plug-load data to test how occupants in selected residence halls responded to receiving detailed information about their energy usage patterns, its environmental impacts, and associated costs. The project team examined electricity use in each of the buildings over a ten-week period in order to understand which intervention, a technology intervention or education intervention, would have a greater effect (if any) on floor-wide energy consumption. The experiment demonstrated that in residence halls, neither educational nor technical plug-load reduction interventions had any significant impact on the occupants' electricity consumption: Occupants appeared to have higher energy use throughout the study, and educational intervention failed to produce statistically significant results. The research group listed small sample size, inexpensive energy, subjects who do not pay individual energy bills and technical difficulties as some of the factors that may have contributed to these results. Despite the inconclusive results, the team suggests that University has potential to educate students and successfully reduce energy use though other approaches. However, the use of plug load monitoring systems was not recommended as it was found to be an expensive and ineffective tool for changing energy behavior in the context of the University’s residence halls (Black et al. 2014).
The goal of our study is to conduct a comparative analysis by replicating the plug load monitoring campaign conducted in residence halls in a faculty/staff office setting. In addition to collecting monitoring data, we conducted a survey of the university administrators that were involved in the 2013 residence hall plug-load study to learn more about the challenges and opportunities related to plug load monitoring on campus setting. The study will serve as a preliminary study for a plug load monitoring campaign that will be implemented in one of the office buildings at UW campus later in 2015. We believe that the results will provide universities around the country with valuable information on how to design and implement an on-campus plug-load reduction intervention with quantifiable energy-saving potential.

2 METHODS

2.1 Plug load monitoring

2.1.1 Equipment

Plug load monitoring systems with control capability were installed in four faculty offices. The systems consisted of smart power sockets and strips, a Wi-Fi-connected touchscreen monitor with control capability over smart sockets and strips, and an online user account for data collection. (Figure 1) A total number of 20 appliances were plugged into the smart sockets and strips that were connected to the touchscreen monitors over Wi-Fi. High power appliances, such as refrigerators, fans and microwaves had to be excluded from the study as the monitoring system only supports devices with up to a maximum of 15 amps (EnergyHub Inc. 2011). In addition, University’s IT staff requested that desktop computers were kept on at all times to allow for software and security updates.

![Figure 1. Set-up of the plug load monitoring system](image)

2.1.2 Installation and education

The monitoring systems were set up over a period of one week. Prior to installation, the office occupants conducted an inventory of their electronic appliances together with the research staff and identified the appliances that were to be connected to the monitoring system. In addition, each appliance was given a status on the basis of occupant’s requests: If appliance was given an “always on” status, it would stay on even if the smart strips and sockets were turned off. Other appliances with an “on-off” status would turn off normally when the power to the strips and sockets was cut off.

The installation process consisted of three phases. In first phase, sockets and strips were connected to the touchscreen monitor by using strip- and socket-specific set-up codes. In the second phase, the electronic appliances in each socket and strip were named in order to allow appliance-by-appliance electricity monitoring. In the last phase, the status of each appliance was determined by typing the information in the touchscreen monitor. In order to minimize the disturbance to the occupants, installation work was completed when offices were unoccupied.
All study participants were given guidance on system control through touchscreen monitor. Occupants were also introduced to two short-cut commands for electricity use control. By setting the touchscreen monitor to "home" mode, the occupants were able to turn on all sockets and strips, and the appliances plugged into them. By choosing "away" mode, the occupants were able to turn off all appliances with "on-off" status. Apart from this introduction to the monitoring system control, the occupants were not given any additional information about electricity consumption or potential savings.

2.2 Administrator survey

An administrator survey was conducted by personal interviews and e-mail questionnaires. The three participants were chosen among the university employees who had been involved in the residence hall plug load study in 2013 (Black et al. 2014). A set of 14 questions was created on the basis of the following research topics:

1. The staff resources available for administrating plug load monitoring campaigns and other energy interventions
2. The attitudes of campus engineering and operations staff towards the feasibility and value of energy interventions (plug load monitoring and other methods)
3. The findings and shortcomings of previous studies, and recommendations for future studies

Each question addresses at least one of the research topics under the two study dimensions, human resources and study design, and serves the purpose of finding out the feasibility of a plug load study in the UW campus. The questions were formulated in a way that facilitates the response process: comprehension-related issues were designed out by using unequivocal terms and simple phrase structures, and the retrieval/recall process was made easier by giving respondents background information about the theme of each question and allowing the use of retrieval cues by choosing the conversational interviewing method (Schober & Conrad 1997). As some of the questions asking about respondents personal opinions were classified as potentially sensitive, thought was given for the neutrality of the context in which each question was introduced (Tourangeau & Yan 2007). In order to avoid response order effects and allow for more diverse answers, answer options were not given for any of the survey questions. A diagram of the dimensions and sub-dimensions the questionnaire addressed is presented in Figure 2. The interview questions are presented in Appendix 1.

![Concept specification diagram with research dimensions and subdimensions.](image-url)
3 RESULTS

3.1 Plug load monitoring

3.1.1 Monitoring system installation & operation

Depending on the amount of electronic devices in the office, the installation process took approximately 30 to 45 minutes per office. After installation, the exact locations and identifying information of all smart sockets, strips and touchscreen monitors were collected to a directory, which was kept up to date about the performance of the study equipment through the monitoring period. Apart from couple of malfunctioning smart sockets, the monitoring hardware functioned as expected and did not require maintenance over the 9-week study period. The total time used for hardware installation and operation was approximately 1-1.5 hours per office per 9 weeks.

The initial plan was to connect all monitoring systems to the University’s Wi-Fi but after unsuccessful attempts in all office rooms it became evident that the touchscreen monitors did not communicate with the server: users were unable to access their devices remotely and no electricity consumption data were saved to the system database online. The issue was temporarily resolved by connecting the monitoring systems to a wireless server outside University’s network but occasional network problems continued throughout the monitoring period. The unreliable network connection caused frequent disruptions in data collection and strong bias in the individual electricity consumption data. In addition, network problems caused additional workload to University’s IT specialists whose help was needed whenever the Internet connection went down.

3.1.2 Occupant behavior

The inventory of electronic appliances in the four faculty offices revealed a high variability in the number of appliances. Where some offices only had a computer, monitor and printer in them, others were equipped with microwaves, fans, radios and other miscellaneous electronic devices. (Table 1) Consequently, the average plug load level also varied highly between faculty offices. The rooms with highest amount of appliances had a high baseline plug load (plug load level when appliances are plugged in but not used) and higher plug load peaks (highest plug load level when offices are occupied and appliances are in use) during office occupancy. However, the frequent network problems precluded accurate estimation and comparison between per office plug loads and electricity consumptions.

The plug load data also revealed a high variability in occupant schedules during the 9-week monitoring period. The office was assumed to be occupied whenever the plug load level rose above the observed baseline consumption. The monitoring data showed that none of the four occupants followed a traditional office occupancy schedule. The offices were rarely occupied at the same time or for an equal amount of time per day (Figure 3a-d). Only one of the four occupants used the option to control appliance status through the touchscreen monitor and shut off smart strips and sockets when leaving the office. (Figure 3c) None of the participants set schedules for their plug load system to shut off automatically at a certain time of the day. Overall, the consumption patterns of the occupants stayed unchanged during the monitoring period: the occupants who did not use the system features, such as “away” and “home” modes, in the beginning did not develop interest in using them later in the monitoring period either. Respectively, the occupant who used the modes to control office plug load did so throughout the monitoring period.

3.2 Administrator Survey

The interviewed University administrators had different levels of involvement in the plug load monitoring study implemented in UW residence halls in 2013. While first interviewee was the overall project manager and the second interviewee responsible for student involvement and recruitment throughout the project, the third one was only responsible for planning the distribution of the plug load monitoring systems. However, when asked about issues related to the design of plug load monitoring studies, all three interviewees mentioned the lack of long-term engagement as the main challenge. According to the interviewees, participants are usually engaged and motivated to reduce their electricity consumption in
the beginning of any energy intervention, but the involvement fades as the “individuals lose interest” and
“everyday life gets in the way”. From the future plug load monitoring studies, the interviewees hoped for
more data on occupant behavior and long-term impact measurement both in individual and community
level.

Two of the three interviewees saw more potential in plug load monitoring in office environments than in
residential buildings. One of the respondents supposed that the routines and schedules of an office
environment might facilitate the implementation of a plug load monitoring campaign and lead to more
long-term occupant engagement. Another administrator speculated that the engagement level in an office
environment would be higher as occupants are more exposed to a positive peer pressure than in a
residential setting. Overall, respondents considered plug load monitoring as a key method for changing
occupants’ consumption behavior, “raising awareness and help drive decision making processes”. However, the respondents did not see plug load monitoring as an efficient way to reduce University’s total
electricity consumption as plug load was considered to be “fairly inconsequential in the overall electrical
demand of the University buildings”.

In addition to the problems related to the long-term occupant engagement, respondents mentioned
several miscellaneous factors that challenged the implementation of the residential hall plug load study
and might cause problems in the future studies as well. As possible technical difficulties, respondents brought up problems with Wi-Fi connection and the resulting interruptions in data collection. One of the administrators also anticipated that if a plug load study was implemented in a much larger
scale, the operation and maintenance might become an issue due to university staff’s lack of expertise in
the utilized plug load monitoring technology. Other non-technical challenges were mentioned as well. One
of them was the lack of focus in the study design: according to one of the respondents, the residential hall
experiment did not have a strong objective that would have guided the monitoring process from the
beginning to the end. The studied demographic group was also described as challenging: the occupants
of the monitored residential halls were mainly freshmen who had just moved on campus and were
struggling with their new lifestyle in academic environment. Moreover, they did not generally have high
interest in issues related to electricity consumption, as electricity costs were included in their rent. Respondents estimated that student involvement might have been stronger, if situation would have been
different.

* ○ In the office ● Monitored
Figure 3a-3d: Office occupancy during a 5-day work week in 18.8.-22.8.2014. The electricity consumption (kWh/min) data shows differences in base loads and plug load peaks between four faculty offices. The typical office occupancy schedule is from ASHRAE 90.1-2004.
4 DISCUSSION AND CONCLUSION

The feasibility of an office plug load monitoring study was evaluated by implementing a 9-week monitoring campaign in four faculty offices at University of Washington campus. The findings of the 9-week mini study were compared with the results of a residence hall plug load study that was conducted at the same campus in 2013. In addition to monitoring plug loads, the researchers collected data by surveying university administrators that were involved in the prior residence hall plug load study. The administrators were asked about the findings, shortcomings, and recommendations for future studies. The study was able to identify possible challenges and barriers the stakeholders face when deploying plug load monitoring campaigns on campus settings. Moreover, it was able to characterize the load profiles of the faculty/staff offices, even though it failed to make accurate quantitative analyses of the participants’ individual electricity usage.

Throughout the 9-week study period, the unreliable network connection caused frequent disruptions in data collection and strong bias in the individual electricity consumption data. The disruptions eventually precluded accurate estimation and comparison between per office plug loads and electricity consumptions. In addition, network problems caused additional workload to University’s IT specialists whose help was needed whenever the Internet connection went down. These findings are in accordance with those of the 2013 residential plug load study, where problems with wireless connections between devices precluded plug load analysis on individual level (Black et al. 2014). Problems with wireless networks have been mentioned by other studies as well: Ghatikar et al. (2013) observed that in addition to being limited by their range, wireless plug load monitoring systems can be prone to high attenuation due to common obstructions in the office environments, such as cubicle separations and concrete walls. As many monitoring systems rely heavily on customers’ wireless networks, such connection problems introduce numerous walk away opportunities and limit wide spread occupant participation (Gilbert et al. 2011). Improvement to the current situation could be received by using more efficient network protocols, i.e. preferring 6lowpan protocol over more limited Zigbee protocol that is currently being used by most wireless monitoring systems (Ellaboudy 2012).

The inventory of electronic appliances in the monitored offices revealed a high variability in the number of devices. Consequently, the base consumption and peak plug loads also varied highly between faculty offices. (Figure 3a-3d) Murtagh et al. observed similar variability in their study with weekly energy use of the monitored workstations ranging from near 0 kWh to 21.4 kWh. Both results indicate that even though the work setting for academic office-based researchers is similar to other office settings, there are fundamental differences in occupant behavior and energy use. For instance, depending on their field of study, researchers may have very different needs for IT and other electronic appliances. Moreover, as was observed during this study, some researchers are physically present at their workstations for most of the time, while others are working remotely or sharing their time between several workstations and offices. (Figure 3a-3d) The observed variability in occupant schedules and hours of attendance differs significantly from the widely used ASHRAE 90.1 occupancy profile and implicates that fixed occupancy profiles are not ideal for modeling electricity use and plug loads in academic offices. (ASHRAE 2004) These findings are in line with other recent studies that have suggested updates to the current ASHRAE recommended practice (Bouffaron 2014, Davis & Nutter 2010).

The lack of occupant engagement was found to be the main challenge in the implementation of plug load monitoring campaigns. Although all participants of the 9-week office study were taught how to control their electricity use through monitoring equipment, only one of the four occupants used the option. The lack of occupant engagement, especially in longer term, was also mentioned as the main challenge by all of the interviewed University administrators. These results are in great agreement with prior findings of several short- and long-term plug load studies (Hargreaves et al. 2010, Ueno et al. 2006, Murtagh et al. 2013, Ecova 2011) and indicate that the design focus of future plug load monitoring campaigns should be on long-term occupant activation and engagement.
Acknowledgements

The research for this paper was financially supported by the Valle program at University of Washington. We would like to thank the faculties for allowing us to monitor their plug-load use and the university administrators who supportively participated in the interview.

ROAD MAINTENANCE INFORMATION MANAGEMENT SYSTEM
BASED ON PRODUCT DATA MODEL CONSIDERING DISASTER USE

Satoshi Kubota
Kansai University, Japan
skubota@kansai-u.ac.jp

Abstract: Maintenance management is an essential operation that should be carried out effectively for maintaining, repairing, and rehabilitating highways and roads. It is necessary to accumulate information produced during the entire life cycle of roads in order to analyze problems and find solutions within a temporal sequence and to maintain them strategically and effectively. In road maintenance site, the administrators and engineers want to refer and utilize the road ledger and its drawings. It is difficult to carry and use the ledgers, because they are paper based documents. The primary objective of this study is to develop the product data models, which systematic information is defined for accumulating, exchanging, and sharing in civil infrastructure. And, this paper proposed a road maintenance information management system to collect, accumulate, share, and utilize the information considering disaster use. It is used in maintenance and disaster site by tablet PC. Road data models are effective for building an environment where the various data generated in a construction enterprise are used in an integrated manner. The constructed road data model has structural and work information. Structural information includes road structures such as bridges, carriageways, sidewalks, and road furniture. Inspections, repair judgments, repair of pavement, and construction of pavement are defined as work information. And, disaster information was added in structural information. The location-based expressions ‘GM_Point’, ‘GM_Surface’, and ‘GM_Polygon’ are defined to connect the road data model to spatial information. The proposed system was evaluated the usability and capability in road maintenance.

1 INTRODUCTION

Roads are networks that connect social infrastructure and accommodate the delivery of emergency services. Because of the importance of roads, they should be safe and kept in good condition. Maintenance management is an essential operation that should be carried out effectively for maintaining, repairing, and rehabilitating roads. It is important that the maintenance process is effective and that the quality of inspection is ensured. Cost-effective and high-quality maintenance depend on reliable inspection and condition assessment information (Osama 2003). Furthermore, reliable maintenance information influences management systems (Thompson et al. 2003). Existing management systems do not use standardized information, and cannot exchange, share, and reuse information. In order to carry out effective road maintenance, it is necessary to construct a system where the latest and highest-quality road information can be used and shared, thereby facilitating road planning, design, construction, inspection, and repair.

The primary objective of this research is to facilitate the sharing of road maintenance information with project participants. A fundamental requirement of such a system is the ability to support the modeling
and management of design and construction information and to enable the exchange of such information among different project disciplines in an effective and efficient manner. A Web GIS-based maintenance information management system is proposed using smart devices such as smartphone and tablet PC, and a prototype system is developed and evaluated for an actual road maintenance project. The system has the function of reference of road ledger using smart devices. The information is standardized by constructing a conceptual data model. Conceptual data models for road maintenance are constructed for use in the proposed system.

2 ROAD DATA MODELS

Road data models are constructed so that information within the information management system can be shared among those involved in the management of roads. A road data model is defined as the product data model of a road structure to which attribute information is added in order to link the model to the spatial data infrastructure.

Product data models of social infrastructure facilities are made by various organizations and research institutions (Stumpf et al., 1996; Karim and Adeli, 1999; Hastings et al., 2003; Chau et al., 2004; El-Diraby et al., 2005; Owolabi et al., 2006; Halfawy and Froese, 2007). However, the attributes defined in these data models, and in the data model schemas, are different from the attributes and schemas for road data models. If the same information is stored in accordance with different data models, this could lead to problems with information compatibility in the future. Data models that have already been constructed by various methods are difficult to standardize into a uniform format. Therefore, according to the objectives of the various social infrastructure facilities, standardizing the functions that must be fulfilled by the data models, and the types and items of information to be maintained, can be considered.

Road data models can be classified into two types: geometry information models and business information models. Geometry information models contain information associated with the constituent parts of roads. Business information models contain information necessary for road management work, as well as the results of information analysis produced as the result of such work. Interoperability and compatibility are important for the exchange and sharing of road information. It is, therefore, useful to define the rules of information exchange and sharing using existing standards and specifications. In constructing the geometry information models, design and dimensional information was extracted from the models. This includes information regarding the composition of the particular structures, information from the design and construction stages, and information that should be stored for future road management work. Information regarding the structure composition includes information for roads, slopes, bridges, tunnels, and ancillary items. Information from the design and construction stage includes design documents, numerical calculations, and as-built drawings. Information that should be stored includes the results of work such as inspection, repair, or strengthening of structures. In constructing the business information models, the information resulting from construction, inspection, detailed inspection, and repair and strengthening was extracted. Information resulting from construction includes initial inspection results. Information resulting from inspection includes determination as well as inspection outlines and inspection results. Information resulting from detailed inspections includes detailed inspection outlines and detailed inspection results. Information resulting from repairs and strengthening includes the outlines of repairs and strengthening, as well as the results of the repairs and strengthening.

Information on the geometric shape and attitude of items such as roads, buildings, and rivers has been generated from a wide variety of construction projects. This information should be shared and utilized by project participants. The road data model is a concept for sharing and utilizing information collected over the life-cycle of a construction project. The road data model is a method for analyzing the situation and solving the problem. Construction stakeholders and computer software can share and utilize the standardized information by using the road data model, as shown in Figure 1. The road data model has information from documents, CAD data, drawings, design calculations, and other sources which can be used by those involved in a construction project.

The road data model is shown in Figure 2 the location-based expressions ‘GM_Point’, ‘GM_Surface’, and ‘GM_Polygon’ are defined to connect the road data model to map information. The information
A management system was developed based on the proposed idea. Road data models are constructed so that information within the information management system can be shared among those involved in the management of roads.

### 3 SYSTEM DESIGN AND DEVELOPMENT

#### 3.1 Design principles

In maintenance, the management system with high accuracy is necessary, so analyzed information in lifecycle should be accumulated. This system is used in each phase of design, construction, inspection, soundness evaluation, deterioration forecast, and maintenance plan. The database of system has the role to support the each stage of life-cycle. For operating the management system, standardized information should be accumulated and shared based on product data models on considering a long-term service stage of concrete highway bridges. The concept of model oriented management system is shown in Figure 3. It is difficult to define unitary the information used in various existing systems and databases.
because of feasibility and operation. Standardized information can be exchanged and shared by exchanging the maintenance information through the product data models in maintenance management system and databases.

A road maintenance information management system was designed based on following design principles. (1) Uniform management of road maintenance data: Road maintenance information such as inspections, repair decisions, and repair work should be uniformly managed. Data is collected in a database and the system is used to retrieve the information. The system has a map interface, through which road administrators can gain an overall view of road damage and repair locations. (2) In disaster use: The system can be used for confirming the site situation when power blackout and network disconnect are occurred in wide-scale disaster. (3) The system is developed which has the functions of handwriting input, posting photos and reference of road ledger data.

![Figure 3: The concept of model oriented management system](image)

### 3.2 System architecture

A road maintenance information management system was constructed to allow those engaged in road maintenance to collect, store, share, and use information. As shown in Figure 4, the four-dimensional information management system consists of a spatial data infrastructure, a road database, road data models, a model library, a common system interface, system sharing functions, and a road application system. The system is structured so that new information items and system functions can be added in the future using the common system interface and road data models.
The proposed information management system is access through the Internet. The system architecture is shown in Figure 5. The system was consisted of a server with database, PC of road administrator for referring road ledger data, and tablet PC in use of site. The system is used for confirming the site situation when power blackout and network disconnect are occurred in wide-scale disaster.
Figure 5: System architecture

The system was developed on a Linux server using Apache, MySQL for database, HTML for showing road ledger data, XML (Extensible Markup Language) for marker on map, and Java for using API and Programming. Digital earth web API (Application Program Interface) of Geospatial Information Authority of Japan was used for Web GIS. In this study, Arrows Tab F-01D (Fujitsu Co., Ltd.) was used. For off-line use, the system was developed as application of smart devices using Java. It has the road ledger data and drawings in tablet PC.

3.3 System functions

The system has four functions: retrieving road ledger data and drawings, reference, input of inspection results, and submission of photographs.

(1) The function of retrieving road ledger data and drawings is used by location point of GPS and road name. The location of road ledger data and drawings is shown by marker of Web API on the map. The marker information are described by XML which represents longitude and latitude of location of road ledger data. The system screens retrieved by GPS are shown in Figure 6. A road administrator updates and stores road ledger data. A database management system was developed for retrieving and registering the information. A user sends a retrieve request from their web browser to the database server and subsequently receives the retrieved results.

(2) The road administrators can refer the road ledger data and drawings using tablet PC through the Internet. The drawings were exchanged from PDF data to PNG data. The each PNG data is about 400 KB and 1600*1200 pixel data. There are 1500 drawings in the system. Figure 7 shows the screen of reference function. The system can be used in online and offline situation. In large scale disaster, power blackout and network disconnect are occurred, and the system should be used in offline situation. In offline system, the road ledger drawings are retrieved by road name and shown on tablet PC. The example of offline use is shown in Figure 8. And the users can write the notations.
(3) The users can write the inspection results and notation on the road ledger drawing or photograph. The examples of this function are shown in Figure 9.

Figure 6: Retrieved results by GPS

Figure 7: Reference function

(4) The photographs are submitted by inspectors when they patrol the managed road and notice the damage using the system.
4 EVALUATION OF THE PROPOSED SYSTEM

The system was used to evaluate usability, smoothness of information flow, application capability, and usefulness. The demonstration data was about 211 MB of data on 550 pages of road ledger drawings in local government. The system operated normally without error. The results of the evaluation show that users rated the performance of the system as average or good. In terms of application capability, the system could possibly be practical for use in road maintenance. The system can be used to retrieve and use past road maintenance information, which can be difficult to find in offices and computers. However, the system has a few problems limiting its practical use.

The system can be used to refer a site situation by road ledger data and drawings, notations, and photographs. The road administrators can share the information stored in the database with workers carrying out maintenance operations. The data model has an environment for exchanging, sharing, and utilizing road maintenance information in road maintenance operation. The system, because it handles historical information, is applicable to road work management. There are barriers to implement the proposed system in a municipal or state road maintenance department where ontology and vernacular are different from those in the proposed system. Accordingly, the system would need to be modified to account for such difference and differences in departmental culture.
5 CONCLUSIONS

In this paper, a road maintenance information management system for storing, controlling, sharing, and using road ledger data and drawings, notations, and photographs in inspection was proposed, and a prototype system was developed. The system consists of a spatial data infrastructure, a road database, road data models, a common system interface, a system-sharing functions, and an application system. The road data model was constructed based on product data model concept. A prototype system was developed using tablet PC and evaluated in actual use. The system has the functions of retrieving road ledger data and drawings, reference, input of inspection results, and submission of photographs.

The main contribution of this study is a significant effort to extend the applicability of product data model. The system approach is based on a road data model. The system handles inspection and road ledger data, and can be used for maintenance management of road work. It is necessary to update the road data model in order to use these data in the process of maintenance operations. The proposed system has a data model framework that can be applied to road asset management, earthquake disaster reconstruction management, road buried objects management, and other types of structural maintenance.

SCHEDULING REFRESHER-BASED RESCUE AND EVACUATION TRAINING FOR WIND TURBINE TECHNICIANS

Kenneth Lawani1, Billy Hare2 and Iain Cameron3
1, 2, 3 Department of Construction & Surveying, Glasgow Caledonian University, Glasgow G4 0BA, Scotland

Abstract: The adage “once trained, always trained” is a recognized myth. A look at the refresher skill training of wind technicians show that rescue and evacuation skills deteriorate over a period of time of non-practice. Therefore, the importance of safe and efficient rescue and evacuation of wind turbine technicians working at height cannot be over emphasized. An evaluation of the wind technicians’ skill and knowledge proficiency in the use of rescue and evacuation devices after acquisition indicates that poor retention of technician skill in the safe and procedural execution of a rescue during an emergency is a potential problem that is yet to be addressed. This research quantitatively assesses if wind turbine technicians are capable of retaining knowledge and skills learned over a 24 month period, evaluates pre-acquisition, acquisition and follow-up primary measurements at retention intervals of one and three months and proposes a refresher timeframe and benchmark performance that can maximize the proficiency level of technicians. Due to the infrequent nature of practically carrying out on-the-job rescue and evacuation roles, there is a likelihood of skill and knowledge decay in times of significant emergencies except where there is a support system available to the technicians. Possible solutions to overturn these problems are discussed based on the data obtained during the study. Draft results were used to propose a refresher timeframe and benchmark performance that can maximize the proficiency of technicians to an acceptable level as guidelines for management towards scheduling safe wind turbine rescue and evacuation training.

1 INTRODUCTION & BACKGROUND

Skill decay after periods of non-use or non-practice is well known and has substantial implications when relatively long periods of time separate training from the application of learned skills, (Hall, Stiles and Horwitz 1998). Skill retention is significant because of the time that potentially separates skill acquisition and use of the same skills on the job. Without comprehensive evaluation of performance, accurately identifying and predicting skill decay is not feasible.

Researchers have spent a considerable amount of time identifying the relevant factors that affect skill retention, (Arthur Jr., et al. 1998). This is, for the most part, a practical decision because determining the quantitative relation requires greater expenditure of resources in terms of time, equipment, test subjects, etc. Among the factors that have been examined are: length of retention interval; task characteristics; methods of testing for original learning and retention; conditions of retrieval; use of mnemonics and other task aids; prior experience (Arthur Jr., et al. 1998). There are several job situations that demand the application of skills that have not been used over extended periods of time. Despite the apparent importance of skill retention on performance, however, few empirical studies have tested factors that
mediate skill retention in the wind energy sector. Other factors such as extended practice of skills have been associated with increasing skill retention. While practice has been established as a strong predictor of skilled performance, it has not been established whether reliable contexts, such as those found on the job, are related to retention. The work of Hurlock and Montague (1982) concluded that most skill deterioration is the result of several factors which include level of initial learning, non-utilization periods, skill type, events during skill non-use, and lack of effective feedback.

However, some types of skills tend to be better retained than others e.g. the two kinds of motor skills – continuous and discrete. Continuous motor skills are those involving the repetition of a movement pattern with no distinctive start or end (e.g. riding a bicycle) while procedural task which is the main focus of this study are a series of discrete responses, such as operating a rescue and evacuation device system, moving a gear shift etc. Another significant difference is that continuous motor skills decay slowly over a period of months and years while discrete/procedural skills decay rapidly over a period of days, weeks or months. Unlike continuous motor skills, procedural proficiency cannot be maintained in the absence of practice (Schendel, Shields and Katz 1978). Though these responses are usually self-paced and easy to execute, the main problem for the learner is response selection, i.e., deciding what responses to make and in what sequence to make them. In general, the retention of procedural tasks, the sequencing of tasks, and the ability to perform a task in a required time period deteriorate rather quickly.

Skill retention can be addressed using the concept of comparison of performance before, during and after a period of controlled activity – regarded as the retention interval. Performance measurements can vary from different studies and tasks, but ideally, it is based on combinations of speed, accuracy, and the number of procedural steps the subject can correctly recall. An individual’s post-training score on a performance test, combined with the length of the retention interval, according to (Bodilly, et al. 1986) is considered the best predictor of skill retention. Refresher training is typically used to stabilize the effects of forgetting and maintaining proficiency of skills. The significance to this study is to determine the rate at which skills decay, and schedule refresher training such that proficiency does not decay below an acceptable benchmarked performance. Schendel and Hagman (1980) stated that extra training enhances retention regardless of whether it is provided during the initial training or in a refresher training session at some point during the retention interval. Practical issues of cost and availability of personnel however, require that refresher training be conducted in an efficient manner that will both reduce the probability of further accident happening during rescue procedures and reinstate the performance levels of the technicians.

Strategic components of skills and knowledge should be periodically evaluated and supported to determine whether they meet the ever changing needs of the learners and to ensure effective training. Therefore, training needs analysis (TNA) which is a systematic assessment of training can affect improvement in the knowledge, skills or attitude of individuals or teams in the workplace, (Drummond 2008). It forms the basis for structured training and identifies current work-based ‘training gap’ or problems in performance standards that may be resolved through training. TNA identifies the current standard of performance being achieved, and the required standard of performance with the aim of attaining such standards through the scheduling of refresher trainings. The cost of training technicians to an organization when taken into account can be significant in terms of instructor time, cost of preparation, participant time, materials, training venues and equipment etc. Therefore, the money and time may not yield a satisfactory performance benchmark if the training gap of the technicians have not been clearly identified and defined i.e., training objectives, training plans and training programs which are designed based on identifying their training needs.

There is currently no procedure in place to determine skill deterioration, or refreshing needs of wind turbine technicians that will enable efficient technician refresher training decisions. Therefore, this research aims to propose a timeframe for considering when and how often such rescue skills should be refreshed for a ‘benchmark of good practice’. The industry assumption is that wind technicians maintain their individual skills over time and are ready to use such skills whenever needed in carrying out on-the-job rescue and evacuation roles. If this assumption does not hold, then the employers may wish to initiate an effective refresher training program.
A study conducted by Prophet (1976) concluded that the time needed to refresh is less than the time needed for original training. This finding also supported by Shields, Goldberg and Dressel (1979) found that even with skill decay following a no-practice interval, residual skills still remain. In addition, Rose, et al. (1981) found that tasks that were supported by job aids i.e. written materials that are used in the normal performance of the job were retained longer.

2 STUDY OBJECTIVES

- To quantitatively assess if wind turbine technicians are capable of retaining knowledge and skills learned over a 24 month period.
- To evaluate pre-acquisition, acquisition and follow-up primary measurements at retention intervals of one and three months.
- To propose a refresher timeframe and benchmark performance that can maximize the proficiency level of technicians.

3 METHODS

Figure 1: Method of data gathering using basic map explorer

Figure 1 shows the breakdown of the method employed in this study using a simple map explorer. The research participants were those registered to undergo the basic RenewableUK/Global Wind Organization (RUK/GWO) approved height safety and rescue training (purposive-expert sampling) and the study focused on the final 30 wind technicians. The ‘refresher participants’ connote returning trainees while the ‘fresher participants’ are first time trainees. The training was procedure- and system-based averaging 6-hours per day over two-day sessions with emphasis on emergency rescue, how to approach rescue situations in wind turbine generators (WTG) and competent use of rescue equipment. The research implemented longitudinal design approach for data gathering (de Vaus 2001) in order to track changes over time and establish the sequence in which events took place.

Closed-ended questionnaires were designed based on ‘Job Knowledge inventory Test’ (JKT) (Teachout, et al. 1993). This was used for the entire knowledge assessment from pre-acquisition to retention. Retention measures using JKT was administered online at intervals of one and three months. Skill pre-acquisition and acquisition involved ‘hands-on practice’ using the automatic constant rate descender (CRD) RG9A, (Lawani, Hare and Cameron 2014b). Only refresher participants were assessed during skill pre-acquisition stage because they have used this device in prior training sessions. Data for skill acquisition was collected for all participants while skill retention assessment was administered online using ‘Situational Judgment Test’ (SJT) (Lievens, Peeters and Schollaert 2008), with the aid of cued recognition using pictograms to prompt the participants. The participants were required to evaluate the randomized written performance description and the associated pictograms by correctly sequencing the
procedural execution of the use of RG9A for rescue and evacuation. These retention assessments 
engaged participants in the use of computer-based information displayed using two-dimensional (2D) 
images of the RG9A device. The performances were based on the number of device steps recalled and 
recognised in the correct sequence (skill) and the number of job knowledge information correctly recalled.

4 RESULTS & ANALYSIS

This study having been piloted, reviewed and amended is based on results of 30 research participants 
that fully participated all through the assessment period. This reflected an overall response rate of 36.6% 
out of a total of 82 initial research participants.

4.1 To quantitatively assess if wind turbine technicians are capable of retaining knowledge 
and skills learned over a 24 month period.

The magnitude of procedural skill and knowledge decay are presented in Tables 1 & 2. The refresher 
participants display an average of 14.9% and 21.8% decay in skill performance after one and three 
months respectively while the fresher participants show 19.8% and 29.6% decay in skill performance, 
(see Table 1). The magnitudes of knowledge decay for refresher participants were 10.5% and 9.5% after 
one and three months while the fresher participants were 20.4% and 21.4%, (see Table 2). Result of skill 
(59.8%) and knowledge (30.5%) decay at 24 months reflects the actual mean performance of refresher 
participants before embarking on the height safety and rescue training (see Table 1 & 2). Figure 2 (a) & 
(b) depicts the trend estimating that at 24 months retention, refresher participants will retain averagely 
35% skill and 66% knowledge competency indicated by the dotted red lines. These 24 month estimates 
were accomplished using actual pre-acquisition refresher assessment data to generate the theoretical 
curves describing the path of skill decay.

4.2 To evaluate pre-acquisition, acquisition and follow-up primary measurements at retention intervals of one and three months

Visual inspection for trends to determine the relationships for both skill and knowledge retention and any possible interactions was done using actual performance data. It was observed that after initial task proficiency, quantitative relationship between a task’s factors and its associated performance data at a particular time interval could serve as a generalizable model of skill decay. Figure 3 depicts the mean percentage performance for both skill and knowledge assessment from pre-acquisition to retention highlighting performance trends for refresher and fresher participants. Both set of participants experienced rapid increase in performance score from pre-acquisition to acquisition respectively with peak performances at T1 (Figure 3a) and T2 (Figure 3b). The participants experienced significant drop in performance levels for skill and knowledge assessments at one month and gradually dipping toward three month retention. Figure 3a confirm refresher participants outperforming the fresher participants from acquisition to retention periods suggesting the probable influence factor might be due to prior training and experience. Although this study reveals that at acquisition, both refresher and fresher participants can attain almost same level of peak performances (Figure 3b), however, over the retention periods, the probable impact of prior training and experience of the refresher participants seem to enhance their ability to retain knowledge longer than fresher participants. It shows that development is relatively continuous and gradual, and the participants are never at the same level for all skills, (Fischer 1980).

Statistical analysis (knowledge assessment) of tests of normality using Kolmogorov-Smirnov test with conservative alpha level ($\alpha = 0.01$) at T0; T1; T3; T4 ($p > 0.01$) meet the assumption of normality while T2 ($p < 0.01$) did not. Levene’s test for equality of variance ($\alpha = 0.05$) for knowledge test at T0, T1, T2, T3 ($p > 0.05$) show that there is not a statistically significant difference between the group’s variances. Therefore “Equal variances assumed”. T4 with ($p < 0.05$) show variance is significantly different and assumption of equal variance is not met. Independent sample test results ($\alpha = 0.05$) compared the Sig. ($p$) values for refresher and fresher participants: T0; T1; T2; T3; ($p \geq 0.05$) indicating that the refresher participants did not statistically significantly perform more than the fresher participants during the knowledge assessment. T4 ($p \leq 0.05$) conclude that refresher participants performed significantly more than the fresher participants.

Skill tests T0, T1 with Sig ($p < 0.01$) did not meet the assumption of normality while tests at T2; T3 Sig ($p > 0.01$) satisfy the assumption of normality. Levene’s Test for equality of variance ($\alpha = 0.05$) show T0 with ($p < 0.05$) and conclude there is a statistically significant difference between the group’s variances, “Equal variances not assumed”. T1; T2 and T3 had Sig ($p > 0.05$) and conclude that there is not a significant difference between the group’s variances. Therefore, “Equal variances assumed”. Independent sample skill test ($\alpha = 0.05$) for refresher and fresher participants T0 ($p \leq 0.05$) concludes that refresher
participants performed statistically significantly better while performances at T₁; T₂; T₃ (p ≥ 0.05) indicate no statistically significant difference.

### 4.3 To propose a refresher time-frame and benchmark performance that can maximize the proficiency level of technicians

The education sector has a history of setting 75% as the benchmark for passing score (McKnight 1999). This study adopted Table 3 as guideline for diagnostic assessment of performance benchmark at limit state of 70%. The structure implemented for carrying out these assessments for benchmarking skill and knowledge is shown in Figure 4. Mean skill performance score for refresher participants at one and three months were 74% and 67.5% while the fresher participants performed at 65% and 57.22%, (Figure 5a). The skill performance at one month for refreshers at 74% was above the 70% threshold which this study considers as the limit state performance, while at three months, it falls short (see Table 3). The fresher participants performed below this threshold. Results for knowledge performance (Figure 5b) show that the mean retention score for the refresher participants at one and three month was 84.5% and 85.5% while the fresher participants performed at 77.9% and 77.1% which are above the 70% benchmark considered as the limit state performance. This indicates that the participants are capable of retaining their knowledge up to three months after acquisition.

5 DISCUSSIONS

The results of this study build on existing knowledge by extending skill decay theory to field-based application. Further, empirical data has been used to identify the actual magnitude of procedural skill decay. Significantly, the magnitude of procedural skill and knowledge retention declined rapidly after one month and gradually toward three month. This is comparable with the study of Wetzel, Konoske and Montague (1983) which reveal that immediately after training and a four weeks interval, participants had a 21% drop in scores while Austin and Gilbert (1973) observed a 16% loss of basic problem solving skills after 8 weeks. A common construct regarding this is based on the feedback the trainees receive during acquisition (Ramaprasad 1983; Gibbs and Simpson 2004; Sadler 2010). When such feedback contains information about the magnitude and direction of performance errors, it directs the trainees towards ways of correcting the error and improving their performance while the infrequent or the total absence of feedback is associated with skill and knowledge loss, (Hurlock and Montague 1982; Driskell, Willis and Copper 1992). Another factor, whether direct or an intervening variable, is the time interval between training and performance. It is therefore not startling that the longer the time interval between practice and performance, the greater will be the skill decay. This study revealed that rescue skills decay over time where performance decreases rapidly soon after training then occurring at a slower rate, which is similar to results reported in the works of (Arthur Jr., et al. 1998; Wixted and Ebbesen 1991). According to (Driskell, Willis and Copper 1992; Wixted and Ebbesen 1991), this pattern appears to be consistent across a variety of skills and tasks. Previous skill retention research has sought to identify factors that influence the rate of individual skill decay (Rose, et al. 1985; Wisher, et al. 1991). If tasks could be reliably described according to these factors it would then be possible to examine, using actual performance data, how particular combinations of factors influence performance at some time interval (e.g. 24 months) after initial task proficiency had been achieved.

Learning is characterised by an initial steep learning period that asymptotes to maximum proficiency, while forgetting is characterised by an initial steep drop in proficiency, which then levels off, dropping more slowly as time goes on (Stothard and Nicholson 2001). According to Stothard and Nicholson (2001), the major decay in skill occurs in the first few weeks/months after training, with smaller differences over time. Findings from this study which are based on in-situ real life field data validates that the theory of skill decay is correct with proficiency dropping between time zero and three months. This confirms the results of Stothard and Nicholson stating that the drop in proficiency was greater between time zero and three months, than between the sixth and eighth month as suggested by others. ‘Forgetting’ over the three-month period occurred at different rates for refresher and fresher participants. The refresher participants tend to perform better on average than the fresher participants as depicted in the mean plots for both skill and knowledge tests. It should be noted that the degree of successful performance of an individual on any of these tests is largely reliant on the learning experience, or the type of practice and instruction received. Also, this study identified that task steps that are forgotten tend to be those that are not suggested by the previous sequence of steps or by the equipment and Shields, Goldberg and Dressel.
(1979) identified these as amongst factors accountable for differences in retention. The initial level of learning which is obviously related to the amount of initial training is one of the most important factors in determining retention (Hurlock and Montague 1982). An individual's level of initial proficiency has a direct relationship with the level of skill retention, and relation between recall success and skill level (Watson and Fischer 1977). Other contributing factors to procedural skill decay of wind technicians could be associated to their peripatetic nature of work which has limiting factors in this research; practice; aptitude; equipment design and task difficulty. Safe working requires robust procedures and it is suggested that training, practice and experience are major contributing factors influencing procedural skill decay during rescue and evacuation. This study also discovered that technicians mostly forgot task steps at the beginning and end of a task and steps related to safety and this was validated by the work of Osborn, Campbell and Harris (1979). Different literature has shown that skill retention for all tasks deteriorates; and the rate of retention differs by task characteristics. Tasks with performance that deteriorates rapidly tend to be procedural tasks which involve a number of steps, have no performance cues, and have time requirements similar to the use of the RG9A device while tasks with performance that deteriorates more slowly are continuous tasks with cues or an obvious internal logic. Ericsson and Lehmann (1996) pointed out that the attainment of exceptional performance is usually accompanied by sustained, deliberate practice and this is not possible with the technicians as the rescue device is considered as being deployed and not fit for purpose if taken out of the airtight storage bag. A central feature of deliberate practice is in the setting of performance goals and the application of practice strategies to attain these goals. Learners also make use of feedback to adjust the quality of practice and feedback is considered critical to remembering information, and timely and accurate feedback will enhance the ability of a learner to retain a skill.

Scheduling refresher training is costly, entailing time, personnel, and equipment costs which are necessary when training is periodic. For refresher training to be effective, technicians need to experience a range of job situations involving information or skills previously acquired but impaired through non-practice. Job-like problems should be varied and practice in solving them should provide feedback on the quality of performance. People generally need feedback, or “knowledge of results” to correct errors, observe and use cues associated with task performance, and generate effective procedures (Hurlock and Montague 1982). Therefore, implementing the proposed benchmark performance of 70%, it is advisable that refresher participants be scheduled to undertake rescue and evacuation practice drills within three to six months after skill acquisition. For fresher participants, it is recommended that they undertake an early practice drill within one and three months after skill acquisition to restore their proficiency to optimum. Performance benchmarking should be a continuous process of validating technician's performance to determine best practice and to establish process goals for improvement. Determining the limit state performance which is considered as the critical margin of safety performance for wind technicians involved four steps (see Figure 5): the ‘safety assessment’ of key competencies and the ability to perform those competencies within a specific task safely; the ‘accurate planning’ of an achievable path that a technician can follow to maintain or improve identified competencies by mapping strengths and weaknesses; the ‘acquisition’ of skills and knowledge required to maintain or improve identified competencies; and lastly, ‘timely validation’ of performance-based test conducted to determine if a technician retained proficiencies three months after skill acquisition. This structured approach towards benchmarking skill and knowledge can serve as a standardized scenario within which collective or individual performance can be assessed frequently as required to maximize basic skills and knowledge. Therefore, a limit state performance benchmark of 70% indicates that the study participants barely attain this limit after one month of skill retention assessment while their knowledge performance was beyond the outlined benchmark. It should be noted that even one error can be fatal in a rescue e.g. participant could score 80% which is a pass but the 20% wrong can result in fatality.

6 CONCLUSION

The skill and knowledge assessment is a strategy for sustaining technicians’ readiness toward efficiently using the RG9A device in carrying out rescue during periods of emergencies whilst working at height. Dynamic simulation technique is a favoured approach that can be applied to boost the strategy for refresher training rather than static representations (pictographs) used in this research. When employed,
such techniques can provide training of progressively greater complexity and realism. Dynamic simulation will permit technicians to apply real world and real time decisions to specific rescue and evacuation problems and to observe realistic responses to those decisions.

The principal application of this study addresses the facilitation of instructional and practice strategies that can lead to competent application of acquired skills and knowledge in the field. This is beneficial for practicing procedural skills that require timing and precision that can only be acquired through deliberate practice with authentic tasks.

Data on the feasibility of using technician-generated retention estimates to facilitate predictions about the scheduling of refresher training timeframes are suggestive, but not absolute. In general, the literature indicates that, in the absence of practice or other reinforcement, skill retention declines over a period of time. Since relearning or refreshing of skills can take significantly lesser time than original learning; this study has attempted to estimate relearning needs of wind technicians by adopting a benchmark performance and tentative timeframes for scheduling refresher trainings. Given that skill decay will occur even if wind technicians are over-trained, another approach of defining means to optimize the schedule of refresher training is needed so that technicians will receive training when needed to preclude them from falling below a set criterion level of performance. This can be accomplished by instituting the type of assessment used in this research where the technicians are required to carry out a situational judgement test and job knowledge inventory test as a function of estimating their training needs.

This assessment can also be used as ways of examining and predicting skill retention with the ultimate goal of improving the sustainment of performance or readiness. This study therefore recommends two comprehensive approaches to sustaining skill and knowledge of the wind technicians: enhancing initial learning, enhancing the prediction of skill retention for effective scheduling of refresher training thereby reducing the rate of skill decay. This can be achieved through the development of these potentially practical and accurate means of predicting skill decay to aid the scheduling of refresher training.

Abstract: Both physiological status and jobsite environmental stressors influence workforce behavior and performance. Understanding these relationships at the individual worker level is paramount for sustainably managing the construction industry workforce. Astonishing improvements in sensing technology can benefit field research by providing ways to validate occupational performance models based on data that measure workers' physiological variables and environmental stressors. However, only a few studies have taken advantage of these technological improvements to conduct construction field studies. This paper describes a field monitoring study hosted at a mid-rise, mixed-use building construction site in Seattle, WA. This study was valuable in terms of its breadth and period of the observations because it used some of the latest off-shelf wearable biosensors to collect 339 hours of workers' biosignal data from five subjects, during summer and fall, for a total of up to three weeks per subject. This research empirically validated that the heart rate is a good predictor of a worker's physical strain. Descriptive statistics and a time series plot were used to analyze the heart rate pattern as a predictor of worker's physical strain level. Correlation analysis was used to analyze the association between the workers' heart rate and jobsite environmental stressors. Also, analyzing video recordings and questionnaires helped interpreting the analytical results. This paper reports the lessons learned and the challenges of implementing a selected combination of wearable biosensor and environmental sensing technologies. These research findings are preparatory to validating a demand and capability model to be used for predicting construction workers' performance.

1 INTRODUCTION

Identifying the human factors affecting the performance of labor in terms of productivity, quality, and safety is important for sustainably managing workforce in the labor-intensive construction industry. Worker's low performance is critically related to an unhealthy and overloaded physiological status. In 2010, there were 4,690 fatal occupational accidents in the United States with 802 fatalities being in the construction industry (CPWR 2013). In regard to the workforce employed, the construction industry caused more deaths than any other major industry including transportation, agriculture, retail, and manufacturing. Similarly, the rate of days away from work caused by nonfatal injuries and illnesses is 39% higher for the construction industry than the average in all major industries (CPWR 2013). Accounting for 33% of the total 74,950 non-fatal injuries, bodily reaction and exertion was the largest cause of nonfatal injuries and illness in the U.S. construction industry.

Previous studies have identified workers' accumulated fatigue originating from continuous work activity, and bodily overexertion or repetitive motion as some of the causes of safety accidents and work-related
musculoskeletal disorders (Everett 1999; Putz-Anderson et al. 1997). Cardiovascular diseases, high blood pressure, and obesity are also major health-risk factors for construction workers (CPWR 2013). Workers’ overexertion and high fatigue are known to be negatively associated with labor productivity and quality of work (Astrand et al. 2003; Bernold and AbouRizk 2010). Overall, increases in physical strain and stress are expected to decrease work quality and productivity (Bernold and AbouRizk 2010; Ringen et al. 1995), and have a negative influence on safe work behavior due to an increasing of distractions and fatigue among workers (Hallowell 2010). Moreover, bodily exertion causes declines in work efficiency, reduces attentiveness, and increases errors (Abdelhamid and Everett 2002).

This paper summarizes results and reports lessons learned from a recently-completed field monitoring study that relied on a combination of wearable bio- and environmental sensing technologies. The study aimed at assessing opportunities and challenges in the use of biosensors and tracking devices in a construction site to promote the evaluation and validation of occupational performance models. The study relied on mainstream technology to help collect data related to worker physiological status, activity levels, and jobsite stressors. The adopted technology included a weather station with a wireless data logger, off-the-shelf physiological status monitors (PSM) as the option of biosensors, and global positioning systems (GPS) for tracking workers.

2 DATA COLLECTION AND METHODS

2.1 Data Collection Methods

2.1.1 Biosensor

Heart rate (HR) is one of the most important parameters to indirectly measure the physiological demands of workers (Beek and Frings-Dresen 1995; Garet et al. 2005; Takken et al. 2009). Among wearable sensors that measure HR, the Zephyr BioHarness™ 3 was selected for use in our research because it was considered to have high reliability and applicability (Dolezal et al. 2014; Gatti et al. 2011, 2014). Frequent bending and twisting of the waist is often required by construction workers, and for this reason, a sensor mounted on a chest belt, was considered to be more appropriate than a wrist-mounted sensor. Wrist-mounted sensors accurately measure HR of workers when they are resting or performing moderate activities (Terbizan et al. 2002); however, the pulse reading sensors may lose accuracy because of the unexpected fall-out from the wrist during harsh working activities. Also, chest-belt-mounted sensors measure HR similarly to electrocardiogram (ECG) sensors by recording the electrical activity of the muscular tissue of the heart. They are considered to be more reliable than wrist-mounted sensors using photoplethysmogram in physically active states (Schäfer and Vagedes 2013). The selected biosensor provides the functionality to collect HR (bpm), breathing rate (bpm), posture (degrees), activity level (g) and estimated core body temperature (°C).

2.1.2 Environmental Sensor

Outdoor temperature is one of the environmental stressors affecting construction workers’ performance. An increase in air humidity also influences sweat evaporation and can increase the heat stress of workers in hot weather. Wind speed also affects the velocity of sweat evaporation, and this may differ depending on the type of clothes worn by the workers (e.g. long-sleeve vs. short-sleeve shirt). If exposed to ultraviolet (UV) rays from the sun for long periods of time, workers may experience dehydration that is one of the variables associated with a worker’s physical strain level. Therefore, the amount of ultraviolet exposure the workers received was measured through UV sensors on a weather station in our research. A wireless weather station (Vantage Pro2™ Plus, Davis Instruments Corp.) was installed in the midsection of the tower crane. The height of installation of the weather station changed from summer to fall data collections to adapt to the building floor level on which the subjects were performing their tasks.

2.1.3 Other Data

Location Tracking: Location tracking was added with the expectation that it could help in performing work sampling to assess how long workers spent in various work areas versus the time they spent travelling
between working areas. To track the workers’ location, they wore portable global positioning system (GPS) devices throughout the work day. The i-gotU USB GPS Travel & Sports Logger (GT-600) from Mobile Action Technology, Inc. was selected because previous studies found it to be a fairly accurate GPS device for tracking human movement patterns in urban areas (Paz-Soldan et al. 2010; Vazquez-Prokopec et al. 2013).

Perceived Fatigue Level and Workers’ Major Tasks Performed: Surveys were administered at the beginning of each break and at the end of the work day to (1) assess each worker’s subjective fatigue level using the Samn-Perelli Fatigue Checklist (Samn and Perelli 1982), and (2) identify the major tasks each worker had performed between breaks. The Samn-Perelli seven-point fatigue scale (SPS) is a well-established subjective measurement of fatigue. Samn and Perelli (1982) validated the relationship between subjective fatigue levels on a 7-point scale and the performance capabilities of aircraft operators; a higher score indicated the operator felt a higher level of subjective fatigue. The SPS has been used to measure employee fatigue in most transportation industries including aircraft, truck, and rail. Dorrian et al. (2011) used the SPS in rating rail workers’ levels of fatigue to validate a statistical correlation between shift work and fatigue.

Video Recording: Previous studies relied on video recording to capture subjects’ productivity, activity, and behavior. The research participating contractor installed a webcam on an adjacent building, but this camera was only able to capture low-quality videos. Moreover, many critical working areas were located outside of the webcam’s line of sight. After an initial site investigation, the authors deemed it infeasible to install a high resolution site camera in a fixed position, as done in previous laboratory experiments (Cheng et al. 2012, 2013), due to line of sight requirements. Instead, the authors compromised to video recording only small portions of the workday with the plan of using this additional data feed to help interpret the data gather from the wearable devices. Using a digital camcorder (Canon Vixia HF S21), five-minute video observations were recorded three times for each worker: once in the early morning, once in the morning, and once in the afternoon. Video recordings were helpful for interpreting some of the analysis results and identifying the presence of other intervening factors.

2.2 Data Collection

Five healthy workers (age range: 27 to 40 years old; height range: 175 to 190 cm; weight range: 84 to 104 kg) were recruited from the selected construction site, a mid-rise mixed-use building project in Seattle, WA. The field observation was approved by the University of Washington Institutional Review Board (IRB). Table 1 includes additional information on these subjects. To guarantee the subjects’ anonymity, specific information such as height, weight, and race are ruled out in the table. Data were collected on workdays usually spanning from 7:00 a.m. to 3:00 p.m.; however, subjects often worked 10-40 minutes of overtime to complete daily assignments or to recover from delayed tasks. Throughout a typical workday, workers started with a short stretch and flex session at 7:00 a.m., and then returned to the trailer to prepare a pre-task plan. At this time, biosensors and GPS devices were provided to subjects to be worn. Workers had two break sessions, one between 10:00 a.m. and 10:15 a.m., and another between 12:00 p.m. and 12:30 p.m. During these two breaks sessions, and again at the end of the workday, short surveys were conducted to assess the workers’ perceived fatigue levels and identify major tasks performed. Data were collected during two different seasons (i.e., hot and cold weather) to increase the variability of environmental stressors. Ideally, the authors would have preferred to collect data in winter (between January and March) that is well representative of the cold weather data to increase the inter-seasonal variability contrasted with the one collected in summer. However, the authors were forced to compromise due to the schedule of the activities supporting the concrete placement that were being performed by the subjects. Because this task was scheduled for completion at the end of October, the data were collected in the following periods: (1) July 29th to August 8th (hot season in Seattle), and (2) October 14th to October 18th (mildly cold season). As workers performed tasks on the ground level in the summer, a weather station was set up at the lowest possible level of the tower crane. As workers worked on the roof in the fall, the weather station was moved and set up at the roof level of the tower crane. While working at the ground level, subjects often performed their activities under a temporary deck; therefore, the weather station data are not fully representative of the environmental stressors on these subjects.
Grubbs’ tests were used to detect outliers to be removed from our HR and BR datasets as described in a previous paper (Lee and Migliaccio 2014). Weather data were collected every five minutes, whereas HR and BR data were collected every second. Therefore HR and BR data were calculated as mean values over a time period of five minutes (300 seconds) to perform a correlation analysis.

3 RESULTS

3.1 Heart and Breathing Rates as Predictors of a Worker’s Physical Strain

Our data analysis strongly suggests that HR is a more useful parameter in monitoring workers’ physical exertion than BR. For instance, Figure 1 shows HR and BR time series plots for a selected day of the hot season. The plots show clear drops in HR during the break (10:00–10:15 a.m.) and lunch times (12:00–12:30 p.m.), when the workers were resting. The same trend was observed for all five subjects in both seasons, independently from the tasks being performed. On the other hand, the BR data do not provide the same information. This analysis shows how real-time HR data are important to monitor and predict workers’ physical exertion, which is in return associated with workers’ physical strain levels (Bernold and AbouRizk 2010).

3.2 Jobsite Environments

The field weather conditions during the observations are described in Table 2. As expected, higher ambient temperature levels, higher solar radiation levels, and lower relative humidity levels were measured in the summer season than in the fall. The variability of these factors was lower in the fall season than in the summer season. The daily raw data show that the outdoor temperature continuously increased from the beginning to the end of the workday. Conversely, the humidity level decreased throughout the workday. The rainfall data collection failed due to the existence of a hole in the rain collector, which was blocked by wood dust from the construction site. This event suggested that a debris filter should be installed for rain collection in future developments of the research. The amount of solar radiation was generally higher in the summer than in the fall. We did not find differences in wind speed patterns between summer and fall.

3.3 Heart Rate versus Climatic Conditions at the Season Level

Jobsite environmental stressors are expected to affect HR, and so we analyzed our data to this end. To compare the two seasons, we focused our analyses on the subjects who had participated in both summer and fall data collection efforts: S.F.1 and S.F.2. For our analysis, five minute subject-level data were segmented into three sessions per workday depending on the break schedule (i.e., early morning, later morning, afternoon). Moreover, we only included in the analyses those data points corresponding to sessions for which we had data for both the subjects. Finally, we excluded data from August 5th-7th from the data analysis because an unusually heavy workload was performed on these days by subject S.F.2. Therefore, sessions from the following dates were included in the dataset: July 29th-31st, August 1st-2nd, and October 14th-18th. Finally, our dataset included a total of fifteen data points per subject per season (i.e., three sessions multiplied by five days per season). Each data point was represented by a four-dimensional vector that included average, median, minimum and maximum sessional values per subject.

Using this dataset, season-level descriptive statistics were computed (see Table 3). For both the subjects, we found that maximum HR values were higher in fall than in summer. Similarly, we found that average HR values were higher in fall than in summer. To analyze whether this higher average HR in the fall over the summer was statistically significant, a one-sided two-sample t-test was performed. For this analysis, the week 1 summer data were compared with the week 1 data collected in the fall. For the subject S.F.1, the average HR was 115 bpm in the fall season and 109 bpm in the summer season. With 95% confidence, the null hypothesis that the average HR between the two seasons would be the same was rejected ($p=0.047$, $\alpha=0.05$ level). In the case of subject S.F.2, the average HR was 107 bpm in the fall season and 101 bpm in the summer season. With 90% confidence, the null hypothesis was rejected ($p=0.061$, $\alpha=0.1$ level).

This result contrasted literature-based expectations that suggested a positive association between HR and outdoor temperature. An analysis of the amount of clothing used by the workers in the two seasons...
can help explain this result. In fact, our subjects wore longer sleeves and thicker clothes during the fall season, which may have restricted their physical movement (see Figure 2). Consequently, this may have caused an increase in their core/skin temperatures, and limited the mobility of their arms and torsos while working, which would have required more worker movement, and therefore increased overall physical exertion. As a result, workers reached higher level of physical strain. This result suggests a significant role of clothing insulation in physical exertion, which should be evaluated in future studies.

### 3.4 Heart Rate versus Climatic Conditions at Peak

In addition, we analyzed the dataset for peak climatic conditions on August 6th. This day was selected because the daily deviation of the ambient temperature was high and biosignal data from three subjects (S.F.1, S.F.2, and S.4) were collected fully over the eight work hours. S.5 was also present, but the last 3 hours of data for that subject were lost due to malfunctions in the chest belt unit. Subject F.3 did not participate in the summer study because he enrolled only for the fall dates. A Pearson correlation analysis found no correlation between ambient temperatures and HR for subjects S.F.1 and S.F.2, and a positive weak correlation for S.4 (r=0.24, p<0.05) (see Table 4).

Since previous studies have suggested that wet-bulb globe temperature (WBGOT) rather than outdoor ambient temperature should be the index used to evaluate workers’ heat stress levels and can be a more useful parameter for predicting workers’ heat strain (OSHA 1999; Rowlinson and Yunyan 2014), we also performed a correlation analysis between WBGOT and HR (see Table 5). The outdoor WBGOT is estimated
by the weighted sum of the natural wet-bulb temperature ($T_w$), the globe temperature ($T_g$), and the
ambient temperature ($T_a$), as shown in Equation 1.

\[\text{WBGT}= 0.7T_w + 0.2T_g + 0.1T_a\] 

To estimate the $T_w$, the dew point temperature, the ambient temperature and atmospheric pressure data
collected by the weather station were cross-referenced in the American Society of Heating, Refrigerating,
and Air-Conditioning Engineers (ASHRAE) Psychrometric Chart. The $T_g$ calculated by Tonouchi et al.
(2001) was estimated from the wind speed and solar radiation as shown in Equation 2 below:

\[T_g= T_a + 0.007 \times S - 0.208 \times U\]

where $T_g$ is the black globe temperature (°C), $T_a$ is the ambient temperature (°C), $S$ is a solar ration
(W/m²) and $U$ is wind speed (m/s). Since the equation is developed in SI base units, imperial units were
converted to SI units to apply this equation. From these processes, the WBGTs were estimated for every
five minute period from 7:30 a.m. to 3:00 p.m. on August 8th. Since the WBGT calculation model is
empirical, it should be different from the measured WBGT from heat stress monitors incorporating WBGT
sensing technology. With this calculated data set, additional Pearson correlation analysis found no
statistically significant correlation between WBGT and physical strain measured by HR for subjects S.F.1
and S.F.2, and a positive weak correlation for S.4 ($r=0.23$, $p<0.05$), as shown in Table 5, from the
uncontrolled field data.

4 CONCLUSIONS AND LESSONS LEARNED

The study narrated in this paper used some of the latest off-shelf wearable biosensors to perform an
extensive field observation that produced a raw dataset: 339 hours of workers’ biosignal data from five
subjects, during two seasons (summer and fall), for a total of up to three weeks per subject. The research
empirically validated that HR is a good predictor of a worker’s physical strain. Descriptive statistics and a
time-series plot were used to analyze the HR pattern as a predictor of worker’s physical strain levels.
Correlation analysis was used to analyze the association between the workers’ HR and jobsite
environmental stressors. Whereas no association was observed between the climatic data and HR, the
approach initially selected to evaluate environmental stressors may have been flawed. In fact, at the end
of the study, the site environmental health and safety (EHS) manager, who performed several daily walk-
throughs of the jobsite, informed us that there was a considerable difference in conditions between the
location of the weather station in the tower crane and the microenvironment on the deck or in the
basement where the workers were working. Ideally, the authors would have preferred to collect data in
winter (between January and March) that is well representative of the cold weather data to increase the
inter-seasonal variability contrasted with the one collected in summer. However, recent advances in
sensor networks may provide a solution to this need for a diffused network of environmental sensors that
could be resistant to the harshness of a construction jobsite in the future. The preliminary findings from
this extensive field study with five subjects are not sufficient to generalize the statistical outcome to all
construction workers in Washington State or the United States because the purpose of this study was to
evaluate the use of bio- and environmental sensing technologies for understanding processes affecting
construction workers’ performance and health.
The authors were challenged by various practical issues during this first extensive field study. These issues are shared hereafter for the advantage of other researchers.

**Use of GPS Trackers:** Whereas the adopted GPS units were found reliable in urban environments by previous studies on tracking general human movements, they did not seem as adequate for tracking construction workers. GPS data lacked reliability due to serious signal disconnections. This issue was attributed to the many barriers (e.g., working under the slab formwork, working in the basement, and using a portable toilet) that obstructed clear GPS satellite communications, as well as artificial errors caused by electrical power lines near the site (see Figure 3). Still, we expect that the same devices may provide satisfactory tracking in open-sky conditions.

![Figure 3: Causes of GPS Malfunction](image)

**Confounding Factors:** We observed that some subjects frequently drank energy drinks and smoked during the breaks. These confounding factors may have affected the HR and BR data. Thus, additional survey instruments on the subjects’ dietary and smoking habits should be implemented, and potential compounding variables need to be controlled in the field study.

**Fear of Reporting to Supervisors:** Based on early conversations during the design of the field study, we perceived construction workers being concerned that the study’s results would be reported to their supervisors at the individual level. This created a sense of resistance for the workers to be monitored through wearing sensors. Therefore, we implemented a careful recruitment process in which a consent form was used to instruct workers about the confidentiality of their data and to assure them that the results of the research would not cause them any disadvantages relative to their supervisors. Still, we adopted a top-down recruitment approach wherein project management helped recruit workers. As a result, a member of the field management team was able to “figure out” who the subjects were and manifested an extreme curiosity in knowing his individual workers’ HR trends. Although the researchers strongly protected the confidentiality of the subjects, this behavior resulted in some residual diffidence by the workers that may have caused some of the dropouts. In the future, we will explore alternative approaches to recruitment that are more bottom-up and use unions and apprenticeship programs as recruitment venues. In addition, we will avoid installing instrumentation in the same trailer used by the field management.

**Fear of Underperforming against Peers:** Insincere reporting probably occurred among subjects in the SPS perceived fatigue survey. For example, a worker was caught looking at other subjects’ survey forms, and another worker asked researchers what levels of fatigue other subjects had reported. These behaviors may indicate attempts to report fatigue levels that did not reflect the actual perceived fatigue. Thus, subjects should complete the surveys away from one another.

**Trades to be Observed:** All the subjects worked for the general contractor on site. As a result, the types of tasks assigned to the subjects presented high variability in scope and target outputs. Some of the inconclusive results may be attributed to this issue. In the future, we plan to perform field observation of subjects belonging to specialty trades as the variability in their scope and target output will be reduced.

**Use of Video Recording:** While recording short videos of construction activities that could help capture confounding factors, we observed that subjects often became aware of being recorded and changed their
work behaviors. This was expected and we kept these periods very short. However, positioning several fixed cameras may overcome this issue in the long term.

The cited challenges allowed the authors to outline a roadmap for the successful implementation of bio- and environmental sensors in the construction field. First, it is important to carefully design a study and a managerial strategy to minimize both workers’ resistance to recruitment and insincere reporting of perceived variables. Second, subjects should be recruited from subcontractors involved in the slab framework, roofing, drywall, or masonry trades because these tasks are repetitive and physically intense, require less multitasking, and limit the dimensions of the traveling area, which in return increase the chance of successfully using tracking devices to perform automatic work sampling (Cheng et al. 2013). Third, the use of GPS tracking should be limited to open-sky tasks with minimal barriers presented by built slab framework or roofing. Whereas a need of analyzing indoor activities in established, traditional visual work sampling (Liou and Borcherding 1986) could be applicable to provide an indirect measure of physical exertion and performance. Fourth, cooperation and advice from site superintendents and safety managers is needed to appropriately place environmental sensors for local measurements and cameras that would limit the confounding factor of having a researcher on-site operating these devices.

OPTIMIZING EARTHWORK HAULING PLAN WITH MINIMUM COST FLOW NETWORK

Duanshun Li¹, Chang Liu¹ and Ming Lu¹, ²
¹ Department of Civil & Environmental Engineering, University of Alberta, Canada
² mlu6@ualberta.ca

Abstract: Linear programming is commonly used in earthwork hauling plan. However special expertise in forming and solving linear equations, along with considerable efforts in interpreting results, is required to apply these methods in practice. Moreover, previous methods mainly focus on cost estimation and thus largely ignore the constructability issues; this makes earthwork hauling plan impractical for construction planning. We aim to address these problems by introducing an intuitive graph based approach which optimizes the earthwork hauling plan using the minimum cost flow network. We choose the total traveling time as the objective function to be minimized in order to separate the earthwork hauling plan from other factors such as fleet combination. Our method directly connects adjacent sections allowing accessibility between them, instead of connecting the centers of cut and fill cells as potential haul routes as in previous methods. As a result, the proposed method is capable to handle constructability issues caused by "soft blocks" -which cannot be eliminated in establishing the standard flow network as their existence impose constraints on the grading plan. The graphic earth flow network can be used to guide the execution of the earthwork project and generate multiple grading plans, providing more flexibility compared to traditional methods. We present an earthmoving example with a reserved soft area and show that the proposed method is graphically intuitive, easy to establish and able to handle soft blocks.

1 INTRODUCTION

For large infrastructure construction projects such as road construction, it is common that earthwork accounts for about 25% of the total construction cost (Hare 2011). As a result, an optimized earthwork design is essential to enhance the performance of the project. Aiming to reduce the total quantity of earth to be moved, cut-fill balancing algorithms were proposed to equalize the quantity of earth for cut and minimize the quantity of earth handling from borrow pit and to landfill (Goktepe and Lav 2004). The technique has been well-studied and can be easily applied through commercial software such as Auto CAD Civil 3D which facilitates generation of the final topographic surface of the site. The quantity of materials in each cut and fill sections can then be derived from the elevation difference between the original and final as-designed surfaces.

A well designed grading plan can reduce the total amount of earth excavated, however the most significant savings can be achieved by optimizing earthwork operations which involve large numbers of costly heavy equipment such as excavators, loaders, trucks and compactors. According to the research conducted by Hare et al (2011), an approximate optimal earthwork operation plan can result in as much as 48% to 74% cost improvements. The fleet composition and earthwork hauling plan are important factors in earthwork operations hence become the focus of productivity enhancement in earthmoving
projects. Though plenty of research has been done on fleet optimization (Moselhi and Alshibani 2009, Morley et al. 2014), it highly depends on the predefined earthwork hauling plan. Therefore an optimized earthwork hauling plan is critical to further reduce the amount of hauling efforts and facilitate the fleet optimization. Peurifoy and Schexnayder (2002) suggested three most significant factors of an earthwork hauling plan, i.e. the quantity of earth to be moved, the haul distances to move the material and the grade of the road that the material must be hauled over. This research addresses quantity of earth to be moved and hauling path explicitly; the grade of road is represented by travel speed implicitly.

Mass-haul diagram is widely used for making earthwork hauling plan in road construction, but it is limited to linear type of construction. Linear programming (LP) based earthwork hauling plan optimization was first introduced by Stark and Nicholls (1971) and then implemented by Mayer and Stark (1981) using haul distance as the unit cost. Easa (1988 a) proposed building a similar model aiming to optimize road way grades by minimizing the earthwork cost. Given that the unit cost of purchase and excavation of borrow pits is proportional to the quantity of materials required (Easa 1987), Easa (1988 b) modified the model by taking the variability of unit cost for purchase and excavation of borrow pits into consideration. However it is noteworthy that once the final grading design is defined, the purchase and excavation will be fixed and thus will not affect the total direct cost. The commonly applied shortest route cut and fill problem (SRCFP) model in road construction is intended to grade a project site with minimum total distance traveled by earthmoving vehicles (Hare et al. 2011). Because SRCFP considers the variation of return distance due to change in excavation sites, the model is much more realistic but also more complicated. To handle large earthwork projects in road construction, Ji et al. (2010) proposed a one dimensional earthwork section division LP model which minimized the earth handling between sections. Taking the duration into consideration, Jayawardane and Harris (1990) incorporated fleet selection into the linear model. Chu et al. (2012) proposed a time-space network which generated earthwork hauling plan and schedule simultaneously for projects with single type of trucks, the applicability to multiple trucks was undisussed. More recently, Son (2005) introduced a minimal haul distance LP algorithm and proposed a graph based earthwork hauling plan visualization method.

Building the models and solving the complicated equations in previous studies require a large amount of time and expertise, which in turn hampers wide utilization of those techniques in practice (Alshibani 2008). In real world construction projects, establishing these equations in a finite time frame in support of decision making creates additional challenges. Besides, executing a project based on interpretation of numerical results obtained from analytical or simulation algorithms with many “hidden” conditions, assumptions would be more difficult for coordinators on site. These conditions may include “hard blocks” which can be identified without the final hauling plan, and even more complicated “soft blocks” which depend on the final hauling plan. Previous methods like linear programming are able to handle “hard blocks” if well defined, however they usually generate hauling roads with ungraded “soft blocks” due to mutual reliance. To address these problems, this research applies the minimum cost flow network algorithm into earthwork volume balancing. Through a graphic way, the network provides users with an intuitive medium to build the underlying equations. Current linear programming models generally produce a unique grading plan, largely neglecting practical site conditions such as safety of particular haul roads. Such solutions can only serve the need of cost estimation and will likely result in unrealistic grading plans for implementation. Noting this critical issue, this research proposes a neighborhood method based on the classic minimum cost flow network with 4-connected neighborhood, aimed to make the solution ready for execution by integrating constructability issues.

2 PROBLEM DEFINITION AND TRADITIONAL MINIMUM FLOW NETWORK

In graph theory, a flow network is a directed graph \( G(N, A) \) defined by a set \( N \) of \( n \) nodes and a set \( A \) of \( m \) directed arcs. Each arc \((i,j) \in A\) is associated with three properties. The unit cost \( c_{ij} \) indicates the cost of unit of flow on the arc. Capacity limits \( u_{ij} \) and \( l_{ij} \) are used to constrain the maximum and minimum flow on arc \((i,j)\). For each node \( i \in N \), an integer number \( b(i) \) denoting supply/demand is also defined. The nodes can be divided into three different categories based on \( b(i) \). If \( b(i) > 0 \), node \( i \) is a supply node with a supply of \( b(i) \); if \( b(i) < 0 \), node \( i \) is a demand node with a demand of \(-b(i)\); otherwise if \( b(i) = 0 \), the node is a transshipment node. The minimum cost flow aims to find the flow \( x_{ij} \) on each arc \((i,j)\) that
minimizes the total cost subject to the supply and demand constraints formulated as follows (Ravindra et al. 1993):

[1.1] Minimize \( \sum_{(i,j) \in A} c_{ij} x_{ij} \)

subject to

[1.2] \( \sum_{j \in (i,j) \in A} x_{ij} - \sum_{i \in (j,i) \in A} x_{ji} = b(i) \) for all \( i \in N \)

[1.3] \( l_{ij} \leq x_{ij} \leq u_{ij} \) for all \( (i,j) \in A \)

With the original topography and the final layout of the construction site, the site is usually subdivided into small sections as raster format commonly used in a digital earth model (DEM) in order to facilitate cut and fill quantity estimation in commercial software. The DEM is then resampled at a suitable resolution for earthwork volume balancing optimization. Figure 1 gives an example of a balanced grading project with 0 borrow and 0 landfill. In this example the DEM is resampled onto 125m × 125m grids.

![Figure 1: Typical balanced earthwork divided into sections: Positive values in light color indicate cut volumes; negative values in dark color represent fill volumes](image1.png)

![Figure 2: Traditional minimum cost flow network in earthwork hauling plan with cut and fill connected directly. Red indicates cut and blue represents fill. B is borrow pit and L is land fill.](image2.png)
The earthwork hauling plan problem can be depicted as the flow of earth on the construction site from one section to another; thus it can be modeled as a flow network. Each sub-divided section can be regarded as a node in the graph, and the supply/demand \( b(i) \) will be the cut or fill quantity of earth. For extra materials, borrow and land fill sites can be added as either a node or a connected sub-network. In previous research, the equations usually assume that the supply and demand nodes are connected directly as illustrated in Figure 2. Each arc in the figure represents a hauling path which can be built in the field to haul earth.

As the aim of earthwork hauling plan is to minimize the total cost of the project, the definition of unit cost is critical. Considering that various types of costs (such as time, capital, environment etc.) may apply, the unit cost is assigned accordingly. Current algorithms use either the hauling distance or the unit capital cost of material excavation & transportation as unit cost. For rough estimation or linear construction projects, the hauling distance between sections are usually determined as the direct distance between the centers of the two sections. For precise estimation, the hauling distance can be derived with shortest path algorithms (Liu and Lu 2014). The unit capital cost of traveling on the surface relies heavily on the fleet combination, which can be optimized based on the earthwork hauling plan.

The proposed neighborhood method utilizes time as the final criterion based on the observation that no matter how the condition changes, both direct cost and indirect cost are proportional to time. As the amount of earthwork for excavation and dumping will be fixed as per the grading design, the only variable which can be optimized would be hauling. Therefore, only hauling time is considered when define the unit cost.

Previous earthwork hauling plan methods mainly focused on cost estimation and thus barely catered to field construction needs. This often leads to oversimplification or neglecting constructability issues in connection with project execution. However, ignoring certain existing blocks in the field would result in inaccurate estimation of optimal earthwork costs and poor haul road design. These blocks can be divided into hard blocks and soft blocks according to the occurrence condition. The occurrence of hard blocks such as waterways, ponds and rock-bed is independent of the earthwork hauling plan. On the contrary, the existence of soft blocks can affect the final earthwork hauling plan. As hard blocks are known before the establishment of the earthwork hauling plan model, they can be embedded into the flow network with well-defined connections and unit costs. Take river as an example. An extremely high unit cost can be assigned to paths or sections crossing a creek on site. Through this approach the total cost to move the earth across the river will be extremely high and the paths crossing the creek will be automatically discarded through optimization if alternatives are available. On the contrary, the occurrence of soft blocks is unpredictable because they may rely on the earthwork hauling plan which is actually the final output of such optimization analysis. One typical constructability issue in earthwork hauling plan planning is that the sections along the path for particular earthmoving operation should have already been graded into temporary haul road while part of the path lies in soft blocks to be excavated or filled.

Soft blocks may be produced due to mutual reliance when the earthwork plan is not generated properly. To illustrate the mutual reliance, assuming the volumes of C-1, C-2, F-1 and F-2 in the linear earthwork hauling plan (Figure 2) are all the same and regarded as 1 unit. In addition, the unit cost between the sections are defined as \( P1 = 2, P2 =3, P3 = 100, P4 = 1, P5 = 2, P6 = 100, P7 = P8 = P9 = 100 \). The optimal minimum total cost defined in Equation 1.1 for this problem will be 4 units. An earthwork hauling plan with two paths is given as: (A) moving earth from C-2 to F-2 passing F-1 (C-2, F-1, F-2); (B) Moving earth from C1 to F1 passing C2 (C-1, C-2, F-1). In this case, to move the earth excavated in C-2 (operation A), the intermediate sections along the path (C-2, F-1, F-2) will be regarded as soft blocks and should be removed first. Regarded as a soft block, F-1 has to be filled and graded beforehand. However to get F-1 filled, operation B must be completed which requires that C-2, as a soft block, to be excavated and graded first. For earthmoving projects with numerous sections in two dimensions, the mutual reliance will be even more complicated, which is commonplace in solving classic minimum cost flow network problems. Considering the random nature of traditional minimum cost flow algorithms, a conflict-free solution is not guaranteed.
3 NEIGHBORHOOD METHOD MINIMIZING TRAVELING TIME

The proposed neighborhood method is similar to the minimum cost flow network. The major difference between the neighbourhood method and traditional minimum cost flow network is how the flow network is constructed. One of the critical limits of the traditional method is that cut and fill sections are connected directly with predefined hauling route. To improve the accuracy of the cost estimation and make the optimized earthwork hauling plan practical enough to serve the construction needs, the hauling route and cost have to be estimated simultaneously. The neighborhood method establishes the flow network in a way that connects adjacent sections directly with bidirectional arcs instead of connecting cut and fill sections directly with unidirectional arcs.

To get a clear view of the method, Figure 3 shows the flow network for a grided worksite with uniformly distributed unit cost between neighbor cells based on 4-connected neighborhoods. Each section is connected with the sections immediately to its north, south, east and west. Sections 6, 7, 10 and 11 in Figure 3 clearly illustrate a 4-connected neighborhood. Without any other constraints, the connections representing potential transportation directions between neighbor-sections in the example are given as bidirectional arcs with the same unit cost. With combinations of directions and properly defined unit costs, the algorithm enables users to incorporate hard constraints into the system. In some cases, certain areas of the site need to be reserved for particular uses such as snow stockpile or temporary storm water basin after grading. Thus passing through these areas are not permitted. Figure 4 gives an example of this situation. The red area indicates a reserved area which needs to be kept for other uses. To forbid transportation through this area, different unit costs need to be assigned in terms of transportation between reserved and un-reserved areas. If the total amount of earth needs to be moved out of the reserved area is positive (cut), a large unit cost (p3) needs to be assigned to the directions flowing inward from outside (highlighted as red arrows). On the contrary, if extra earth needs to be borrowed from outside, a large unit cost (p2) needs to be assigned to the directions outward (highlighted as blue arrows).

![Figure 3: Neighborhood method: blue indicates cut and orange represents fill](image1)

![Figure 4: Neighborhood method with reservation area: blue indicates cut and orange represents fill](image2)

Compared to hard blocks, soft blocks are associated with the mutual reliance of hauling routes, hence, are much more difficult to deal with. It is observed from previous research that the hauling routes are generated before earthwork hauling plan optimization, while the lack of such consideration during later optimization analysis is exactly the cause of mutual reliance in designing haul roads. Based on this observation, the neighborhood method optimizes the grading plan and hauling road simultaneously, thus avoids soft blocks caused by mutual reliance of the haul roads. In addition, the neighborhood method produces an earth flow network recording the amount of materials passing through each cell, instead of generating the traditional grading plan with source, destination and volume of materials.

Assume the volume of earth in each cut/fill section is 1 unit and the unit cost between neighbor-sections is equal to 1 if not specified. Based on the neighborhood flow network constructed (as shown in Figure 3...
and Figure 4), the earth flows can be generated through the minimum cost flow algorithm (as shown in Figure 5 and Figure 6). The amount of earth transported between sections is 1 unit if not given explicitly in the network. The resulting total cost for earthwork in the reserved area is 15, while the total cost for earthwork with reserved area is 16. For earthwork hauling plan planning with reserved areas, because extra amount of earth needs to be moved out, the unit cost of earth coming into this area is set to 1000 in our case to avoid materials passing through this area. The result given in Figure 6 shows that the proposed method is able to handle the "reserved area" problem as no earth from outside of the reserved area passes through this area. On the contrary, if the area is not reserved, section 2 will be transported passing through this area and then distributed to other sections.

![Figure 5: Flow of earth without reservation area](image1)

![Figure 6: Flow of earth with reservation area](image2)

Because the method only records the quantity of materials passing through the cells, users can distribute the materials passing a certain cell to any other connected cells based on specific requirements in order to obtain the traditional grading plan. The process can also be conducted through automatic algorithms based on the network, which is beyond the scope of this paper. More importantly, redistributing the materials by altering the source and destination will not change the incoming and outgoing amounts of materials, and thus will not increase the total cost because the source and destination do not constrain the cost in this model at all. Due to this advantage, multiple feasible grading plans can be identified to make up a set of optimal grading plans. On the contrary, traditional earthwork hauling plan methods usually produce one single result. The relationship between the solutions of the traditional method and proposed neighborhood method is represented in Figure 7. As the resulting solution set provides managers alternative execution plans, it increases the flexibility and reduces the risk considerably during the execution of the plan especially in earthmoving operations with inaccurate volume estimation due to uncertain field conditions.

![Figure 7: Relationship of solutions from the traditional and neighborhood methods](image3)

Table 1 shows the potential grading plan produced for each flow separately. Soft blocks are the major problem in generating the grading plan. Two rules are used to deal with this problem: 1) "cut from the
boundary”; 2) “fill from the boundary”. The boundary is defined as the interface between a cut area and a fill area with direct or indirect links at a certain stage. At the beginning, the boundary from the cut to the fill will be 3, 5, 6, 7, 10 and 4, 9, 11, 12, 14 respectively. After the cut sections on the boundaries are excavated, the boundary from the cut side will be 6, whilst the boundary from the cut side will be 15, 16. Section 2 will be the boundary eventually after section 6 is done.

4 EXPERIMENTS AND RESULTS

A case study to apply the neighborhood method was conducted based on a real earth moving project with an area of 1000m × 375m. For optimization purpose, the area is divided into 8 × 3 sections with equal width of 125m in both directions. The layout and volume of the cut and fill cells are illustrated in Figure 1. To improve productivity, two temporary haul roads are designed to increase the speed of the trucks. The objective is to evaluate the design of haul roads and find the optimal grading plan at the same time. The layout of the haul roads is shown in Figure 7. The speed of the trucks on temporary roads is higher than the speed on rough ground, assuming that the average speed of the trucks is 24km/hr on temporary roads and 18km/hr on rough roads.

The flow network of the site is generated with the 4 connected neighborhood without hard blocks. Two minimum cost flow networks corresponding to haul road design scheme A and B are generated through the proposed neighborhood method as illustrated in Figure 8. The final result shows that the optimal average unit cost is 70.72s for the first temporary road design and 61.68 for the second temporary road design. Because the earth is hauled per truck capacity each time rather than per cubic meter, the average unit cost is scalable due to the uncertainty of the capacity of the trucks.

5 CONCLUSION

We propose a 4-neighborhood connection based the minimum cost flow network that takes design constructability and field constraints into consideration to optimize the earthwork hauling plan problem. Due to the utilization of graphs, both the construction of the model and the execution plan are intuitive and simple to use compared with widely used linear programming methods. The method is also proved to
be more practical and realistic because the proposed model not only optimizes the total cost but also provides an efficient way to handle both hard constraints and soft constraints such as reserved areas and mutual reliance of hauling roads which are not solved in previous methods. Moreover, the generated results can be translated into multiple grading plans which can provide alternative plans and support decision making in field execution.

Abstract: Poor workstation design in a manufacturing facility negatively impacts the health and safety of workers, which hampers productivity. A systematic tool, Physical Demand Analysis (PDA), is utilized in a case-study project to quantify and evaluate physical labour and body posture for various production line tasks in a window and door manufacturing company. This paper presents the implementation PDA focusing on the design of the PDA form template, plant observation, and ergonomic risk identification. The data collection methodology and the implementation of time studies for plant observation are described. Four main ergonomic risks are identified: static whole body posture, manual material handling, sensory problem, and awkward body postures. Detailed observation findings, risk assessment method, analysis results and suggested corresponding corrective measures with regard to these four risks are described in this paper.

1 PLANT OBSERVATION AND ERGONOMIC ANALYSIS

A well-designed workstation which takes into consideration ergonomics can ensure the health and safety of workers while improving the productivity of a manufacturing plant's production line (Deros et al. 2011). On the other hand, workstation the design of which fails to consider ergonomics often require awkward body postures for workers, which may contribute to musculoskeletal disorders or injuries. These disorders and conditions, in turn, delay the production line accordingly. Thus these stations need to be redesigned in order to avoid awkward and potentially detrimental postures for workers.

Ergonomic concerns must be considered in the design phase of construction, and this involves negotiation among the ergonomist, engineer, customer, implementer, and management team (Burns and Vicente 1999). The same can be said of manufacturing plant design, whereby worker comfort, wellness, and productivity can be upheld through proper break times and ergonomic measures.

For an existing manufacturing plant that either has not incorporated ergonomic principles in the design phase or needs to be improved or modified to enhance working condition, researchers can address these challenges by conducting observations in the plant and recommending corrective measures accordingly. Physical Demand Analysis (PDA) is a method that enables the health and safety department to comprehend the plant operation in detail for each production line and analyze the potential ergonomic risks for workers station-by-station.
1.1 Physical Demand Analysis

PDA uses a methodical process to collect data pertaining to the physical demands of a given job on specific areas of the human body. The Industrial Accident Prevention Association (2009) defines PDA as “a systematic procedure to quantify and evaluate the physical, cognitive, and environmental demands of the essential and non-essential tasks of a job”. These documents are records, station-by-station, of all the collected physical demand data, which is obtained from plant observations. PDAs can be used as a proactive means of preventing injuries by identifying ergonomic risks, and, in response to an incident, as an aid for rehabilitation. In particular, PDAs can be used for the following purposes (Industrial Accident Prevention Association 2009):

- to assist in identifying tasks for each job, work processes, and equipment that may require further ergonomic assessment and intervention
- to assist in identifying and prioritizing safety risks
- to provide useful documents for recruitment and training workers
- to assist with job assignment and identification of appropriate modified duties for injured workers;
- to devise strategies for modifying tasks in order to prevent injuries on the job
- to provide details on job demands to health care providers and the workers’ compensation boards corresponding to the locations of the company’s manufacturing facilities—the Workers’ Compensation Board (WCB) of Alberta and the Ontario Workplace Safety and Insurance Board (WSIB).

PDAs play a vital role in ensuring the effectiveness and efficiency of return-to-work programs. A PDA is carried out for each job, where each job consists of several tasks that are described in detail in the PDA. A typical PDA usually includes a job overview, work shift schedule, and details pertaining to meals and breaks, job rotation, personal protective equipment, critical tasks, equipment utilized, strength demands (lifting / lowering / carrying / pushing / pulling / grasping), repetitive motion requirements, body posture requirements, sensory demand, environmental conditions, and ergonomic risks. The PDA displays in a form, which has a wide range of uses in the workplace, varying from rehabilitation to injury prevention. Companies are free to select which job receives a PDA form. PDA forms should be kept up to date as a company undergoes innovation and improves its practices.

Performing a PDA can be especially difficult for highly variable, infrequent jobs. For such jobs, direct workplace observation is inconvenient, since these jobs may only be performed for short periods of time and infrequently. One solution is to use video recorders to capture footage of workers performing tasks. The videos are then consolidated and analyzed, giving the rater the ability to perform analysis as if the worker was completing one lengthy task.

1.2 Methods for Data Collection and Time Study

Different methods for collecting time data in a workplace environment can result in drastically different results. Two methods for data collection exist—subjective and objective data collection. Subjective data collection involves the gathering of data by communicating with workers, using questionnaires, and reading logs; objective data collection is carried out either by direct observation or photography / videography. Besides the associated financial burden on the employer, subjective method tends to yield inaccurate risk assessments that exaggerate instances of injury or chronic pain based on anecdotal evidence (Palmer et al. 2000). Descatha et al. (2009) similarly showed that questionnaires tend to identify a higher level of risk than what is actually present as determined through direct observation. Although questionnaires may be a less costly alternative, they fail to encompass all the potential health exposure problems (Descatha et al. 2009). In cases where the employer is interested in minimizing losses due to health and productivity risks at the expense of a lengthier study, an objective method is preferred (Palmer et al. 2000).

A study was performed by McCallig (2010) in a construction company to compare three data collection methods—questionnaire, interview, and direct observation—on estimation of exposure time to hand/arm and whole-body vibration. The study found that the interview and direct observation could provide more reliable results than self-reported questionnaires or surveys (McCallig et al. 2010). Deros et al. (2011)
carried out an observation recording video footage of a motorcycle component manufacturing plant. The video footage was found to allow ample time for observation of posture and movement of the workers. Also, face-to-face interviews were conducted to obtain better understanding of the work being done, problems faced and health concerns. Based on their observation they found that, as a result of poor ergonomic design of workstations, workers are required to frequently bend their spines and twist their necks, which further results in musculoskeletal disorder (Deros et al. 2011). Video-based observation can also be used together with technical measurements to indicate the non-neutral and extreme postures for repetitive motion leading to work-related musculoskeletal disorders (Juul-Kristensen et al. 2001). In the case study presented in this paper, direct observation and video-based observation with the support of interview and manual measurements are the primary methods selected by which to analyze ergonomic risks.

1.3 Objective

This research project has been built upon the hypothesis that the implementation of PDAs in a manufacturing construction plant enables the health and safety department to better assess job requirements, ensure that the workload is within the workers’ capacity, and lower the potential risks of work-related injuries. The paper proposes a methodology to effectively process PDAs in manufacturing facilities and discusses the benefits to industry of implementing PDAs.

2 PDA PROJECT METHODOLOGY

The PDA project includes three steps: PDA form creation, plant observation, and ergonomic risk identification (see Figure 1). A PDA form is selected as the basis of ergonomic risk identification in the manufacturing plant. Developing a new custom form can have certain advantages over using a pre-existing one. A few PDA templates do exist, such as those available from the Industrial Accident Prevention Association, Occupational Health Clinics for Ontario Workers, and the Workplace Safety & Insurance Board. A new PDA template can be achieved when those physical demand factors to which workers are not exposed are omitted. Based on the framework provided by the PDA template, the PDA form specifies which job it pertains to by including job name, department line, and other basic information. A given job may or may not require a PDA, depending on the requirements of the company. Plant observation is required in order to identify tasks, work processes, and equipment that may be required.
In plant observation, required information can be obtained by three approaches: data collection, time study, and photography of tasks. Direct Observation and video recording methods are selected in this methodology due to their high reliability. Interviews are also included as part of the PDA project since communication can assist external observers in better understanding the tasks being analyzed. Other data collection methods include manual measurements (e.g., use of weighting machine). Forms for the “strength demands of job”, “sensory demands”, and “environmental conditions” where frequency data is not required can be completed by this time.

The frequency and body posture requirements can be ascertained through a time study. A 60-minute time study is proposed in this methodology for cases in which most tasks involved can be completed within 30 minutes. In the time study, body postures are recorded in a spreadsheet on one-minute intervals for each job (Figure 2). A combination of direct observation and video recording observation should be used, since video cameras offer the advantage of recording hours of footage for multiple stations simultaneously. This footage is later analyzed by the research team to extract the relevant data. (Video recording, it should be noted, may be unsuitable in cases where the workers are highly mobile since the viewing angle of video cameras is limited. In addition, some stations may be found to have limited working space, resulting in problematic camera positioning. In these cases, manual / direct observation is the recommended method.) The workers should be made aware that they will be observed and informed of the nature of the work prior to observation commencing. Furthermore, in the case of video recording, observers should be cognizant of working hours and scheduled breaks in order to avoid collecting footage during breaks.

![Figure 2: Time Study Sheet](image)

It should be noted that “frequency” in this study is defined as the number of times a motion is repeated over a specified period of time by a worker, which can be estimated using Equation [1].

\[
\text{Percentage of shift} = \frac{\text{number of checkmarks in spreadsheet}}{60} \times 100\% 
\]

Once the percentage has been calculated for each posture, a frequency descriptor is assigned to each percentage range as follows: Never (0%), Rare (1 – 5%), Occasional (6 – 33%), Frequent (34 – 66%), Continuous (67 – 100%).

The last step is collecting photographs for each task to be inserted in the form in order to help visualize the task. Scheduling this process as the last step in the PDA project allows for the workers to become more comfortable with the research and for the observers to familiarize themselves with the production process at the plant. For those workers who decline consent for their face to appear in a photograph, the alternative is to arrange the photograph in such a way that the subject’s back is to the camera. Those who decline this option as well do not appear in any photographs of their respective workstations. In these cases the photographs are taken of the production process, tools, and materials under use but not of the worker/s. Plentiful photographs ensure accurate representation of the tasks performed and of the inherent ergonomic risks.

After the plant observation, researchers can identify ergonomic risks based on the data collected in previous processes and propose corresponding corrective measures. The objective of this process is to identify ergonomic risk factors, ensure that tasks are within the workers’ capacity and limitations, and devise corresponding corrective measures. Based on data collection and time studies, ergonomic risks can be identified. However, risk factors vary in each case study; risk factor assessment is further
discussed in the case study section below. As outputs of the project, the corresponding company is delivered not only a PDA template ready for future use, but a list of current ergonomic risk for each task and corresponding suggested modifications.

3 PDA IMPLEMENTATION

A PDA is implemented as a collaborative project between All Weather Windows (AWW)—a major window and door manufacturer—and the University of Alberta. The manufacturing facility observed in this project is located in Edmonton, Alberta, Canada. PDAs are integral to their operations. PDAs enable workers to perform duties suited to their abilities, while also assisting others to ensure that when injury incidents do occur, the company has a clear picture of worker responsibilities and how to best develop return-to-work strategies. A well-managed return-to-work program allows the company to continue production operations seamlessly while providing meaningful work opportunities for employees rehabilitating following injury. Obtaining PDAs for each job on every production line ensures that the company can work pro-actively to better promote worker wellbeing by lowering the risk of work-related injuries.

With existing PDAs outdated, unnecessarily lengthy and complicated, and not accurately representative of the current state of the plant, the company sought a PDA which reflects recent changes in the plant in terms of tasks and production line allocation, thereby necessitating the PDA revision. The objective of the case study was thus to create a new PDA template suited to completing PDA forms and identifying ergonomic risks for all workstations in the collaborating company’s production facility.

3.1 PDA Template Creation

Based on the existing PDAs and a literature review regarding the content of PDA forms, the researchers develop a new template with detailed task information, basic ergonomic risk identification, strength demands of job, body posture requirements (expressed as frequency per shift), sensory demands, and environmental conditions, as shown in Figure 3. In terms of efficiency and effectiveness, the new PDA template is more practical. It is better organized (contains six tables), shorter (4-5 pages) but more informative compared with the previous PDA, which is lengthy (10-12 pages) and includes redundant content. Thus, the new PDA allows company health care personnel to quickly scan through the form and conveniently identify the primary cause of the worker’s injury.

Figure 3: New PDA template

3.2 Plant Observation

Plant observation involves data collection, time study, and photographing of tasks. The day shift is selected for the plant observation. This shift begins at 7:00 a.m. and ends at 3:30 p.m. with a 30-minute
lunch break and 15-minute coffee breaks in the morning and afternoon. Before any observations are carried out, certain terminologies in the PDA form must be clarified.

A 60-minute time study is implemented. This is considered to be sufficient for most workstations, as most tasks can be completed within 5-25 minutes. Consent of the workers is obtained and efforts are made to minimize any interference with the production line work during observation. The time study observations are followed by short interviews with the workers being observed. Workers are asked to describe which aspects of their work are the most physically taxing and to explain which body parts are strained after a day’s work. Information collected in these interviews is used for ergonomic risk identification.

3.3 Ergonomic Risks Identification

Based on the data collected during plant observation and the summarized documentations, the main ergonomic risks are identified. Four main ergonomic risks are described below. Some of the ergonomic risks can be prevented by taking easily implemented measures, while others may require further machinery development at the workstation.

1. Static Whole Body Posture

Most of the workstations require prolonged standing throughout the workday, which leads to back and foot pain. To counteract this, anti-fatigue matting or shoe insoles can significantly decrease the pressure placed on the spine and feet. Providing footrests for the workers is another effective method to decrease the strain that contributes to back and foot pain.

<td>Static whole body posture</td>
<td>Prolonged standing</td>
<td>Provide anti-fatigue matting or insoles; Provide footrest for workers to have a rest while standing</td>
<td></td>
</tr>
</tbody>
</table>

2. Heavy Material Handling

Workers are required to lift / push / pull heavy products manually without the aid of wheeled carts. These actions pose ergonomic risk to the back and shoulders. Heavy lifting also occurs in various production lines. The Infrastructure Health & Safety Association (IHSA) has provided a general guide for identifying ergonomics-related hazards (IHSA, 2014). In terms of manual material handling tasks, two worker weight capacity tables are provided by IHSA. If the profiles to be lifted exceed the worker weight capacity as outlined in these tables, the worker will be exposed to a dangerously high risk of injury. These two tables present the lifting/lowering weight limits for males only and for females only or both males and females. Based on this guideline, the ergonomic risks related to material handling can be identified for various tasks.

However, the weight capacity also varies based on four factors: (1) the relative distance the object is to be moved (far/close), (2) the size of the profiles (long/short), (3) the working height (hands end below knuckle height / hands end between knuckle and shoulder height / hands end above shoulder height), and (4) the approximate duration of the move (15 seconds, 1 minute, 2 minutes, 5 minutes, 30 minutes, or 8 hours). The distance to be moved and the working height are obtained from observation, and the description of the profile provides the dimensions and weight. The duration of the move can be estimated based on the shift working hours and the observation results. Shift A is from 7:00 a.m. to 3:30 p.m., and shift B is from 4:30 p.m. to 1:00 a.m., with a 30-minute lunch break and two 15-minute coffee breaks per day. Therefore, the total working hours per shift is 7.5 hours. With the results of the 60-minute time study,
the weight limitations for manual lifting can be calculated using Equation [2]. By comparing the results calculated using this equation against the numbers given in the two IHSA tables (IHSA, 2014), the potential high-risk exposure tasks can be identified.

\[ t_c = T_s \times t \times F \]

Where,

\( T_s \) is the working hours within one shift

\( t \) is the observation time

\( F \) is the frequency (%) of lifting/pushing/pulling within the observation time

<table>
<thead>
<tr>
<th>Risk Factors</th>

</tr>
<tr>
<td></td>
<td></td>
<td>Switch task;</td>
</tr>
<tr>
<td></td>
<td></td>
<td>Work with others;</td>
</tr>
</tbody>
</table>

The risk and corresponding corrective measures are given in Table 2. The use of a lifting machine to make this task semi-automated should be explored. A direct transfer and feeding machine to transfer the profiles from the cart to the machine or from the machine to the cart would be an even more proactive, albeit more costly, measure. The simplest measure, which the organization can implement immediately, is to stagger the tasks among workers so that particular workers are not disproportionately exposed to ergonomic risks.

3. Sensory risks

The third type of ergonomic risk identified from the observations is sensory risks, including eye fatigue and hand or arm vibrations. As can be seen in the photograph in Table 3, installation requires workers to locate pre-drilled marks in order to install the hardware on the sash. However, this task is difficult for workers, who may have to strain their eyes in order to visually locate the pre-drilled holes. From the researchers’ observation, workers will additionally measure the installation positions manually in order to install the hardware accurately. To overcome these difficulties, an auto-colour marking machine should be used for the predrilled marks, and the accuracy of the markings should be improved so that there is no need to measure manually. The auto-colour marking could be added to the welding machine or designed as an independent machine.

Another sensory problem has to do with hand or arm vibration. An array of tools is utilized in each production line. For many of these tools, such as chop saws, power drills, pneumatic staple guns, and air guns, the worker is exposed to a considerable amount of vibration during operation, with frequent use posing a serious health hazard. Carpal tunnel syndrome is one condition that may result from exposure to this hazard (Health and Safety Executive, 2014). The symptoms may include only moderate pain, white fingers, and sleep disturbance, but in more serious cases it may lead to numbness and loss of strength in the hands, among other symptoms (Health and Safety Executive, 2014). To prevent the onset of Carpal tunnel or other conditions or injuries, two corrective measures are recommended. One is to provide tools and equipment at the workstations, which minimize worker exposure to hazardous vibration. The other is to limit the duration of exposure to this type of hazard for a given work, which can be achieved, (as with risk due to lifting of heavy materials), by staggering the work assignments so that no particular worker is disproportionately assigned to activities which pose this type of ergonomic risk.

4. Awkward body postures

Awkward body posture is the main ergonomic risk identified in the manufacturing facility. Postures are categorized into five groups (Table 4): (i) back/neck bent forward or shoulder reaching forward; (ii) reaching above shoulder; (iii) back backward bending; (iv) kneeling, crouching/ squatting; and (v) elbow, wrist flex/extension.

</tbody>
</table>

1.1. Back/neck bent forward, shoulder reaching forward

Whenever a worker needs to reach an item at the workstation, their back bends forward and shoulders reach forward. The neck is also strained by installations completed on a flat table. Based on the time study, the frequency of each posture can be obtained and further analyzed with regard to ergonomic risk. There are also various measures that can be taken to correct a worker’s posture. First, the height of the machine, computer, or working table can be adjusted to minimize muscle strain. Due to the varying heights of employees, there is no ideal height for these components. Rather, the ideal scenario is for the heights of these working surfaces to be adjustable to the height of the worker. Such a measure is
beneficial in terms of both health/safety and productivity. A second corrective measure is to locate the workstations as close as possible to one another and the profiles for installation as close as possible to the relevant workstation. Third, providing a lifter or tilter for the hardware container at each workstation can ease access to hardware by workers during installations.

1.2. Reaching above shoulder

For instance, large and long window frame profiles are used in three workstations in the organization, which requires workers to reach above the shoulders, rotating and locating the profiles to the cutting machine. As shown in the photograph in Table 4, the profiles are custom designed. However, due to the fact that the profiles are not placed in the proper position, workers must lift the profiles up and transfer them overhead. The profiles are symmetrically cut in pairs and, as a result, workers must rotate the profiles in the same direction before positioning them overhead. Considering the large number of profiles a given worker will handle at the workstation in a given shift, reducing or eliminating the need for manual overhead transfer or rotation can lower ergonomic risk while significantly improving productivity. This can be achieved through improved inventory allocation and management.

1.3. Backward bending of the back

Backward bending of the back occasionally occurs at some workstations, such as the punching and welding station. For instance, when the foot pedal is too close to the punching and welding machine, the worker must step on the foot pedal while bending backward in order to avoid injury through contact with the machine. However, this posture involves ergonomic risk of back pain. The simplest way to address this issue is to locate the foot pedal away from the machine but close to the worker. Alternatively, a hand-operated button could be programmed to control the operation of the welding and punching machine.

1.4. Kneeling, crouching/squatting

There are also situations that require workers to kneel, crouch, or squat to complete a task. For example, product assembly tasks in the display line must be finished on the ground (refer to the first photograph in fifth row of Table 4 for kneeling posture). Frequent kneeling causes pain and strain in the low back and knees and involves a high risk of developing serious muscle and joint problems. Providing a kneeling mat is the simplest measure to protect workers’ knees. On the other hand, for the glazing task (refer to the second photograph in the fifth row of Table 4 for crouch/squat posture), the tops of small windows and the bottoms of large windows are below the height at which glazing can be completed from a standing position, so crouching or squatting is necessary. Accordingly, the organization should invest in an ergo-auto-lift frame, which not only holds the window during glazing, but also raises or lowers the window automatically according to the comfortable working height for the worker. The same measure can be taken for other cases in which workers are assuming a crouching or squatting posture.

1.5. Elbow, wrist flex/extend

A worker occasionally needs to twist their wrist and elbow as part of a task, which may cause pain and strain. Adjusting the height of the workstation components (i.e., tables, computers, and machines) can help to solve this problem. In addition, as indicated in the photographs, using better-designed pliers, which can themselves bend to a certain degree, will minimize the need to twist the wrist.

4 CONCLUSION, CHALLENGES, AND RECOMMENDATIONS

Ergonomic analysis can be achieved after carrying out plant observation and completing the PDA project. As a result of this initiative, health care personnel in the organization’s health and safety department are better informed about the job requirement and better able to determine proactive measures to mitigate potential risks. It also assists with worker recruitment and allocation. After implementing PDA in the manufacturing plant, modifications can be made in the interest of worker safety and production line productivity.
In the case project, as the project progressed some challenges were encountered, such as some workers’ reluctance to cooperate with the research being carried out. Clarifying with the workers the purpose of the PDA, its importance, and the various potential uses of the PDAs served to overcome this challenge. With respect to the time studies in particular, some limitations of video recorders (e.g., battery life, view angle, etc.) were encountered. Manual observations could thus be used to supplement the video recording observation. Meanwhile, for cases in which the operators are highly mobile and the field of view of the video recorders is not sufficient, manual observation is also used. Alternatively, a video recorder with a wider angle of view enables observers to capture multiple workstations at once.

5 FUTURE STUDY

The paper has proposed a methodology to implement PDA in manufacturing facilities. The project involves plant observation, completion of PDA forms, and ergonomics risk identification with corresponding corrective measures. In future studies, different risk assessment methods can be applied based on the same data collected from the observations in order to improve the accuracy of the ergonomic risk assessment. Moreover, it is recommended that the corrective measures be implemented and another PDA be completed comparing the ergonomic risk reduction between two versions of PDAs. It is also recommended that further investments be made in semi-automated machinery to reduce labour-intensive work and mitigate ergonomic risks.

Acknowledgements

The research team would like to acknowledge the assistance and support of All Weather Windows. The research team wishes to thank Melissa Ristau (Health and Safety Nurse), Estelle Carson (Occupational Health and Safety Manager), and all the production line supervisors who aided in the completion of the project.

Abstract: Transportation is among the highest energy-consuming economy sectors. Therefore, new national priorities and laws passed in the United States in an effort to control the environmental impacts of highway rehabilitation efforts. This created new challenges to planners and decision makers in transportation agencies to optimize, under budget constraints, rehabilitation efforts of aging networks in order to maximize net public benefits while minimizing network energy consumption. This mandates a substantial change in existing ad-hoc and need-based decision-making practices in order to add new criteria to evaluate and measure network energy consumption. Accordingly, this paper presents a new model for planning highway rehabilitation efforts that is capable of identifying near optimal program(s) in terms of maximizing net public benefits while minimizing energy consumption of transportation networks. The new model is designed to: (1) evaluating and measuring the impact of decision making in highway rehabilitation programs on network energy consumption; (2) evaluating the impact of rehabilitation decisions on the cost of travel delays due to highway construction work; (3) estimating the expected savings in road user costs due to the completed rehabilitation efforts; (4) estimating the lifecycle public costs and benefits associated with highway rehabilitation decisions; and (5) optimizing rehabilitation decisions in order to search for and identify the highway construction program(s) that simultaneously maximize public benefits and minimize energy consumption under budget constraints. An application example for a transportation network in South Florida is analyzed to demonstrate the model capabilities and examine the relationship between lifecycle net public benefits and total network energy consumption. The analysis of the application example showed that there is a trade-off between the expected net public benefits and network energy consumption. The new model should prove useful to transportation agencies in identifying rehabilitation program(s) that satisfy public expectations while minimizing energy consumption in transportation networks.

1 INTRODUCTION

Transportation agencies in charge of planning and programming highway repair and rehabilitation efforts face the challenging task of allocating limited funding to an increasing number of competing projects. The American Society of Civil Engineers is forecasting the funding gap is continuing to widen, which will have a direct and significant impact on surface transportation and therefore the United States’ economy (ASCE 2013). Currently, the transportation agencies use ad-hoc and need based approaches to identify and implement their highway repair and rehabilitation programs. For example, rehabilitation programs can be programmed by selecting projects that address roads with the worst pavement conditions and/or highest traffic volume. This approach might not be optimal and leaves ample room for improvement in order to...
include other significant factors to maximize public benefits (Sharaf and Mandeel 1998; Sathaye and Madanat 2011). In addition, the United States government passed a new law, the Moving Ahead for Progress in the 21st Century Act (MAP-21) of 2012, requiring transportation agencies to integrate a number of national goals into highway construction planning efforts (FHWA 2012). Since transportation is among the highest energy-consuming economy sectors with the vast majority of this energy from fossil fuels (EIA 2014), one of the national goals considered in MAP-21 is related to environmental sustainability. This will bring about substantial change to the current ad-hoc and need-based decision making approaches adopted by transportation agencies.

Several research studies focused on planning and optimizing highway rehabilitation efforts. Many of these studies had a single optimization objective focusing on: minimizing construction costs (Chan et al. 1994; Ferreira et al. 2002); and maximizing overall network performance (Wang and Lui 1997). Other research efforts had multi-objective optimization models that focused on: integrating energy consumption, GHG emissions, and construction costs into a single optimization objective (Zhang et al. 2012); minimizing construction costs and maximizing pavement performance (Mathew and Issac 2013); maximizing net benefits while minimizing network service disruption (Orabi and El-Rayes 2011); and minimizing construction costs and GHG emissions (Lidicker et al. 2012). Despite the significant contributions of these research studies, no reported research focused on optimizing highway rehabilitation programs in order to maximize public benefits while minimizing network energy consumption under budget constraints.

In order to address this important research gap, this paper presents the development and implementation of a new model for optimizing highway rehabilitation programs. The model consists of five modules that are capable of (see Figure 1): (1) evaluating and measuring the impact of decision making in highway rehabilitation programs on network energy consumption; (2) evaluating the impact of rehabilitation decisions on the cost of travel delays due to highway construction work; (3) estimating the expected savings in road user costs due to the completed rehabilitation efforts; (4) estimating the lifecycle public costs and benefits associated with highway rehabilitation decisions; and (5) optimizing rehabilitation decisions in order to search for and identify the highway construction program(s) that simultaneously maximize public benefits and minimize energy consumption under budget constraints. The following sections describe these five modules in detail.

Figure 1: Highway rehabilitation programming and optimization model

2 ENERGY CONSUMPTION ESTIMATING MODULE

The main objective of this module is to evaluate and measure the impact of decision making in highway rehabilitation programs on network energy consumption. In order to achieve this objective, energy consumed in transportation networks is categorized into two main types: (1) energy consumed during highway construction operations; and (2) energy consumed during regular operation after the completion of highway rehabilitation works to improve pavement conditions.
First, network energy consumption during highway construction operation is expected to increase, compared to regular operation, due to the reduction in vehicle speed when travelling through construction zones. This reduction in vehicle speed can cause an increase in fuel consumption rate (NCHRP 2012). The change in vehicle speed can also cause the volume of traffic using the road under rehabilitation to change due to some travellers opting to use alternative routes. The total change in fuel consumption during the highway construction operations will also depend on the number of road sections in the network undergoing rehabilitation, road section lengths, and duration of construction operations. In this model, equations 1 and 2 are used to estimate the change in network total fuel consumption due to construction operations, as follows:

\[\text{TFC} = \sum_{r=1}^{R} (V_{W,r} - V_{F,r}) \times L_r \times D_r \times \Delta FR_r\]  

\[\Delta FR_r = FR_{W,r} - FR_{F,r}\]

Where,
- \(TFC\) = change in total network fuel consumption (in gallons) due to construction operations;
- \(R\) = number of road sections in the network;
- \(V_{W,r}\) = traffic volume under work-zone conditions;
- \(V_{F,r}\) = traffic volume under free-flow conditions;
- \(L_r\) = length of road section (r);
- \(D_r\) = construction duration that affects road section (r);
- \(\Delta FR_r\) = change in fuel consumption rate due to construction;
- \(FR_{W,r}\) = fuel consumption rate under work-zone conditions; and
- \(FR_{F,r}\) = fuel consumption rate under free-flow conditions.

Second, the improvement in pavement conditions, as a result of the rehabilitation efforts, will also result in changes to the network energy consumption. In this model, the pavement roughness index (IRI) is used to represent pavement conditions. The IRI of road segments that undergo rehabilitation will decrease after rehabilitation and will therefore cause a significant reduction in energy consumption (Amos 2006) compared to pre-rehabilitation. Equation 3 is used to estimate lifecycle energy consumption in the transportation network over an analysis span of \(Y\) years after rehabilitation. This lifecycle energy consumption takes into consideration the gradual increase over time in IRI and therefore energy consumption. Therefore, network energy consumption is expected to be lowest directly after rehabilitation and gradually increases with time until the network is due for new rehabilitation, as shown in figure 2.

\[\text{TF} = \sum_{y=1}^{Y} \sum_{r=1}^{R} V_r \times L_r \times FR_{N,r}^y \times 365\]

Where,
- \(TF\) = total fuel consumption (in gallons) during operation phase;
- \(Y\) = number of years to new rehabilitation effort;
- \(V_r\) = traffic volume (in terms of AADT) on road section (r);
- \(L_r\) = length of road section (r); and
- \(FR_{N,r}^y\) = fuel consumption rate of road section (r) after year (y) of rehabilitation.

![Figure 2: Impact of rehabilitation efforts on energy consumption](image-url)
3 TRAVEL-DELAY COST ESTIMATING MODULE

The main objective of this module is to estimate the cost of travel delays increased from the expected traffic delay during the construction. Repairing a road can significantly affect traffic conditions on other roads in the highway network. For example, travelers tend to change to a faster route for driving to a destination in order to avoid the disruption that happens in the construction zone. However, this traffic diversion can increase volume in the alternated route and finally exceed the road capability. As a result, all vehicles on the road, including the routine travelers, will be affected from traffic congestion and a lower average travelling speed, which increase travel time. Additionally, travel delays can increase in the construction zone due to speed limit reduction. Therefore, construction is expected to change traffic patterns and increase travel time of all travelers on the highway network.

Equations 4 and 5 represent the estimation of entire travel-delay cost during the construction and change in travel time due to operating speed change, respectively. The cost of travel delays can be estimated from traffic volume, length of road, change in travel time, and unit time value. The last parameter, the predefined value from the user, will convert total travel delays (in hours) to monetary value (in dollars per hour). However, the cost of travel delays in this study was only estimated based on the effect of speed reduction.

\[
4 \quad TTC = UT \times \sum_{r=1}^{R} V_{W,r} \times D_r \times \Delta T_r
\]

\[
5 \quad \Delta T_r = \left( \frac{L_r}{S_{W,r}} \right) - \left( \frac{L_r}{S_{F,r}} \right)
\]

Where,

- \(TTC\) = total cost of travel delay (in dollars) during construction; \(UT\) = unit time value (in dollars per hour);
- \(\Delta T_r\) = change in travel time; \(S_{W,r}\) = average vehicle speed under work-zone conditions; and \(S_{F,r}\) = average vehicle speed under free-flow conditions.

4 ROAD USER COST SAVINGS ESTIMATING MODULE

The main objective of this module is to estimate the expected savings in road user costs from the implementation of rehabilitation programs. This module accounts for the impacts of rehabilitation programs on the road operation phase. Two main components of road user costs are considered, which are: (1) tire depreciation cost, and (2) repair and maintenance costs (as shown in equation 6). However, the cost of fuel consumption is excluded from this module to avoid double counting of the planning objectives in the optimization module. Tire depreciation cost takes into consideration traffic volume, the length of the road section, and variation in tire depreciation rate as shown in equation 7. Tire depreciation rate can be calculated as a result of vehicle speed, vehicle type, and pavement conditions, which is an IRI in this study. The module also takes into account the effect of pavement deterioration over a lifecycle period. As deterioration has impact on pavement conditions, tire depreciation rate tends to increase over time until the next rehabilitation.

Similarly, repair and maintenance costs take into consideration traffic volume, length of road section, and changed rate in repair and maintenance costs as shown in equation 8. This cost rate depends on vehicle type and pavement conditions resulting from deterioration throughout lifecycle. Change in repair and maintenance cost rate can be calculated by comparing the pre-rehabilitation and post-rehabilitation stages.
[6] \( \text{TRS}^{y} = \text{DS}^{y} + \text{MS}^{y} \)

[7] \( \text{DS}^{y} = \sum_{p=1}^{P} V_{p} * L_{p} * (\text{DRI}_{p} - \text{DRN}^{y}_{p}) \)

[8] \( \text{MS}^{y} = \sum_{p=1}^{P} V_{p} * L_{p} * (\text{MRI}_{p} - \text{MRN}^{y}_{p}) \)

Where, 
\( \text{TRS}^{y} \) = total road user savings (in dollars) after year \( y \) of rehabilitation; \( \text{DS}^{y} \) = tire depreciation cost savings after year \( y \) of rehabilitation; \( \text{MS}^{y} \) = repair and maintenance cost savings after year \( y \) of rehabilitation; \( P \) = number of road projects undergoing rehabilitation; \( \text{DRI}_{p} \) = tire depreciation rate of road project \( p \) at pre-rehabilitation conditions; \( \text{DRN}^{y}_{p} \) = tire depreciation rate of road project \( p \) after year \( y \) of rehabilitation; \( \text{MRI}_{p} \) = repair and maintenance rate of road project \( p \) at pre-rehabilitation conditions; and \( \text{MRN}^{y}_{p} \) = repair and maintenance rate of road project \( p \) after year \( y \) of rehabilitation.

5 LIFECYCLE PUBLIC COST AND BENEFIT ESTIMATING MODULE

The main objective of this module is to evaluate the net expected benefits as a result of implementing rehabilitation programs. The calculation employs the concept of lifecycle since the costs and benefits can be found along the lifespan. Figure 3 presents the concept of lifecycle assessment and all related components that are used for calculating the net public benefits in this study, which include (1) cost of travel delays and (2) road user cost savings.

![Figure 3: Expected public benefits of rehabilitation programs](image)

First, the cost of travel delays is the cost incurred from increasing the total time of all travelers on the network. In this study, this cost is assigned by a single value at the beginning of the lifespan (year 0) of the lifespan (see figure 3), as it occurs during the construction stage. The second component is the savings in road user costs, which are the expected cost savings of traveling on the transportation network regarding the improvement of road conditions. It is calculated based on the savings in tire depreciation cost and the vehicle’s repair and maintenance costs in this study. However, the savings are likely to decrease over the time after rehabilitation because the road tends to deteriorate regarding the traffic load and current road conditions. Until the pavement conditions reach an unacceptable threshold, the next rehabilitation is required to keep the road’s better quality.

To evaluate the net public benefits of rehabilitation programs, the concept of net present worth is adopted to calculate the net present value of each component. The discount rate and number of lifecycle year are initially defined by the decision maker. Equation 9 presents how to calculate the net present value of total public benefits for a rehabilitation program.
$$[9] \text{NPV}_B = \sum_{y=1}^{Y} \text{TRS}^y(P/F, \text{ir}, y) + \text{TTC}$$

Where, 
\( \text{NPV}_B \) = net present value of total public benefits; \( \text{ir} \) = discount rate for the public benefit calculation (in percentage); \( \text{TRS}^y \) = total road user savings (in dollars) at year \( y \) after rehabilitation; and \( \text{TTC} \) = total cost of travel delays (in dollars) during construction.

6 MULTI-OBJECTIVE OPTIMIZATION MODULE

The main objective of this module is to optimize highway rehabilitation decisions in order to identify the program(s) that can maximize public benefits while minimizing network energy consumption under budget constraints. To this end, the decision considered in this the module is identifying which projects to select among the competing highway rehabilitation projects. This project selection is constrained by limited rehabilitation funding. In addition, the selection of rehabilitation projects will have a significant impact on the two optimization objectives of: (1) maximizing net public benefits; and (2) minimizing network energy consumption.

The impacts of decision variables on the planning objectives and constraints depend on decision making in project selection. Because of a limitation in financial resources, decision makers are restricted to select only some potential projects from the entire set of rehabilitation projects. In fact, decision making in project selection will have different effects on travelers and the economy since each project has its own characteristic, such as different pavement conditions, traffic volume, and speed limit. For instance, repairing the road with a high traffic volume can save a larger amount of road user costs and energy consumed compared to upgrading a low traffic-volume road. However, a high traffic volume usually requires a high capacity and the road is expected to be a large project. This also requires a higher construction budget. Similarly, improving a high-roughness pavement requires an intensive maintenance and rehabilitation method with a large expenditure. However, it can have a higher saving in road user costs and energy consumption than repairing a low-roughness road.

In this study, an evolutionary algorithm is utilized to solve the optimization problem. NSGA-II, which is the most superior multi-objective genetic algorithm nowadays (Deb et al. 2001), is used to generate the optimal rehabilitation programs to satisfy the planning objectives and constraints. It has proved that NSGA-II is capable of overcoming several challenges in the optimization problem: (1) the multi-objective nature, (2) the nonlinear and non-continuous objective functions, and (3) the large search space. To deal with the constraints, NGPM Version 1.4, which is the recent implementation code of NSGA-II in Matlab, is employed from Song (2011).

The genetic operations of this optimization module are given as shown in Figure 4. The process starts by generating an initial population of random solutions. The population is the set of decision variables that consists of the combination of project selections. In this study, project selection is coded as a binary variable by assigning 1 for selected and 0 for unselected projects, respectively. Then, the fitness functions of each population are evaluated in terms of public benefits and energy consumption. After that, the solutions are sorted based on the fitness values and the best solutions are selected. The genetic operators of crossover and mutation are then performed to generate a new population of better solutions. The steps are continuously repeated for a predefined number of generations or until the error between two successive generations is smaller than a predefined tolerance. The operations then can be stopped and the optimal/near optimal solutions are extracted from the final set of population.
7 APPLICATION EXAMPLE

An application example is analyzed to illustrate the model capabilities in optimizing the highway rehabilitation efforts. The example aims to search for the optimal rehabilitation program(s) that simultaneously maximize total net public benefits and minimize network energy consumption. In this section, the roads in the South Florida’s transportation network are assumed to have rehabilitation needs due to pavement deterioration. The deteriorating roads at ten different locations are hypothetically selected under the limited funding in order to identify the optimal plan(s) that satisfy the planning objectives. Table 1 shows the data for all ten candidate rehabilitation projects. The data include: (1) current pavement conditions in terms of roughness index, (2) traffic volume in terms of annual average daily traffic (AADT), (3) section length, (4) free flow speed, (5) work zone speed, (6) rehabilitation cost, (7) rehabilitation duration, (8) number of lanes in each direction, and (9) total equivalent standard axle load for each project.

In this example, the available funding for the rehabilitation program is assumed to be 35 million dollars. The total benefits are calculated based on a 5% discount rate net present value over a 20-year lifecycle period. All candidate projects are assumed as a rural road with the rehabilitation cost $0.8 per lane-mile (CDTC 2003) for a simple calculation. The rehabilitation durations are estimated by using an average unit time per lane-mile (approximately 5 days per lane-mile) from OECD (2005). The unit cost of travel time ($23 per vehicle-hour) is adopted from Copeland (1998). All rehabilitation costs and the travel-delay costs are adjusted with the customer price index (U.S. Bureau of Labor Statistics 2014) for the analysis.

The result shows the model capabilities of generating a wide set of optimal solutions. These solutions illustrate the trade-off between the two planning objectives: (1) maximizing total net public benefits and (2) minimizing energy consumption. The thirty seven optimal programs were generated as shown in figure 5. The result presents that minimizing energy consumption of rehabilitation efforts can lead to a lowering in public benefits. The trade-off also contains the generated solution of one of the current ad-hoc planning models, which depends on a need-based criteria of pavement conditions, by selecting projects 1,5,6,7,8,9, and 10. This solution provides the highest energy consumption and net public benefits as 144 million gallons and 9.8 billion dollars, respectively (see solution 1). However, the rehabilitation program selected by a high traffic volume, which is another need-based criterion, is not contained in the optimal set. As projects 2,3,4,6,8,9 and 10 were selected, the total energy consumption and public benefits were able to be estimated as 162 million gallons and 6.5 billion dollars, respectively (see solution 2). It is shown that this alternative is dominated by the other optimal solutions. Therefore, selecting projects with a high traffic volume might not be an effective way for highway decision making.
The result can be different from figure 5 if a minimum threshold for available budget is predetermined in the analysis. Under this condition, the optimal solutions will follow the same pattern of trade-off relationship. The number of optimal solutions, however, is smaller for the one with a minimum threshold. As a result, planners and decision makers can adjust their strategies to effectively select the most suitable rehabilitation programs and allocate the remaining funding for other purposes such as transportation safety improvement.

The result can be different from figure 5 if a minimum threshold for available budget is predetermined in the analysis. Under this condition, the optimal solutions will follow the same pattern of trade-off relationship. The number of optimal solutions, however, is smaller for the one with a minimum threshold. As a result, planners and decision makers can adjust their strategies to effectively select the most suitable rehabilitation programs and allocate the remaining funding for other purposes such as transportation safety improvement.
The analysis in this example presents the application and capabilities of the developed model in searching for and identifying the optimal rehabilitation programs under the trade-off between total net public benefits and environmental sustainability maximization. This contributes to provide planners and decision makers with a wide range of optimal trade-off solutions, which can be effectively selected to satisfy with transportation agencies’ conditions and requirements.

8 CONCLUSIONS

In this study, a new model to support decision making in highway rehabilitation programming was developed in order to optimize the net public benefits and energy consumption in transportation networks. The model is capable of: (1) evaluating and measuring the impact of decision making in highway rehabilitation programs on network energy consumption; (2) evaluating the impact of rehabilitation decisions on the cost of travel delays due to highway construction work; (3) estimating the expected savings in road user costs due to the completed rehabilitation efforts; (4) estimating the lifecycle public costs and benefits associated with highway rehabilitation decisions; and (5) optimizing rehabilitation decisions in order to search for and identify the highway construction program(s) that simultaneously maximize public benefits and minimize energy consumption under budget constraints. The application example was analyzed to demonstrate the performance and capabilities of the developed model. The optimization result generates the optimal trade-off between total public benefits and energy consumption for highway rehabilitation programs.

The developed model should prove useful to planners and decision makers in promoting the sustainability concept and simultaneously addressing a public perspective in the planning of highway rehabilitation efforts. However, some further improvements can be extended to advance the capabilities of the model. For example, the optimization decision variables can be expanded to include other types of decision. Not only the decision on project selection but it can also be made to prioritize the competent projects and identify the impacts of different rehabilitation methods on the projects. Future works are planned to expand the optimization scope of the developed model to be more practicable to transportation agencies' decision making processes.

Abstract: Panelization, a form of off-site construction with origins in the manufacturing industry, has emerged as a popular, more efficient approach to constructing residential projects. This approach transfers some of the construction activities traditionally carried out on site into factory production tasks, and divides construction management into factory production management and on-site assembly management. This change poses some challenges to construction practitioners with respect to project planning and management, such as how to efficiently create work flow, balance the production line, and satisfy various panel requirements to ensure smooth on-site operations. This paper thus explores an automated approach for construction planning in the production plant with the objective of improving productivity and balancing the production line, which achieves a seamless integration of building information modelling (BIM) and discrete-event simulation (DES). Specifically, a BIM-based special-purpose simulation (SPS) template for the production line is developed in Simphony.NET in order to facilitate more efficient modelling of the production line. The new simulation template provides a BIM-based interface which permits enriched information exchange between the BIM model and the simulation model. A case study of a production line for light gauge steel panels is presented to demonstrate the methodology. The simulation results show that proper production sequencing improves production performance, and that the newly developed simulation template is a useful planning tool for the panelized construction system.

1 INTRODUCTION

The light gauge steel (LGS) panel system provides a cost-effective building solution for mid-rise multifamily residential buildings. In this panelized construction method, most building components, such as the walls and bathrooms, are prefabricated in the factory and then delivered to the site for on-site assembly. Compared with conventional construction systems or methods whereby the majority of construction tasks take place on site, the on-site work involved in LGS construction is limited to the assembly of factory-built building components, such as wall panels and floor joists. This process thus has the potential to minimize the waste involved in the construction process and enhance efficiency. Nevertheless, due to the large number of components (panels) involved, the success of such projects relies on accurate and reasonable scheduling for the production, shipping, and installation of the panels, and delays in panel delivery or overproduction in the factory can result in project delays and increased inventory costs. More importantly, prefabricated panels are unique and vary in product design features (e.g., length, having windows or doors, having various connections). Panel fabrication is recognized as a low-volume and high-variety product mix production process. Consequently, it is a challenge for construction practitioners to formulate
production plans which can balance the production line, and satisfy various panel requirements to ensure smooth on-site operations. Still, in current practice construction plans are typically planned manually based on practitioners’ experience and intuition, a practice which can be subjective, tedious and error-prone.

Building information modelling (BIM) is an information technology that has the ability to change the Architecture, Engineering, and Construction (AEC) industry in terms of boosting productivity and enhancing communication. Since BIM hosts enriched product information, which is required for planning analysis, it is capable of supporting the automatic generation of construction plans. Meanwhile, a simulation-based approach can be utilized to perform operation-level construction planning due to the fact that discrete-event simulation (DES) can mimic the construction operation logic and investigate the allocation of available resources among activities. Nevertheless, simulation-based planning at present only utilizes limited building information (e.g., quantity take-offs) for planning analysis, and it has yet to take full advantage of the rich product information in BIM models in order to automate construction plan generation. It necessitates a large amount of human judgment and intervention for simulation model development and information exchanges between BIM modeling tools and planning tools. In this case, both BIM and DES in current practice have not yet been leveraged to their full capabilities with regard to construction planning. To address these issues, this paper thus explores an automated approach which achieves a seamless integration of BIM and DES for construction planning in the production plant, with the objective of improving productivity and balancing the production line. More specifically, a BIM-based special-purpose simulation (SPS) template for building panel production lines is developed in Simphony.NET, a simulation engine developed at the University of Alberta (AbouRizk and Mohamed 2000). The new simulation template provides a BIM-based interface which permits enriched information exchange between BIM and DES, and customized simulation elements with specific simulation behaviour that are helpful and more efficient in simulation modelling of the panel production facility. A case study of a production line for LGS panels is presented to demonstrate the methodology. Various production scenarios with respect to panel production sequence are evaluated in the simulation model. The results show that proper production sequencing improves production performance, and that the newly developed simulation template is a useful planning tool for panelized construction. Finally, conclusions are summarized and limitations of the present research are identified with respect to future research.

2 LITERATURE REVIEW

BIM is increasingly being embraced within the architecture, engineering, and construction (AEC) industry to support various tasks, including design/drafting, quantity takeoff, cost estimation, and communication among project stakeholders. Efforts have also been made in recent years to formulate construction plans by leveraging the benefits of BIM. For instance, Kim et al. (2013) developed a prototype for the purpose of automating construction scheduling by parsing an Industry Foundation Classes (IFC)-based BIM model. Liu et al. (2014) proposed an approach to generating on-site scheduling under the constraints of structural support and topological relationships among building elements. Later, Liu et al. (2015) further developed a BIM-based integrated approach of detailed construction scheduling under resource constraints, which achieves an in-depth integration of BIM models with work package information, process simulations, and optimization algorithms. Chen et al. (2013) also proposed a CAD-based framework to yield the near-optimum schedule. The 3D CAD model in their framework, however, only provided quantity take-offs for the process simulation model, with a large amount of human effort and simulation knowledge required to develop the simulation model. Moon et al. (2013) developed a BIM-based construction scheduling method with the objective of reducing activity overlaps. Their main focus with respect to BIM was on visualization and did not support construction plan generation.

DES is able to mimic real-world construction systems based on elaborate computer programming and statistical analysis, and could provide construction managers with insight on construction systems by evaluating various construction scenarios. It thus provides a powerful tool to perform comprehensive analysis for the purpose of productivity improvement of repetitive processes (AbouRizk et al. 2010). Halpin (1977) introduced CYCLONE, a simulation environment, which has created the foundation for the advancement of construction simulation. AbouRizk and Hajjar (1998) proposed a framework for the application of simulation in construction, specifically focusing on construction practitioners. They
presented the concept of special-purpose simulation (SPS), which is a computer-based environment specially built for experts in the area, the advantage of this environment being that the user does not need to have prior knowledge of simulation. AbouRizk and Mohamed (2000) introduced Simphony.NET, an integrated environment to model construction activities. This simulation software supports both DES and continuous simulation and can provide different model outputs, such as standard statistical averages, resource utilization, standard deviation, minima and maxima, and charts such as histograms, cumulative density functions (CDFs), and time graphs. There also have been several studies encompassing the use of DES in various fields of construction, such as bridge construction (Alvanchi et al. 2012), tunneling projects (Al-Bataineh et al. 2013; Ruwanpura et al. 2001), simulation-based production line optimization (Altaf et al. 2014), and SPS for industrial fabrication (Sadeghi and Fayek 2008; Song et al. 2006). Based on these studies, simulation modelling provides a promising means enabling engineers to precisely examine different approaches in order to complete the project. Most of the existing research related to BIM and DES-based planning, it should be noted, has focused on building information extraction from the given BIM model or simulation tool/application. However, the development of a BIM-based simulation tool for construction planning which enhances both enriched information exchanges between BIM and DES and simulation network (construction logic) modelling has not yet drawn much attention within the construction industry. This study thus aims to address these limitations in the existing research.

3 FABRICATION PROCESS OF LIGHT GAUGE STEEL WALL PANELS

Presently, in LGS construction practice, some building components, such as structural bearing walls and staircases, are pre-assembled in the factory and installed on site as panels. Washroom modules each consisting of four wall panels, a floor, and a ceiling (which serves as the floor for the level above), are also prefabricated in the factory, with all other components in the washroom, such as the tub, being pre-installed prior to shipment to the site. This research focuses on the wall panel production line in particular. The production line consists of a series of workstations (as shown in Figure 10) where specific operations/processes are carried out to produce the aforementioned building components. The fabrication process begins with steel studs and plates being assembled together into panel frames at the assembly station, regardless of panel category (exterior, interior, or washroom panel). The assembled panels are then moved to the framing station where a pressing process is carried out by a computer numerical control (CNC) machine in order to form the panel into a rigid frame. Subsequently, framed exterior wall panels are transferred to the sheathing station and nailing bridge for placement and nailing of sheathings; interior wall panels, meanwhile, are moved directly to the vertical panel storage area for shipment to the construction site, whereas washroom panels advance to a modular production line where they are assembled into modules. The exterior wall panels, following sheathing and nailing, go through the polysheild station and the polybase and mesh station, sequentially, in order for polysheild, polybase, and mesh to be applied. Finally, exterior wall panels without windows and doors are sent to the vertical panel storage area, while exterior wall panels which are to include windows and/or doors are transferred to the window and door installation station before they are moved to the vertical panel storage area. The prefabricated washroom modules are transferred to the modular storage area for shipment once they are completed.

4 METHODOLOGY

As described by AbouRizk and Hajjar (1998) special-purpose simulation (SPS) is defined as “a computer-based environment built to enable a practitioner who is knowledgeable in a given domain, but not necessarily in simulation, to model a project within that domain in a manner where symbolic representations, navigation schemes within the environment, creation of model specifications, and reporting are completed in a format native to the domain itself.” Hence, a BIM-based SPS template is developed in this research and is utilized to more efficiently build the DES model of the production line, thereby assisting production managers in planning and managing factory production. In general, the developed simulation template can reduce the manual data entry required and enhance information exchange (e.g., quantity takeoff and building design features) from the BIM authoring tool to the SPS model, capitalizing on the developed BIM model parser and the new simulation element “Input” in the proposed simulation template (see Figure 1 and Figure 4). The developed BIM model parser can extract
enriched building information from the BIM model and generate simulation entities in an XML file, while the “Input” simulation element can automatically take the enriched and detailed product design information extracted in the form of an XML file as inputs for the simulation model. In addition, other parameters for the production line, such as Capacity of Station (see Figure 6 and Figure 7), are customized as inputs of simulation elements. Icons of the simulation elements match the production line icons with similar functionality for the purpose of facilitating understanding of the simulation models built from this template among construction practitioners. Furthermore, even construction practitioners who do not have a strong familiarity with simulation can develop DES models of production lines in order to mimic the production processes and to perform “What-If” analyses before actual implementation. More detailed explanations with respect to modelling elements are presented in the following sections.

![Figure 1: Overview of proposed methodology](image)

5 SPECIAL-PURPOSE SIMULATION TEMPLATE ELEMENTS

Simphony.Net (AbouRizk and Mohamed 2000) is selected as the simulation platform to build the proposed SPS tool. Six simulation elements—task, input, station, equipment, entity router, and storage—are developed to mimic the factory production processes for panelized building projects.

5.1 Simulation Entity

In the production line, product features (i.e., design parameters) of building components such as length, height, number of studs, number of windows, number of doors, and sheets of sheathing affect the processing time at each station. The functionality of building components such as exterior, interior, structural, non-structural and partition of building components determines the construction processes these components go through. Rich building information, including the aforementioned information, is embedded into building components (parametric objects) as their attributes or parameters in the BIM model (an assembly of pre-defined 3D building objects). Similar to parametric objects in a BIM model, the object-oriented concept can also be adopted to design simulation entities in the new SPS template. (Simulation entities used in most DES engines, including Simphony are capable of representing semi-products or materials traversing the simulation model.)

In order to mimic the fabrication process, simulation entities in the newly developed simulation template are customized to represent building components (parametric objects in the BIM model) that carry detailed design information from the BIM model as attributes, and move through the DES simulation model. These entities will be processed and guided in the simulation model in accordance with detailed design information. For instance, simulation entities will go through different stations based on panel functionality (e.g., exterior or interior). As such, the integration of a BIM product model and a DES model is realized by enriched information entities, which extract rich building product information of building components from BIM and traverse through the simulation model. Figure 2 shows the entity relation diagram of simulation entities representing building components. As depicted in the figure, all the information denoted by solid circles in Figure 2 is extracted from the BIM product model, while the attributes in the dashed-circles are generated by the simulation model. It should be noted that “opening” information and “panel framing” information (in relation to number of windows and number of studs) are listed under the “SubComponents” attribute.
The BIM model in this research is developed in Autodesk Revit. The in-house Revit add-on is developed to parse BIM models, to extract the enriched building information, and to assign it to the simulation entities. Simulation entities with enriched product information are then stored in an XML file, which is the input for the developed simulation model. Figure 3 shows a screenshot of a sample XML file.

Figure 3: Sample of simulation entities with building information in XML

### 5.2 Input

The input element reads enriched building information and regenerates simulation entities (building panels) in the simulation model. One property of this element is "BIMXMLAddress", which enables users to specify the address of the XML file generated from Autodesk Revit. Once the simulation is triggered, the input element will read this XML file and release simulation entities into the developed simulation model. Figure 4 shows properties of the input element. As noted in the figure, the input has another property, “SequenceRule”, which allows users to specify the sequence rule of simulation entities being released in order to determine the panel production sequence by writing their own scripts. Simulation entities carrying enriched building element information are transferred out from this element sequentially and traverse through the simulation model to mimic the panel fabrication processes.
5.3 Atomic task

A task element is the most basic simulation element, and it is utilized to simulate an atomic operation or process in construction. It is designed based on the process modelling ontological concept, which refers to the actors involved in the various processes of a project (El-Diraby et al. 2003). As a result, simulation entities representing building products request construction resources to trigger the task/operation, and these entities are held for a specific duration. Upon completion of the operation being simulated, simulation entities are transferred out from this element. The inputs for this element, as shown in Figure 5, include duration and required resources. Notably, a task element can be connected to multiple task elements in order to mimic the operations being executed concurrently (see Figure 10).

5.4 Station

As described above, the production line consists of several work stations where specific fabrication operations or tasks take place. In this context, a station element is developed to represent each work station. A station essentially represents a process which can be divided into more detailed sub-processes or sub-tasks. Consequently, the station element is designed as a “Composite” element, which allows users to place as many task elements as desired inside the station element. To start the operation in a station element, simulation entities (building product elements) need to be granted their requested construction resources (e.g., stationary machines). Once the requested resources are available, and provided the station's capacity is sufficient to accommodate the coming simulation entities, these simulation entities are transferred into the element and kept inside until specific operations/tasks are completed. It is important to note that a work station has capacity limitations and cannot process unlimited simulation entities simultaneously. In addition, various stations have different measurements (e.g., panel length or height) for a given production capacity. In this regard, the station element shown in Figure 6 is customized to provide users an opportunity to define capacity and capacity units in order to mimic the production flow. This element can also collect the statistics data of cycle time, utilization, and waiting time for work stations. These statistics are shown graphically and can be used to assist production managers to manage and to balance the production line, and to improve productivity using lean principles.

5.5 Equipment

In addition to stations, various equipment (e.g., overhead crane) is commonly adopted in the prefabrication production line. Similar with work stations, equipment also has capacity limitations and is utilized to perform defined operations and tasks; however, the capacity works differently for equipment. The work stations process panels or semi-products immediately as long as panels arrive at the station provided that the station has sufficient remaining capacity to perform the operation. When the station reaches its full capacity, panels cannot enter the work station and must wait until some panels are released from the station. In this respect, crane operation differs in that it usually does not carry out its operation (e.g., lifting) until it reaches its full capacity. Furthermore, the operation of the crane is performed on batched semi-products (simulation entities). Once the specific operation is completed, the batched semi-products are un-batched and transferred out to the next operation. Another
interesting scenario is when the crane cannot reach its full capacity even if it takes all semi-products in queue. In this scenario, the crane can start the lifting operation without attaining its full capacity. In order to simulate the crane operation, the equipment element is developed. In addition to capacity and unit properties, the element has another two properties—“HavetoBeFull” and “WaitingTime”. If “HavetoBeFull” is set to true, the equipment cannot start the operation until the full capacity is attained. If “HavetoBeFull” is set to false, “WaitingTime” can be further specified to determine the amount of time the equipment waits for the coming simulation entities before the operation is triggered. Figure 7 presents the inputs of the equipment element.

5.6 Entity router

Due to the fact that panels vary in design features, such as IsExterior and HasWindow, they will go through various work stations. Simulation entities thus need to be routed into the correct stations based on the enriched design information they carry. An entity router element is thus developed to solve the simulation entity routing problem. Figure 8 shows the inputs of this element. In this simulation element, the user can specify the routing rules in “RoutingConditionList”, which is a collection of the next stations or tasks to which the simulation entity should be transferred, along with the condition that should be satisfied in order to send the simulation entity to the station. It should be noted that this element routes simulation entities in accordance with the routing conditions list, rather than connecting them with other simulation elements using directional arrows (as shown in Figure 10). This simplifies the graphical representation of a simulation model for the case in which simulation entities require various unique routes through the production line.

5.7 Storage

The storage element represents the storage area where finished panel products are stored for shipment to site. All simulation entities are finally transferred into the storage element in the simulation model. The main purpose of this element is to collect the statistical data for the total cycle times of the panels. The simulation result recorded into simulation entities as shown in Figure 2 is also written into the XML file by this element.

6 CASE STUDY

The newly developed SPS template was tested in an LGS wall panel production facility for residential buildings. The building shown in Figure 9 is composed of two storeys, each comprising four apartment units, one staircase, and two washrooms. In addition, there are 182 panels, including 60 non-bearing walls and 122 bearing walls. The building rests on 29 concrete footings. The building model is initially built in Autodesk Revit 2014, the building design information is extracted into simulation entities using an in-house Revit add-on, and then the simulation entities with enriched product design information are stored in an XML file. The simulation model can subsequently parse the XML file directly and release all simulation entities into a simulation network via the “Input” simulation element. This template significantly
reduces the effort required compared to preparing the simulation input manually, due to the enhanced information exchange between the BIM model and SPS model. Meanwhile, the simulation template speeds up simulation modelling of the panelized building production line by using customized simulation elements. Figure 10 presents the simulation model of the panel production line described in the previous section. As shown in the figure, the prefabrication process for the Window and Door Station can be further divided into several sub-tasks. In this case, a few task elements are placed inside the Station element in order to simulate the window and door installation process. Also, it should be noted that there are two parallel branches for window and door installation. This exemplifies the fact that some sub-tasks can be executed concurrently, as long as the required labour resources are available. Windows and doors can be installed simultaneously, and their respective processing times are different.

Figure 9: 3D view and framing view of a two-storey panelized residential building

6.1 Processing Time Prediction

As described earlier, the process time is affected by the detailed design information about the panels. In the simulation model, process equations are inputted into the Task element (inside the “Station” element) in order to calculate the process time. For instance, the below equation is used to calculate the process time of the panel assembly operation (Altaf et al. 2014; Shafai 2012).

\[ T_{A} = \sum_{i=1}^{N_{ST}} T_{ST} + T_{BP} \times N_{BP} + T_{TP} \times N_{TP} + T_{W} \times N_{W} + T_{D} \times N_{D} + V \]  

Eq. (1)

Where \( T_{A} \) is the process time of the assembly station; \( T_{BP} \) and \( T_{TP} \) are the times, in seconds (s), needed to place each top and bottom plate, respectively; \( T_{ST} \) is the time needed to place a single stud; \( T_{W} \) is the time needed to assemble studs for each window; \( T_{D} \) is the time needed to assemble studs for each door, \( N_{BP} \), \( N_{TP} \), \( N_{ST} \), \( N_{W} \), and \( N_{D} \) are the numbers of subcomponents in the framing component, and \( V \) denotes variation for the assembly process and is assumed in this research to be a triangular distribution.

6.2 Simulation results

The simulation template and developed simulation model are verified by tracking the chronological list and observing the panel cycle time. Figure 11 presents cycle times of wall panels, denoted as “observation”. As shown in Figure 11.a, there are eight peak values for the cycle time, since the test project has eight similar units and wall panels are produced unit-by-unit. For each unit, wall panels are produced in descending order of panel length. In this sequence, the total production duration is 697.98 minutes. Alternative production sequences, such as level-by-level, are also evaluated in the simulation model, and all the production durations are found to be approximately 700 minutes, with the exception of the scenario in which all panels are produced in ascending order of panel length, in which case the duration is found to be 826.63 minutes. This is due to the fact that in this scenario exterior walls are started later than interior walls because they have a greater average length; however, exterior walls also take more time to produce (as demonstrated in Figure 11.a and Figure 11.b). As a result, the concurrent execution of assembly and framing station of Interior wall panels with sheathing and succeeding workstations of exteriors wall panels leads to reducing overall production duration.
7 CONCLUSIONS AND FUTURE WORK

This research focuses on a BIM-based SPS template for a panel production line. A set of new simulation elements in Simphony.Net 4.0 is developed to speed up simulation modelling of the panel production line. This new simulation template can enhance simulation modelling in two aspects: (1) enhanced information exchange via object-oriented simulation entities, which mitigates the need for massive manual inputting; and (2) customized simulation elements with specific simulation behaviour, which are helpful and more efficient in simulating the production facility and mimicking the prefabrication process. This new simulation template thus enables construction practitioners who do not have a strong familiarity with simulation to develop DES models of production lines in order to perform “What-If” analyses before actual production. The simulation template has been tested using a case study of a production line for LGS panels. Various production sequences have been evaluated in the developed simulation model. The statistical data of cycle time, utilization, and waiting time for work stations are represented graphically and provide construction practitioners insights on production performance. On this basis, construction practitioners can plan and manage the production line using lean principles. The developed tool is demonstrated to be...
helpful for assisting in the planning and management of the production line. In the next stage of research, the template will be further validated and applied to other building panel production lines. Also, data mining technology such as Artificial Neural Network (ANN) will be integrated into the proposed simulation template in order to predict operation process time based on historical data.

Abstract: Construction incidents have numerous root causes, but one of the most frequent is worker behavior. Therefore, construction safety management systems should be designed to maximize the number of safe behaviors by workers, and focus on the execution of construction safety management to achieve excellent safety performance. Operational excellence, a safety concept from the chemical processing industry, is defined as doing the right thing, the right way, every time – even when no one is watching. Good operational excellence results in effective reinforcement of appropriate safety systems, and significantly reduces the rate of unsafe behaviors. Researchers managed to embed the concept of operational excellence into construction safety management. Through an extensive literature review, discussions with industry experts on the topic, and subject matter expert validation, the researchers have developed an operational excellence model designed to evaluate and improve safety performance for construction organizations. This paper describes the model development process and the key elements included in the Operational Excellence Model (OEM). The primary contribution to the overall body of knowledge is developing a practical operational excellence model for practitioners to assess and improve safety performance through behavioral and cultural elements.

1 INTRODUCTION

Despite significant reductions of incidents on construction sites in the past several decades, the injuries and fatality rates for construction workers are still higher than other industry sectors (Bureau of Labor Statistics, 2011). Many safety researchers hold a perception that inherent reasons must exist in the construction industry, which are responsible for the poor safety situation on the jobsite (Davies and Tomasin, 1990). Unsafe behavior during the execution of work is considered as an inherent reason, which causes a majority of construction incidents (Tariq et al, 2000; D.-C. Seo, 2005). Many statistical analyses of incident reports conducted in multiple countries found that almost 90% of the incidents can be attributed to unsafe behaviors or human errors (Salminen and Tallberg, 1996; Williamson and Feyer, 1990; Lutness, 1987; D. Chen and H. Tian, 2012). A conclusion can be made that unsafe behavior is the primary direct cause for the construction incidents. However, other researchers go further to explore the inherent reason behind unsafe behavior. Many unsafe behaviors can be attributed to poor construction safety culture. This idea is widely supported by many researchers (Brown et al., 2000; Oliver et al., 2002; Petersen, 1988; Tomas et al., 1999).
Poor safety culture and unsafe behaviors are both drivers of poor safety performance. Operational excellence involves cultural and behavioral constructs. Operational excellence is a concept proposed by the chemical processing industry, which is based on the philosophy that excellent operation leads to excellent safety performance. Operational excellence is defined as doing the right thing, the right way, every time – even when no one is watching. Good operational excellence results in effective reinforcement of appropriate safety systems, and significantly reduces the rate of unsafe behaviors. To achieve operational excellence, a culture dedicated to excellence must be established. Culture exists as an implicit concept that drives tangible safe behaviors. Safe behaviors generate an authentic and lasting effect on the organization, which in turn sustains and promotes the safety culture.

The primary purpose of this research is to develop a safety model involving both cultural and behavioral elements. Operational excellence is the outcome of the model, which in turn, should improve safety performance. The essence of the model is that culture drives behavior and behavior sustains culture (Maloney, 1989). Through an extensive literature review, discussions with industry experts on the topic, and subject matter expert validation, the researchers have developed an operational excellence model designed to evaluate and improve safety performance for construction organizations. This paper describes the model development process and the key elements included in the Operational Excellence Model (OEM). The primary contribution to the overall body of knowledge is developing a practical operational excellence model for practitioners to assess and improve safety performance through behavioral and cultural elements.

2 OPERATIONAL EXCELLENCE

2.1 Definition of Operational Excellence

Operational excellence is a buzzword that is commonly used across various industries when addressing improvements in production, safety, quality, and cost performance, yet it is often ill defined. The fundamental idea of operational excellence is that perfect operations lead to perfect results.

Operational Performance Systems (OPS), a management consulting company, defines operational excellence as “the performance of tasks according to written expectations, policies and procedures in a safe and professional manner” (Philip, 2013). In other words, operational excellence is about creating a written standard and applying that standard rigorously and consistently across the organization.

Another view is that operational excellence should be separated into organizational level and individual level components. The definition of organizational level operational excellence is “the deeply rooted dedication and commitment by every member of an organization to carrying out each task the right way, each time” (Klein et al., 2011). The definition of the individual level is “commitment to working safely by doing every task, the right way, every time” (Klein et al., 2011). In other words, there is commitment by the members collectively as an organization to do it the right way, every time and individually in their own work practices.

Based on these definitions, the aim of operational excellence is to achieve exceptional performance through the engagement of all members in the organization to do the right thing, the right way, every time – even when no one is watching. Hence, determining the “right thing” and the “right way” is imperative, and those are the elements that are identified and validated in this paper.

2.2 Previous Operational Excellence Research

Prior researchers utilize characteristics to describe and embody the makeup of operational excellence. Dennis Johnson (2005) compiled a set of 10 characteristics to represent operational excellence in the context of the oil industry. Brian D. Rains (2012) identified a set of 11 characteristics. James A. Klein and Bruce K. Vaughn (2008) set up an operational excellence framework consisting of 11 characteristics. Both of these models were developed for the safety improvement of chemical processing industry. Robert J. Walter (2002) proposed a more comprehensive version consisting of 15 characteristics. However, it is also designed for the chemical processing industry and the oil exploration and refining industry.
The extensive literature suggests that a lack of research on operational excellence exists, especially in the context of the construction industry. Due to limited resources, developing OEM will take a great effort to identify, categorize and examine elements associated with the construction industry.

3 METHODOLOGY

The critical elements of OEM are identified through an extensive literature review. Efforts mainly focus on previous research and professional guidance by industry association. To verify these elements, subject matter expert validation is conducted through questionnaire survey and statistical analysis.

3.1 Framework of OEM

As aforementioned, this research aims at developing a model that can be used by practitioners to assess and improve safety performance through behavioral and cultural elements. However, the previous characteristics of operational excellence were compiled by other industries, and therefore have limited applicability to this OEM designed for construction projects. After discussion by the research team, the Critical to Quality (CTQ) tree was chosen as the tool to develop measurable characteristics, which arise from the six sigma methodology (Aristide et al., 2013). CTQ trees are used to decompose broad research objectives into more easily quantified elements.

The OEM must be developed into clear, specific, quantitative requirements, so that it can be used by practitioners as an effective and practical tool. In the context of construction safety, these quantitative requirements are called Critical to Safety characteristics (CTSs). CTSs are the measurable safety characteristics that are considered important to sustain and promote construction safety.

The model was structured as a Critical to Safety Tree. The model has four levels: Safety Driver (SD), Critical to Safety (CTS), Critical to Expectations (CTX, X indicates various expectations), and Specification/Measurement (S/M).

SD indicates the factor that will be used to evaluate the performance of the safety program. CTS indicates elements of the driver, which corresponds to “the right thing” in the definition of operational excellence. CTX indicates behaviors and/or processes used to provide the elements, which corresponds to “the right way” in the definition of operational excellence. S/M indicates a quantitative measurement of the CTX, which corresponds to “every time” in the definition of operational excellence. Generally speaking, the four levels model represents the essence of the operational excellence: focus on doing the right thing, the right way, every time – even when no one is watching. However, the important piece of the “even when no one is watching” is not directly measured. The approach to this issue is to embed safety culture into the whole model. Culture drives behavior and behavior sustains culture. Through the rigid execution of operational excellence, the number of unsafe behaviors will be reduced and the safety culture will be reinforced. Once the safety culture is embedded into every member’s mind, the goal of “even when no one is watching” will be achieved. Consequently, CTS trees based on operational excellence will serve as the framework for the OEM.

3.2 Identifying and Categorizing the Elements of OEM

To identify and categorize the elements on each level, the research team employed three main resources:

- Previous relevant research;
- Documentation from industry associations and government; and
- The expertise of the research team.

A preliminary list of SDs was developed by the use of documentation from past research and publications, which constitutes the first level of OEM. Starting from these SDs, further development of CTSs, CTXs and S/M were conducted, and a complete and detailed list was developed. However, the original version was roughly categorized, which causes the overlapping between different characteristics.
During multiple meetings, research team members rigorously examined and refined the list through brainstorming and nominal group technique. Finally, an improved list of OEM was developed. It has 13 SDs, and each of those SDs represents a major aspect of construction safety (see Table 2 Column 2). From these 13 SDs, 75 CTSs that may have a bearing on operational excellence are identified (see Table 2 Column 2). And then 256 CTXs, and 293 S/Ms were also developed. For CTSs and CTXs, they are listed as a complete phrase or sentence, which ensure consistency of the understanding. S/Ms are ways to quantifiably measure a level of performance.

The thrust of the research team is to conceptually validate the OEM at the SD and CTS level. Therefore, the validation results that follow focus on those two levels. Future research efforts will collect data against the entirety of the model.

3.3 Validating the SDs and CTSs

Subject matter expert validation of the SDs mainly focused on determining the relative degree of significant contribution that each SD makes to operational excellence in construction safety. Researchers also obtained professional views on whether each CTS is suitable to its corresponding SD. Validation was conducted through a questionnaire survey.

For each of the SDs, participants are asked to evaluate their level of agreement with the statement that this SD is significant to operational excellence. Detailed descriptions are attached to each SD to help ensure participants’ understanding of the SD under review. The average value will be computed as the final score for each SD. Respondents are required to rate significance of contribution on a 5-point scale where 1=Disagree, 2=Neither Agree nor Disagree, 3=Slightly Agree, 4=Agree, and 5=Strongly Agree.

In the case of CTSs, participants are asked to evaluate the importance of each CTS to developing and understanding of its SD. The average value will be computed as the final score for each CTS. Respondents were requested to rate importance on a 5-point scale where 1=No importance, 2=Little importance, 3=Some importance, 4=Moderate importance, and 5=Great importance. This Likert scale is skewed intentionally. The researchers had a concern that a traditional Likert scale would not show variability in the responses, since many of the items are based on previous literature and unlikely to have high levels of disagreement.

4 DATA ANALYSIS

Data collection is performed through the use of Select Survey’s server-based software. Most of the participants are experienced practitioners. This online survey system is designed to provide researchers credible data and facilitate research. A total of 92 surveys were initiated, but not all were completed. Each question had a minimum of 60 responses. All responses for each question were included.

4.1 Characteristics of the Organizations

Respondents were asked to provide demographic information on their organizations. Organization characteristics are shown in Table 1. Most companies have participated in national or even international projects and conducted construction-related work. Types of projects they participate in cover almost all construction sectors.

4.2 Results of the SDs and the CTSs

Two criteria are developed to examine the subjective opinions from experts. The first criterion is a threshold value of 3.50 for all mean values. Three from the 5-point scale means “some importance” or “slightly agree”, a mean value higher than 3.50 indicates that experts agree with the importance of the item to the construction project safety. The second criterion is comparing the percentage of responses higher than 3 with 80%. If the percentage is higher than 80%, it means more than 80% of experts agree that this item is important to the construction project safety. Mean values are given in column 3, and the percentage of response higher than 3 is presented in column 4. The results of the survey can be seen in Tables 2-14 for each safety driver.

5 DISCUSSION

Every SD has a mean value higher than 3.50 and a percentage higher 80%. This result means most experts agree that those SDs significantly contribute to the operational excellence in construction project safety. The validation of the SDs lays a solid foundation for the development of CTSs.

Each of the CTSs have a mean value higher than 3.50. Most of CTSs have a percentage higher than 80%, except symbols (69.39%), utilizing posters and newsletters (61.22%), evaluating safety information flow (69.39%), and participation in behavior observation surveys (BOS) (74.47%).

Symbols do not convey detailed information, compared to other CTSs under Shared Values, Beliefs, and Assumptions. This is the reason for its low importance. Utilizing posters and newsletters is not specifically-targeted, and employees lack incentives to check things not exclusively delivered to them. This is why experts assign a lower grade to it. Evaluating safety information flow has a relatively higher mean value of 4.06, but a relatively low percentage of 69.39%. That indicates that there is a diverging opinion among experts. Safety information flow is a foreign concept for construction industry. Experts with a lack of knowledge of this concept would tend to reduce its value. Participation in behavior observation surveys (BOS) also has a relatively higher mean value and a relatively low percentage. The divergence of expert opinions exists. Some experts think BOS is not the owner’s work, others think it is. The disagreement on the owner’s role in safety management leads to the lower percentage.

The CTSs that did not meet the criteria were deleted from the model. Thus, the remaining contents describe a conceptually validated model of operational excellence for construction project safety. Future work will collect data to measure the impact that operational excellence has on construction project safety.

6 CONCLUSION

This study investigated the concept of operational excellence in the context of construction project safety, and developed a practical operational excellence model for practitioners to assess and improve safety performance through behavioral and cultural elements. 13 SDs and 75 CTSs were identified through an extensive and thorough literature review. To validate the applicability of the SDs and the CTSs, a subject
matter expert validation process was conducted through an online survey. Results of the SDs shows that each of the SDs has a mean value higher than 3.5, and more than 80% of experts score them with 4 or 5. This proves that experts significantly agree the contributions made by the SDs. Each of the CTSs have a mean value higher than 3.50. Except for 4 CTSs, the remainders have a percentage greater than 80%. This proves that experts significantly regard the CTSs as important for the development of the SDs. The subject matter expert validation results provide solid evidence for the validity of the OEM.

SIMULATED SCHEDULE DELAY MITIGATION VIA FLOAT ALLOCATION

Gunnar Lucko¹ and Richard C. Thompson, Jr.¹
¹ Department of Civil Engineering, Catholic University of America, Washington, DC, USA

Abstract: As delays in construction project schedules are widely documented, new approaches to manage this problem are needed. Previous studies have explored float as an inherent ability of schedules to absorb delays. However, all ignore the critical path; some recommendations as to float ownership directly contradict the inherently unfair ‘first come first serve’ principle; and none have derived testable methods to fairly allocate float to multiple participants. This study therefore employs the mathematical analogy of decision-making among a group of unequally sized individuals to explicitly allocate project float a priori to those most vulnerable – the critical path. While intuition might indicate allocation proportional to activity duration, or perhaps equal shares, it is demonstrated that neither is truly fair and a mathematical compromise can be found. The performance of this approach is tested quantitatively by simulating a case example of project schedules with and without such protection. Delays are modeled as probabilistic events that affect activities. It is found that even a relatively small amount of project float allocated along the critical path provides significant delay mitigation.

1 INTRODUCTION

Construction project schedules in many countries unfortunately are frequently inundated with delays (Gündüz et al. 2013). Delays in this research are defined in a strictly temporal view, i.e. negative changes of start and/or finish of activities between the as-planned and as-updated project schedules. What makes delays particularly perilous is the fact that they are not an isolated local phenomenon within schedules, but may initiate a cascading set of ripple effects in later activities that depend on the earlier delayed one. Whatever the diverse causes of such delays are, which may stem from one or several risk factors that are materializing (González et al. 2013), is less relevant to this discussion than the unfortunate outcome, that it becomes likely that the contractually agreed turnover date will be met, i.e. the entire project will be late.

Contractual effects of late completion typically are that the contractor is required to reimburse the owner for consequential cost (liquidated damages) of postponed occupancy of the new facility, which often leads to further side-effects, e.g. protracted court cases over liability that may damage the reputation and lose future clients. The central question remains not one of identifying and treating symptoms, but of curing the cause: What inherent defenses does a project schedule have against incurring delays? Such capabilities could take two forms, either preventive (lowering the probability of a delay occurring) – akin to inoculation; or reactive (gaining better means of alleviating a delay that occurs) – akin to therapeutics in medicine.

To begin answering this question, this research will first review existing theory of project management regarding conceptual limitations of traditional scheduling and opportunities for protecting against delays, then explore potential theory in decision-making from which inspiration for such resilience will be gleaned.
2 LITERATURE REVIEW

2.1 Scheduling Assumptions

Construction schedules are traditionally conceived and handled as networks, which mathematically are acyclic ‘graphs’ (Chen et al. 2001) that consist of nodes (activities) and arcs (links) between them, whose direction is dictated by the passing of time. Exploiting a rather simple and repetitive structure of relations of temporal data among activities led to the so-called critical path method (Kelley and Walker 1959) with which dates are sequentially calculated: Within activities, adding the duration to its start gives its finish \((S + D = F)\). And between activities, all successors must finish as a condition for the successor to start \((max \{F_{\text{pred}}\} = S_{\text{succ}})\). This forward-looking calculation assumes the best case that all activities start as early as possible at their earliest \((E)\) dates. Its inverse, the backward-looking calculation assumes the worst case that they start as late as possible at latest \((L)\) dates, so as to just not yet delay the project finish itself.

Comparing these two scenarios gives information for each activity on how much it can be delayed without impacting (a) any successor (free float, \(FF_{\text{pred}} = min(E_{\text{succ}}) - EF_{\text{pred}}\), or ‘only’ (b) the project finish (total float, \(TF = LF - EF = LS - ES\)). Thus float is defined by an assumed delay. Due to the aforementioned vital importance of the project finish for contractual liability purposes, this research will focus on the total float. Float in the literature has been presented as the opposite of importance of the project finish for contractual liability purposes, this research will focus on the total float.

Hidden assumptions also lie in the inputs to such analysis, notably links and durations. Links (or schedule ‘logic’) are primarily determined based on technical reasons per laws of physics, but may also be modified for administrative reasons or even to artificaly generate opportunities for success or failure (Zack 1992). This research assumes that links are fixed. Durations are determined based on work quantity as taken off plan drawings and specifications, combined with the crew choice and their unit productivity. However, one must consider that forecasting durations is always loaded with uncertainty. While studies have explored distributions to provide realistic durations for probabilistic scheduling (Khamooshi and Cioffi 2013), project managers in the construction industry have not been oblivious to the need for realistic duration estimates as opposed to overly optimistic ones. In practice, how well it is accomplished depends on the expertise of individual project managers, who determine ‘raw’ durations (from productivity data) and empirically extend them to ‘realistic’ ones by including a contingency (Barraza 2011). Contingency refers to both time or cost (Xie et al. 2012), but here it means additional time. This research assumes that raw durations are known to a user of this new approach, here presumed to be the general contractor. Studies have explored how contingency aids in company performance (Deng and Smyth 2013). It “has been used in project planning to cover activities delays, oversights, and unknowns and as a cushion for possible time-estimating errors” (Barraza 2011, p. 259). Since time contingency is essentially float, it will be referred to as such for clarity. The nature, quantity, and most beneficial distribution of such contingency, or float, will be explored next.

2.2 Criticality Paradox

Whereas risk has been explored in detail, with many studies listing risk factors and how to rank or weigh them, often using survey methodologies (e.g. Tran and Molenaar 2012), its realization in form of delays has been studied primarily to create numerous competing or even contradictory approaches to distribute liability between owner and contractor (Yang and Kao 2012) after excusable delays have been forgiven, i.e. assigning blame, and pondering the vexing issue of concurrent delays (Ibbs et al. 2011). However, a posteriori analysis, while unfortunately necessary, is not even reactive, but merely inculpativ. In other words, delay liability appears has been the focus rather than delay mitigation or, even better, avoidance.

Rephrasing the definition of criticality as ‘an inability to absorb delays’ reveals that it is based upon an assumption itself, that activities in network schedules will necessarily have unequal capabilities to handle delays. However, schedulers control the manner in which activities are linked in network schedules (Zack 1992), so that criticality is essentially an artifact of the schedule itself. Criticality as it is currently defined
for critical path method is not an inherent quality of the activity based on its nature or risk, although this fact is often hidden, because long or difficult activities often actually turn out to be part of the critical path.

Artificially dividing activities into being critical or not by whether or not they have total float in fact creates a paradox (Thompson and Lucko 2012, p. 488): “By definition, noncritical subcontractors have float, but the critical ones have none, even though they need it most.” Such two classes, of which critical activities are designed to be on the verge of failure, run counter to what should be the optimum goal of a scheduler: Creating a schedule that attempts to minimize the overall risk level (or probability of local delays affecting any successor) of its activities by giving each the amount of float that it actually needs. In other words, this approach will advocate for a schedule that does not contain a ‘critical path’ in the traditional definition.

2.3 Float Ownership

Although a notion of overcoming the well-established concept of a critical path may sound ambitious, it is not out of line with project management in practice: Project managers already attempt to set contingency by considering which of the various activities ‘needs more time’. However, this is performed empirically by “subjective management of the project time contingency” (Barraza 2011, p. 260), influenced by various factors, including the contract type that is used (Smith and Bohn 1999), but lacking any rigorous scientific foundation. Thus realism and quality (in terms of predictive ability) of a schedule depend to a large degree on such an individual’s expertise. Quantifying and formalizing this wisdom is the purpose of this research.

If float can mitigate delays by being consumed, then it becomes a commodity with potential value to the project participants (de la Garza et al. 1991). A question naturally arises, who owns float? In practice the ‘first come, first serve’ approach of using float appears to prevail (Pasiphol 1994), which underlines the urgent need of a mathematical approach that is derived from a testable hypothesis. A multitude of studies in the literature has discussed float ownership, which continues to be contentious and unresolved. Among the arguments were that float should belong to the owner, who pays for a project, or the contractor, who is responsible for its schedule (Al-Gahtani 2006), and suggestions to share or split it (Prateapusanond 2003), but without any details on how it could be fairly and equitably accomplished. Splitting this Gordian knot once again can be achieved by rephrasing the initial question to overcome its implicit assumption: Who among the project participants should be allocated float, and how much? The dichotomy of owner and general contractor is not central to resolving this question, because in many cases the individual activities are performed by specialty subcontractors. As Al-Gahtani and Mohan (2007 p. 33) supported, float should be allocated by “linking the ownership with the party who carries the risk”. Subcontractors, being productive agents who perform the schedule activities, will therefore be the focus of this research.

2.4 Fair Allocation

The final step in the logical argument pertains to the question of how much? This is fundamentally an allocation problem, where float takes on the role of a valuable but limited commodity and subcontractors are competing parties who each desire to receive float to protect their individual activities against delays. Since such activities are very different, it is necessary to establish a quantitative measure of need for float (rather than binary criticality) by which the allocation can proceed to achieve a fair and equitable result.

3 RESEARCH METHODOLOGY

This research employs an analogy-adapting methodology to create a functioning mathematical approach and test its hypothesis. An unexpected intriguing analogy is found in the area of social choice (Thompson and Lucko 2011), which will be described in the following section. Different from previous work by these authors that first presented the idea; this research will compare three different possible measures of float allocation and visualize their respective performances regarding the goal of a fair and equitable allocation. The quantitative measure of need for float will use the activity duration, i.e. it is simplifyingly assumed that long activities are at a higher risk of incurring delays. While this is certainly true, characterizing the risk of delays by duration alone in practice likely is less realistic. It is envisioned that a weighted combination of e.g. duration, cost, and any other quantitative measure of relevant risk factors may be used, which will be
investigated under future research. It is assumed for the new approach that initially all durations are raw durations and that a regular calculation per the critical path method has been completed to obtain the raw project finish and a list of activities that are deemed critical. The difference between calculated raw project finish and the known contract turnover date is called contract float (\(CF\)), which is “post-CPM duration float that relates to the overall completion of the project” (Thompson and Lucko 2011, p. CN-002-7). While this approach may superficially resemble critical chain project management (CCPM) from the manufacturing industry, which intentionally accumulates all intermediate buffers into a single large one at the project finish (Steyn 2000), important differences exist, which counteract the simplistic assumptions of CCPM:

- CCPM does not explicitly distinguish raw from realistic durations, but simplistically assumes a generic 50% reduction of the planned duration to determine “the likely duration” (Zhao et al. 2010, p. 1056), which questionably assumes that on average all subcontractors inflate their estimates by as much;
- CCPM radically removes all ‘buffers’ from a schedule, even from the currently non-critical activities, into a single cumulative ‘project buffer’ (Rand 2000) at the project end, thus changing schedule dates;
- CCPM artificially and willfully generates severe criticality across a schedule, because it assumes that the subcontractors will only work timely if they have the impression that they work with zero flexibility;
- CCPM over-ambitiously seeks to minimize project duration (Herroelen and Leus 2001), but does not focus on reducing the project risk by increasing the consistency of achieving a realistic duration;
- “CCPM does not assign safety time to each individual activity” (Ma et al. 2014, p. 1), which is inverse to the philosophy new approach, and prevents determining any mathematically fair float ownership;
- CCPM reinserts ‘feeding’ buffers into non-critical paths (Rand 2000), changing schedule dates again;
- CCPM continues to ignore the critical path, whose risk has increased when all ‘safety’ was removed.

Besides such conceptual discrepancies, neither CCPM nor similar buffering approaches that were purely simulation-based (Gurgun et al. 2013, Barraza 2011) and essentially functioned by “taking off contingency buffers from individual activities and pooling them”, then “putting the resized or newly introduced buffer between activities” (Park and Peña-Mora 2004, p. 630), provided a rigorous scientific foundation for fair and equitable apportionment of buffers, or rather \(CF\). They can therefore be considered to be rudimentary attempts of solving a related ambition, but differed from the analogy-based approach that is presented in this research by turning away from, instead of improving, the vital backbone of a project – its critical path.

Note that this methodology and its assumptions and intended outcome – a project schedule ‘without’ any critical path – are not as radical as they may initially appear. Project managers already will ‘inflate’ the raw durations to what they consider realistic ones, but they do so in an individual and empirical manner. In the best case, this research will thus formalize and codify the best professional practice by providing it with a quantitative scientific foundation whose entire predictive and preventative approach can be validated.

### 3.1.1 Research Analogy

Arrow (1964) distinguished decision-making approaches into being voting (which is used in democratic systems to reach political decisions), and marketplace mechanisms (which are used in capitalist systems to reach economic decisions). Under these approaches, persons or groups engage in decision-making in several ways; e.g. dictatorially or unilaterally, forming a coalition to compose a majority of similar-minded individuals, or collective bargaining (hierarchical negotiation). Such approaches are often refined by extra rules and constraints, e.g. veto power – an ability to overrule a decision, per its Latin meaning “I forbid.”

Regardless of its detailed approach, any type of decision-making process seeks to reach a consensus by systematically aggregating many individual views. A rich body of research has examined decision-making under the heading of social choice; within it problems like fair division (of desirable assets or undesirable chores) and voting models (for parliamentary processes) have been explored mathematically. These offer analogies for the internal structure and operation of network schedule systems. Stated briefly, participants in such system (here: project) are voters (here: subcontractors), who jointly generate a decision (here: to expend float or not) by their actions (here: timely completion or delay) (Thompson and Lucko 2011). This conceptual analogy warrants investigation, especially exploring the applicability of their tenets to network schedule systems and project management in general for the problem at hand; namely float allocation.
A fundamental question emerges when participants are not of equal size (e.g. countries in the European Union), yet each of them should receive a fair weight within a decision-making process. To solve this vexing problem, two related mathematical voting models have emerged; the Penrose (1946) square root law and the Banzhaf (1965) power index. The former was inspired by the founding of the United Nations. It addressed problems of 'resolute' blocs that may dominate decisions and small nations, whose view either is irrelevant or who may become the tiebreaker. In other words, a truly fair balance is necessary to ensure that participants of small size are neither never nor always influencing the decision. Transferred newly to project management, Penrose (1946, p. 53) serves as inspiration for the new float allocation:

In general, the power of the individual vote can be measured by the amount by which his chance of being on the winning side exceeds one half. The power, thus defined, is the same as half the likelihood of a situation in which an individual vote can be decisive – that is to say, a situation in which the remaining votes are equally divided upon the issue at stake. The general formula for the probability of equal division of \( n \) random votes, where \( n \) is an even number, approaches \( \sqrt{2/n} \) when \( n \) is large. It follows that the power of the individual vote is inversely proportional to the square root of the number of people in the committee.

He distinguished voting weight (which is a simple factor) from voting power (how often a participant sways a decision). Of course, all participants should receive equal power, regardless of their size. For countries with population \( n \), a balance between the two unfair extremes of 'one vote per country' (proportional to \( n^0 \), which gives small ones too much power) versus 'one vote per person' (proportional to \( n^1 \), which gives small ones too little power) is required for a fair and equitable decision-making process (Pöppe 2007). He suggested that the newly formed General Assembly should allocate votes based on the square root (\( n^{0.5} \)) of country population. This somewhat counterintuitive principle that using direct proportionality to number of voters in each country is not the fairest possible approach remains a central insight of these studies.

Transferring this conceptual analogy to network schedules systems, political systems in representative democracies with two or more levels (federations like e.g. the United Nations, European Union, or United States) that make binary decisions provide the analogy, which correlates with critical subcontractors, who individually decide to consume their allocated float or not, and collaboratively build a project on time or not. Just as voters cast votes in an election (a decision forum), so subcontractors participate in a project with delay mitigation by deciding on the expenditure of float. “[V]oting typifies a possible determinant for the analogous behavior to those participating in large construction projects; and a potential mitigation approach to network schedule uncertainties and their impacts” (Thompson and Lucko 2011, p. CN-002-4). A question remains of whether \( n^{0.5} \) is the most appropriate value, i.e. a pure Penrose approach to float allocation, or if applying this analogy to construction projects warrants another value between \( n^0 \) and \( n^1 \).

### 3.1.2 Research Hypothesis

It is hypothesized that allocating float to the activities on the critical path based on the square root of the measure of float need leads to less need to project float than an allocation based on order zero or one.

### 4 SIMULATION CALCULATIONS

#### 4.1 Conceptual Approach

To efficiently perform the simulation calculations for the case example and derive comparisons, the entire new scheduling approach has been implemented in commercial computer software. Coding has followed a modular approach: Inputs are provided as a file that contains an activity list with name identifier for each activity as well as duration (distributions with its respective shape parameters) and point-to-point relations between the predecessors and successors that compose a network schedule. The number of repetitions of the simulation (i.e. runs) are specified separately. Output is written to another file and post-processed for analysis and interpretation. During each run the probability distribution of every activity is randomly sampled to determine its respective duration instance for one particular realization of the entire project.
Repeated simulation of a model that contains individual probabilistic variables to observe the probabilistic behavior of the entire system is known as Monte Carlo method (Chantaravarapan et al. 2004). It is often employed if the system (here a network schedule) is sufficiently complex to preclude a direct prediction of how exactly its elements will interact and cannot be solved by direct mathematical calculation. A distant conceptual relation of the new approach of this research exists to the so-called criticality index (Tang et al. 2013, p. 3238), which “is defined as the probability of an activity becoming critical”. However, several fundamental differences must be understood to contrast the criticality index with the new float allocation:

- A criticality index does not pre-allocate any contract float, neither to critical nor to any other activities;
- A criticality index is based on duration distributions for realistic durations, not raw ones, even though the former are more difficult to determine than the latter, which can rely directly on productivity data;
- A criticality index is performed within the calculated project duration, oblivious of its contract deadline;
- A criticality index analysis, using a Monte Carlo approach, tracks whether or not the critical path will pass through a particular activity within a single randomized realization of a given network schedule;
- A criticality index analysis is randomized across a single variable, the duration from the distributions;
- A criticality index analysis generates a single quantitative values to indicate a form of ‘meta-criticality’;
- The float allocation is randomized across two variables, durations and also increasing available CF;
- The float allocation generates a curve for each activity that indicates at what total CF that is available to all critical activities within a schedule said activity ceases to exceed its own allocated portion of CF.

For continuity, the case example is selected from Thompson and Lucko (2011). The left half of Table 1 lists its input with 15 activities that initially amount to a 72-day-long project from mobilization (Mob.) to turnover (T/O) per a CPM calculation of raw durations. Seven bold activities are deemed critical and will be the ones that receive float from the three allocation mechanisms. For simplicity, links have no leads or lags and no link types other than finish-to-start are used; these items will be explored in future research. In the subsequent simulation it is assumed that the duration distribution of activities has an asymmetric triangular shape with a minimum at 90% of the planned duration per Table 1 and a maximum of 125% to reflect that fact that activities rarely take shorter than planned, but often longer (Thompson 2012). Other probability distributions, e.g. beta (Fente et al. 2000), will be examined within the future research as well.

The following approach was taken for simulation. The first module performs the forward pass, backward pass, and float calculations of traditional CPM, which identifies critical activities. Afterward, it replaced the fixed planned durations with aforesaid triangular distribution and performs numerous repetitions (here 1,000) in a Monte Carlo type simulation of the now probabilistic schedule. Data analysis was performed on the list of seven critical activities only. Their actual durations as sampled from the distribution were compared per Equation 1 with the float that had been allocated, called distributed float $DF$ (Thompson and Lucko 2011) and is a portion of the contract float $CF$ itself that is available to the entire critical path.

$$\text{Actual duration} - (\text{planned duration} + \text{distributed float}) = \text{Float overrun}$$

Besides the actual duration of each activity, $CF$ was the second variable in the simulation. It was varied in integer increments between $CF = \{1 \text{ to } 40\}$ days. Efficiently, it was not necessary to re-run the simulation to count all of the individual cases of float overrun (or have sufficient float, which is of course desirable), or even to repeat it 30 times, once for each scenario of $CF$. Rather, only ‘actual duration’ in Equation 1 is randomized. ‘Planned duration’ is fixed and known from Table 1. And ‘distributed float’ depends only on the mechanism of float allocation, planned duration, and $CF$, but not actual duration. The reason for this uncoupling is that the entire approach is designed to function a priori, before actual durations are known.

Rounding presented an important challenge for float allocation, because it directly influenced how exactly the limited valuable $CF$ became $DF$ for each critical activity. It was rounded to integer days and any non-allocated single day of float was not explicitly assigned, but was left to ‘first-come, first-serve’. However, activities were rounded up so that each activity could only start at an integer time, to reflect the fact that if a subcontractor finishes before the end of a workday in construction practice, the next one will not arrive for merely a few hours, but on the morning of the next regular workday as Bashford et al. (2007) implied.

4.2 Results and Interpretation

Float overrun was plotted as the response variable in comparison to the CF as the explanatory variable. Figure 1 shows side-by-side the three different mechanisms of float allocation: Equal shares (planned duration\(^{0.0}\)), square root of duration (planned duration\(^{0.5}\)), and directly proportional (planned duration\(^{1.0}\)). The number of occurrences of float overrun was counted for each CF scenario and for every activity. Said counts were of course different under the three mechanisms. Shapes of the curves in Figure 1 represent the efficacy of each mechanism to protect the critical path against delays. For low CF the critical activities have not yet received sufficient DF to be individually protected. This explains the ‘plateau’ of their curves in the left half of the diagrams: While on this plateau, activities will consume more float than they own, or have not even received any DF yet. The latter is due to the fact that only integer days of CF become DF; and until the CF exceeds the number of critical activities, critical activities exist that have an allocation of zero. Next, activities experience a more or less steep drop-off or ‘cliff’, as float shows its powerful effect in absorbing any delays locally. If all activities will remain within their DF, the entire project will not exceed its planned raw duration plus CF. For each activity, a relatively narrow range exists, where DF changes from insufficient (on average) to sufficient (on average). After this cliff, a lower plateau is reached in the right half of the diagrams, where activities have excess DF and the project contains more CF than is needed.

To capture the cliff behaviour, which is of vital interest for this analysis, these parameters were calculated from the data and listed in Table 1: Left and right cutoffs \( L \) and \( R \) (the right edge of upper plateau and the left edge of lower plateau), and within this range a weighted mean \( m \) and weighted standard deviation \( s \) on the horizontal axis, which indicated where and how narrow the cliff was. For example, if an activity has a result of \( y = \{10, 10, 1, 0, 0, 0\} \) counts of overrun for \( x = \{0, 1, 2, 3, 4, 5\} \) days of CF, then \( L = 1; R = 3; m = [9 \cdot (2 - 1) + 1 \cdot (3 - 2)] / (9 + 1) = 1.6 \) (weighted by drops \( \Delta y \) within their integer ranges of \( x \)); and \( s = \sqrt{[9 \cdot (1.5 - 1.6)^2 + 1 \cdot (2.5 - 1.6)^2] / [10 \cdot ((2 - 1)/2)]} = 0.42 \) (average weighted distance of the integer range midpoints to \( m \)). Note that both \( m \) and \( s \) are only calculated across a cliff itself, not the plateaus besides it.
The ranges of $L$ and $R$ and weighted grand averages and standard deviations across all critical provided a quantitative comparison of the efficacy of the three mechanisms. The equal shares (planned duration$^{0.0}$) has a wide range {3.0 to 18.0} within which all activities exhibit their drop-off behaviour, a weighted mean of 6.55, and a weighted standard deviation of 4.3, which indicates a merely gradual saturation of critical activities with their urgently needed $DF$. This approach is not recommended, due to being oblivious to the relative risk of activities, which here is represented by the proxy of duration. More interesting is comparing square root (planned duration$^{0.5}$) versus proportional shares (planned duration$^{1.0}$) approaches of Figure 1. The former has a narrower average range {3.4 to 14.9} of width 11.5 for all critical activities per Table 1; the latter is even slightly narrower {3.9 to 14.6} of width 10.7. Weighted means and standard deviations give a more distinct view: The former has a weighted mean of 6.19 compared to 6.58 of the latter. Clearly the square root model on average provides all critical activities earlier with the $DF$ that is needed to satisfy their need. In fact, $m$ is almost identical for (a) and (c) in Figure 1, which supports the hypothesis that (b) is the balance approach between these extremes. Finally, weighted standard deviations compare nearly identical at 3.36 versus 3.33 per Table 1. Both are much lower than $s = 4.63$ for (a). Testing for statistical significance at an alpha-level of 0.05 finds the difference between means not significant; however, this is most likely due to the very small case example with only seven different activities. More experimentation is therefore needed to substantiate the positive indications of the square root approach for float allocation.

5 CONCLUSIONS AND RECOMMENDATIONS

This research has presented a vision for overcoming the long-standing and deeply entrenched paradigm within construction project scheduling by uncovering its various implicit assumptions. They have included focusing excessively on dissecting risk factors on the one hand and delay liability on the other hand; not explicitly distinguishing raw from realistic durations and basing criticality assessment on the latter, not the former; and artificially creating a paradoxical two-class society of critical versus non-critical activities that actively contradicts any desire to minimize the overall risk level. It is thus understandable that previous approaches to float ownership failed to solve the true underlying issue – minimizing risk by mitigating delays. This research stipulated that all critical activities should receive float, not by directly inserting it from its location between calculated and contract finish to being distributed along the critical path within a network schedule itself, but rather by providing an unambiguous approach to calculate optimum portions of ownership. This new approach is based on the premise that a directly proportional allocation to ‘size’ of the critical subcontractors’ contributions to the project would not fulfill the overall goal of being fair and equitable. Rather, three cases have been tested for numerical comparison; an allocation based on equal shares ($n^0$), the square root of size – or risk – ($n^{0.5}$), or proportional shares ($n^1$). Initial results are positive, but not statistically conclusive between the square root approach or proportional shares of float allocation. More experimentation with larger and more realistic examples of network schedules is recommended.
This research aids in fulfilling the unrealized vision of “Total Float Traded as Commodity” (de la Garza et al. 1991, p. 716). Only that it will not be the $TF$ of non-critical activities, but $CF$, and that it will be designed to benefit critical activities. And that it will require having completed a pre-allocation of $CF$. Combined with the creative analogy from voting mathematics, which provides the seminal inspiration for how to achieve a provable fairness between large and small subcontractors who compete for $CF$, a market of opportunities can emerge. More research is necessary on how to determine dollar value, which should be listed in the contract to give all subcontractors certainty. Future research should investigate how the emphasis that is placed on measures of ‘size’ – whether it is duration, cost, risk (depending on type and nature of activity) – can be weighted and converted into a single numerical metric (Thompson and Lucko 2011). The current approach has merely assumed that a numeric value of risk (or size) is available as input. Closely related to this, it should also be examined how the potentially different subjective monetary valuations of $CF$ by said contractors can be aggregated. Further analogies from areas of knowledge besides construction project management should be parsed to identify proven concepts that can handle subjective valuation.

Abstract: Concrete made with Portland cement is one of the most used construction material in the world. Engineers and scientists are always looking to improve its sustainable properties. The durability of concrete is a determining factor in the service life of a structure. The durability of cement based materials is strongly influenced by its porous structure. Previous research has shown that the use of fly ash in concrete mixtures as partial substitution of Portland cement produces a pozzolanic reaction that changes concrete’s micro-structure. As a concrete mineral admixture, fly ash improves concrete’s mechanical properties and durability while providing economic and environmental benefits. The objective of this paper is to present the results of a study that investigated the influence of fly ash on the durability of concrete mixed with ASTM C150: Type I cements. The methodology included mixing three different ASTM C 150: Type I cements with three different percentages of fly ash each for a total of 9 different combinations. Durability, physical, and mechanical properties tests were performed on the concrete samples from each mix. The results indicate that the performance of concrete with fly ash varies based on the characteristics of the cement used and the amount of fly ash used in the mixture. Based on the results of this study, it can be concluded that the best result for experimental concrete with 25% fly ash substitution were obtained with concrete Y (C3S = 55.31%), while with 50% fly ash substitution the best results were obtained with cement Z (C3S = 77.04%). These combinations increase the concrete’s durability while reducing costs and providing environmental benefits. This paper contributes to the body of knowledge by increasing the understanding of the influence of cement properties in fly ash on the durability of concrete.

1 INTRODUCTION

Many concrete structures require repairs or reconstruction before reaching their expected service life. In the United States, the annual cost of repairs to parking structures and bridges exposed to de-icing salts has been estimated in a range between 325 million and 1 billion dollars (Kelting and Laxson 2010). According to Fernández Cánovas, placing good quality concrete is the best way to protect the steel reinforcement embedded in it. To reduce the costs of repairs and replacement of structures most experts coincide that the concrete durability must be improved (Fernández Cánovas 2004).

The American Concrete Institute (ACI) defines concrete durability as the ability to maintain its shape, quality, and utility under the exposure conditions for which it was design throughout their expected life span. The deterioration mechanisms such as expansion, retraction, or ionic penetration into the concrete are related to the exposure conditions (ACI 2008). Puerto Rico is an island, and the most relevant
exposure condition for concrete structures is the marine exposure, where chloride ions attack is the most aggressive.

It is widely known that fly ash as a mineral addition to concrete has positive effects on the concrete durability. Among the many benefits of using fly ash, its reaction with portlandite produces additional calcium silicate hydrate (C-S-H) gels (Pihlajavaara and Paroll 1995). Calcium silicate hydrate (C-S-H) gels are the main responsible for cohesion and mechanical properties of concrete. These additional C-S-H gels refine the porous network of concrete, providing additional protection against environmental exposure attacks, like the penetration of chloride ions. At the same time the formation of these secondary C-S-H gels consumes Portlandite, which is the most leachable compound of the hydrated cement. As a result the durability of the material is considerably improved (Naik and Hossain 1994), (Lorenzo García 1993).

Other benefits of using fly ash in concrete are pecuniary and environmental. Fly ash is usually less expensive than Portland cement, making the mixture with fly ash more economical than a mixture by using Portland cement only (Federal Highway Administration 2011). Some of the environmental benefits are the reuse of a by-product of energy production and the reduction of Portland cement production. This last aspect is very important as with a reduction of cement production, the energy required is reduced as well as the CO₂ emissions to the environment (Burden 2006). Also, the use of fly ash as an addition to concrete can help earn credits for the Leadership in Energy & Environmental Design (LEED) certification (King 2005).

In general terms, the effects of fly ash in concrete are widely known, but the effects of fly ash when used with the cements available locally are unknown. In Puerto Rico there are three brands of cement type I commercially available. All of them comply with the specifications of ASTM C150. Even though all of them are classified type I, each one has different chemical and physical properties. The main objective of the present work is to better understand the influence of the durability and mechanical properties of concrete of each type of Portland cement when a partial substitution of fly ash is introduced.

2 METHODLOGY

2.1 Materials

In this research, the materials utilized were those available for commercial use in Puerto Rico. The cements used are classified as type I according to the ASTM C150. They are distributed by Antilles Cement Corporation, Cemex Puerto Rico and Essroc San Juan. For each one of the three cements used, a chemical and mineral composition analysis was conducted according to the standard ASTM C114. The distribution of particle size was determined according to the standard ASTM C204. Tables 1 and 2 summarize the mineral and chemical composition for each cement used; these were denominated X, Y and Z.

The fly ash used in the study has a Type F classification according to ASTM C618, distributed in Puerto Rico by Ecológica Carmelo. The chemical composition analysis for fly ash was made according to ASTM C114. Table 3 shows the summary of the chemical composition of the fly ash used.

The coarse aggregates used are of siliceous origin, crushed with a maximum diameter of 20 mm (3/4"). The fine aggregates used are crushed limestone with a fineness modulus of 3.02. The particle size analysis of aggregates was conducted in accordance with the standard ASTM C33.

2.2 Dosages

The ACI Committee 211 method was used for the concrete mixture design. The reference concrete had 426.6 kg of cement and a water/binder ratio of 0.65. For the experimental concrete, Portland cement was substituted with fly ash by 25 and 50 percent. Table 4 shows the material amounts required for each dosage to produce a cubic meter of concrete.

For each Portland cement type used in the study, one reference batch and two experimental batches were mixed, reaching a total of nine batches. In all cases a concrete mixer with 0.38 m$^3$ of capacity was used. Each batch had a volume of 0.11 m$^3$ that produced 10 cylindrical specimens of 15 cm (6 in) diameter and 11 cylindrical specimens of 10 cm diameter (4 in). The process of mixing and curing was executed according to ASTM C192.

2.3 Testing

The specimens were subjected to different tests in order to characterize the concrete properties of all batches. The mechanical behavior was characterized by the compressive strength. In order to study the durability of the concrete rapid chloride permeability tests were conducted. Finally, to characterize the physical properties of the porous network mercury intrusion porosimetry and air permeability tests were performed, both of them in turn directly related with concrete durability. Table 5 summarizes the results of testing, the age of the specimens at the time of testing and the name of the standard procedure followed for each test.

3 RESULTS

The results of the rapid chloride permeability tests are shown in Figures 1 to 6. Figures 1 to 3 show the passing charge of each concrete batch according to its percentage of fly ash substitution. In figures 4 to 6 the results are shown in accordance to the Portland cement mineralogical composition.

Figure 1: RCPT of concretes with cements X, Y, Z and 0% of fly ash substitution by cements X, Y, Z and 25% of fly ash substitution

Figure 3: RCPT of concretes with cements X, Y, Z and 50% of fly ash substitution

Figure 4: RCPT of concretes with cement X
Reference concretes show high permeability at all ages. Experimental concretes (with fly ash) have higher resistance to chloride ion permeability, especially during a long-term period. After analyzing the performance depending on the cement type, those mixtures with 50% of fly ash substitution improved their resistance to chloride ion permeability in all cases, although the results in the case of cement X were a little worse.

Figures 7 to 9 show the results of the compressive strength tests of concrete cylinders according to the percentage of fly ash substitution. Figures 10 to 12 show the results according to the cement mineralogical composition.
At early ages, the reference concretes show higher compressive strength than concretes with fly ash substitution. In all cases the best results were obtained by concretes mixed with cement Y.

Concretes with 25% of fly ash substitution reach the values of compressive strength of the reference concretes as time progresses. Concretes with 50% of fly ash substitution did not reach the values of compressive strength of the reference concrete at any age.

The results of the analysis of the physical properties of the concretes are presented in figures 13 to 19. Figures 13 to 18 show the results of the mercury intrusion porosimetry tests. The results are arranged by percentage of fly ash substitution and by cement type utilized. Figure 19 compares the volume of accumulated intrusion in macropores and mesopores of all concrete batches. Figure 20 shows the results of the air permeability tests.
The lowest mercury intrusion volumes were obtained with concretes mixed with cement \( Y \), as was the case in the compressive strength results. The best result obtained was the experimental concrete with 25% of fly ash substitution of cement \( Y \).

---

**Figure 15**: Accumulated intrusion volume of concrete with cements \( X, Y, Z \), and 50% of fly ash substitution

**Figure 16**: Accumulated intrusion volume of concretes with cement \( X \)

**Figure 17**: Accumulated intrusion volume of concretes with cement \( Y \)

**Figure 18**: Accumulated intrusion volume of concretes with cement \( Z \)
Figure 19: Volume of accumulated intrusion of macropores and mesopores

In all cases of concretes mixed with cement Y, both the reference and experimental concretes, obtained the lowest volume of intrusion in macropores. The lowest volume of intrusion in macropores occurred in concretes with 50% of fly ash substitution.

Figure 20 compares the permeability to air constant for all concrete batches, arranged by the percentage of substitution by fly ash.

Figure 20: Permeability to air constant (average) of concretes with cement X, Y, Z

In reference concretes, the type of cement used in the mix does not affect the air permeability. On the experimental concretes variations were observed depending on the type of cement used for the mixture. The behavior of the results does not coincide with other tests carried out.
4 CONCLUSION

This study proves that the performance of concrete with fly ash varies based on the characteristics of the cement used and the amount of fly ash used in the mixture. Based on the results of this study, it can be concluded that the best result for experimental concrete with 25% fly ash substitution were obtained with concrete Y ($C_3S = 55.31\%$), while with 50% fly ash substitution the best results were obtained with cement Z ($C_3S = 77.04\%$). These combinations increase the concrete’s durability while reducing costs and providing environmental benefits.

The reference concretes have high permeability to chloride ions at any age. When compared by type of cement, concretes with the highest percentage of fly ash substitution performed better on the RCPT. This coincides with previous investigations. All experimental concretes improved their performance in RCPT and compressive strength test with age. Fly ash refined the porous structure of concretes. The porosimetry results show that in experimental concretes the accumulated volume in macropores decreases and the accumulated volume in mesopores increases when compared with reference concretes. The results show that even when all the cements used comply with type I classification according to ASTM C150, there is a tendency to performance variation of the concretes mixed with cement with different mineralogical composition.

DEVELOPMENT OF AN AUTOMATED 3D/4D AS-BUILT MODEL GENERATION SYSTEM FOR CONSTRUCTION PROGRESS MONITORING AND QUALITY CONTROL

Reza Maalek¹,³ Derek Lichti² and Janaka Ruwanpura¹
¹ Department of Civil Engineering, University of Calgary, Canada
² Department of Geomatics Engineering, University of Calgary, Canada
³ rmaalek@ucalgary.ca

Abstract: Automating the progress monitoring and control process is of great interest to industry practitioners to help improve the limitations associated with the current manual data collection and analysis practices. Two remote sensing technologies, namely, Light Detection and Ranging (LiDAR) and digital camera, are widely used to acquire 3D point clouds as a means of measuring the “scope of the work performed” of structural elements. However, to assign the collected 3D point clouds to their corresponding structural element, current object-based recognition models use the as-planned 4D model, which may not be reliable in cases where the locations of the as-built structure differ from those of the planned, and/or the planned 4D model is not available with sufficient detail. Here, a novel method is proposed to eliminate the dependency on the as-planned data by automatically generating the 3D/4D as-built model through a robust Principal Component Analysis-based (PCA) segmentation algorithm. The proposed system is also independent of the technology used to capture the 3D point clouds. To evaluate the reliability of the proposed automated as-built model generation procedure, two sets of LiDAR data from the "Mechanics of Materials" laboratory and the "Graduate Student Hall of Residence" construction site at the University of Calgary were collected. A novel method of automated registration of the as-built model to the planned model coordinate system is also proposed through which the compliance of the planned vs. actual dimensions of corresponding structural elements are examined. The results of the two experiments demonstrate the applicability of the proposed methods for the automatic generation of the 3D/4D as-built model and the dimension compliance control of structural elements.

1 INTRODUCTION

Project monitoring and control are vital to facilitate decision makers identify deviations between the planned vs. as-built states of the project and take timely measures where required (Maalek and Sadeghpour, 2012). Monitoring is the process of collecting onsite data as a means of measuring the Project Performance Indicators (PPI). Traditionally, onsite data are collected manually, a time consuming, error-prone and labor intensive task particularly on large scale projects (Golparvar-Fard et al. 2009a). In practice, to justify the time and cost associated with such manual approaches, a limited amount (and/or frequency) of onsite data are collected, which diminishes the ability of the project manager to identify the causes of delays and cost overruns on time. In addition, most onsite data collection processes are anecdotal without a proper monitoring plan/strategy (Golparvar-Fard et al. 2011), which influences the time, cost and reliability of the collected PPIs.
Project control involves the processing of the accumulated data for the determination of the performance of the current state of the project. Therefore, the reliability of the determination of the performance of the project is highly dependent on the strategy as well as the accuracy of the collected data during the monitoring process (Saadat and Cretin, 2002). Currently, site supervisory personnel spend 30-50% of their time on manually monitoring and controlling onsite data (McCullough, 1997, Golparvar-Fard et al. 2009). If this time is reduced by means of a novel approach to onsite data collection and analysis, more time can be allocated to improving vital construction related concerns such as safety (Maalek & Sadeghpour, 2011), and workforce productivity and communications (Choy and Ruwanpura, 2007). Therefore, automating the monitoring and control process is proposed in recent years to help overcome the aforementioned limitations of current manual practices.

2 LITERATURE REVIEW

The percentage of completion of an activity is suggested as the Key Performance Indicator (KPI) capable of providing progress information in activity-level (Maalek et al. 2014). In order to automatically extract this metric, the scope of the work performed for each activity is required to be identified by means of a remote sensing technology. Currently, two remote sensing technologies, namely, digital camera and LiDAR, are widely used to generate 3D coordinates of the surrounding surfaces. The overview of the previous research related to the application of these two technologies for progress monitoring of construction activities are presented in the following.

2.1 Digital Camera

In practice, photographs are commonly taken to record the progress of specific activities and/or to help minimize disputes/claims (Golparvar-Fard et al. 2009a). These images are stored without proper documentation and indexing (Brilakis et al. 2006). In addition, the KPIs are manually extracted from the large number of unordered/randomized images, constituting a costly, lengthy and challenging procedure. Current research aims at improving these aspects by means of automating the extraction of meaningful information from the accumulated images. These research studies can be subcategorized into two groups, namely, those using a single pre-calibrated fixed-location camera, and those using multiple cameras to determine the 3D coordinates of the surrounding surfaces.

2.1.1 Single fixed-location camera

Using a single camera at fixed locations, it is not possible to determine the 3D coordinates of the structural elements (Rougier and Meunier 2010); however, some researchers have innovatively used time-lapsed images to determine the completion and production rate of certain construction activities. Lukins and Trucco (2007), Zhang et al. (2009) Ibrahim et al. (2009) aimed at determining the completion of certain activities on site by detecting the changes between consecutive images. Golparvar-Fard et al. (2009a) aimed at visually identifying the deviations between the plan and the actual states of the construction work by means of color-coding the identified differentiations. Ranaweera et al. (2013) developed a system to automatically determine the productivity of tunnel construction by identifying the number of liners lowered into a tunnel during a shift.

2.1.2 Multiple cameras

As mentioned in the previous section, it is not possible to quantify the “scope of the work performed” (i.e. the progress) of construction activities using a single camera. In addition, since construction sites are dynamic environments with many moving objects, the presence of newly added obstacles may block the Line-Of-Sight (LOS) of the camera. Therefore, additional cameras are required to correctly determine the progress of construction activities. At least two camera exposures taken from different locations are required to estimate the 3D coordinates of a point relative to the image coordinate system using collinearity equations and triangulation (Kraus, 1993). In order to determine the position and orientation of each exposure station, at least three (3) tie-points (point correspondences) are required per image. Recent research studies aim at automatically matching similar features (tie-points) from unordered construction site photographs to generate the 3D coordinates of the surrounding surfaces (point clods).
Golparvar-Fard et al. (2009b, 2011a, 2011b, and 2015) developed an automated progress monitoring system, called D4AR, which uses the accumulated unorganized photographs to determine the 3D coordinates of structural elements on site. The system uses a dense pixel to pixel matching algorithm to link the similar features between every two image to create a 3D point cloud of the site at the time the monitoring is performed. The system then estimates the translation and rotation of each of the camera exposures with an arbitrarily defined scale via a bundle adjustment. The scale of the measurement is then identified by manually registering some corresponding key points from the planned to the as-built space. At least three point correspondences are required to solve for the seven parameters (including scale; Horn, 1987). It is to emphasize that the manual registration is mandatory since the true 3D coordinates of the point clouds can only be estimated if the scale is defined with respect to the true space. However, the method assumes that the 3D coordinates of the selected key points remain unchanged between the as-built and the as-planned models. In other words, the potential errors in construction are neglected. Therefore, it is likely that the expected accuracy of the generated 3D coordinates drops since construction errors may cause differences between the as-planned and the as-built structure, which consequently affects the scale of the measured point clouds. In order to overcome this challenge, the correctly-scaled coordinates of the key points should ideally be measured by means of an external measurement system (such as a reflector-less total station or a scale bar), which increases the time and cost of data collection as well as possibility of interruption with construction activities. In (Golparvar-fard et al, 2011a, 2011b and 2015), the constructed point clouds from the D4AR system, proposed above, are assigned to their corresponding structural elements by superimposing the as-planned 4D BIM model to the constructed point clouds.

As indicated above, at least two camera exposures are required to estimate the 3D coordinates of a point. Considering the limited Field of View (FOV) of a camera, a large number of manual photographs must be captured in order to cover every structural element on the site at least twice, which increases the time and cost of onsite data collection and analysis (Maalek et al. 2014). In addition, finding point-to-point correspondences between every image pair requires additional processing. In Golparvar-fard et al. (2011a), the processing of 288 images, constructing only 62,000 points, is shown to take approximately 7 hours. Furthermore, the quality of the images taken by a camera is a function of the lighting conditions and thus the accuracy of the generated point cloud can be highly affected by the lighting conditions (Golparvar-fard et al. 2011a). To summarize, the large number of images required due to limited FOV, the additional processing time due to the correspondence problem between the accumulated images and the need for adequate illumination (Dario et al. 2013) has led researchers to use LiDAR to help overcome the aforementioned limitations of implementing cameras on construction sites.

2.2 LiDAR

LiDAR is a remote sensing technology used to collect 3D coordinates of the surrounding surfaces in LOS using only a single scan-station without additional processing (i.e. directly). In addition, LiDAR is more likely to achieve more accurate data compared to those provided by photogrammetry (Golparvar-Fard et al. 2011b and Bhatla et al. 2012). Therefore, the feasibility of preparation of as-built 3D/4D models using LiDAR technology has been of great interest to researchers in recent years.

In the work of (Bosché, 2010, Bosché et al. 2009, 2015, and Turkan et al. 2013), the as-planned 4D CAD model is used to assign the accumulated point clouds to their corresponding structural elements. In their approach, first, the collected point clouds are manually registered to the planned model coordinate system. For each registered scan-station, the point clouds corresponding to the planned model are then generated by considering the potential random errors associated with the LiDAR equipment. If the distance between the two points is smaller than a threshold, the two points are equivalent. For the corresponding points, the Iterative Closest Point (ICP) registration is used to improve the results of the manual registration. In (Turkan et al. 2013), an earned value analysis on the data captured and processed in (Bosché, 2010) was performed. The point clouds were assigned to their corresponding structural elements; however, the “scope of the work performed” for each object was determined manually, which is a time consuming process, especially for in large scale construction projects. In (Bosché et al. 2015), the same procedure presented above was used to first generate the 3D as-planned point clouds on a piping project. A 3D Hough transform was then performed on both the as-planned and
as-built point clouds to determine the circular cross sections. These cross sections were then matched to identify the dimension compliance, location and the completion of the pipes. Zhang and Arditi (2013) also used the as-planned model in order to determine the completion of an object by counting the number of point clouds inside two predetermined boundaries, representing the tolerance region, of the object. Kim et al. (2013) also used the as-planned 4D Building Information Model (BIM) in order to report the progress of construction activities. In their approach the use of connectivity between components as well as sequence of activities were suggested in order to improve the classification results and to deal with misclassifications caused by missing data.

2.3 Some Limitations of Current State of Research

Current object-based recognition models use the planned 4D model as a-priori knowledge to assign the collected 3D point clouds to a structural element (Golparvar-Fard et al. 2009a, 2011a, 2012, 2015 and Bosché et al. 2009, 2015; Bosché, 2010; and Zhang and Arditi 2013), which may not be reliable in cases where the locations of the as-built structure differ from those of the planned (Shahi et al. 2013) or the Issue for Construction (IFC) plan with sufficient detail is not readily available. In other words, the assumption that there are no significant deviations between the as-built and the as-planned states of a project is contradictory to the nature of monitoring and control. In order to reduce this dependency on the details of the planned model, here, it is proposed to summarize the information carried by the accumulated point clouds (regardless of the method the point clouds are generated) into meaningful information that is comparable to the details presented in the planned model (not vice versa). The procedure is explained in more detail in the following sections.

3 OBJECTIVE AND METHODOLOGY

As mentioned previously, the goal of this research is to automatically summarize the accumulated point clouds into vertices that represent the boundaries of the structural elements, which can be used to determine the scope of the work performed. In other words, a novel method is proposed to automatically generate the 3D as-built model of structural elements. For this matter, the geometric primitives (only the 3D coordinates) are used to determine structural vertices from the collected point clouds. The procedure is as depicted in Figure 1. Each element of Figure 1 is explained in more detail in the following sections.

Figure 1: Point clouds summarization into meaningful vertices

3.1 Point Cloud Classification

Point cloud classification is the process of labeling points with similar physical attributes into predefined classes. Since the most generic building elements as well as most man-made objects (Nunnally, 2010; Vosselman et al. 2004) are constructed from the intersection of planar surfaces, the classification of point clouds into planar surfaces is the major focus of this study. There are two methods commonly used to classify point clouds into planar surfaces, namely, the Hough transform and Principal Component Analysis (PCA). However, the use of Hough transformation for planar classification is computationally expensive and the results of the classification are highly affected by the presence of outlying data (Lari, 2014). Therefore, PCA-based classification is used in this study.

PCA is used to summarize the variation of a multivariate data set into independent (orthogonal) axes. These axes are regarded as the principal components. The magnitudes of these axes represent the variation of the data set in the direction of the axis. This is accomplished by decomposing the covariance matrix of the data set into its eigenvalues and eigenvectors. In case of a 3-dimensional data set such as a point cloud, three orthogonal axes can be determined, which represent the maximum variations of the data set. For noise-free, coplanar points, the data has no variation in the direction of the surface normal. In other words, the eigenvalue corresponding to the direction of the surface normal is equal to zero. For
this matter, many researchers have used PCA for the classification of planar surfaces (Lari, 2014). First, a neighborhood is defined around each point cloud. The PCA is performed on the pre-defined neighborhood of each point. If the pattern of the neighborhood of the desired point forms a planar surface (i.e. smallest eigenvalue is close to zero), the point is classified as a plane. This can be further illustrated in Figure 2.

Figure 2: Classification of accumulated point clouds into planar surfaces

The classification of point clouds into planar surfaces is trivial in ideal, controlled conditions with no data contamination. However, in a construction, due to the data artifacts caused by moving objects, occlusions and dust, outliers are present in the data. The classical method of PCA, which uses the classical estimate of the covariance matrix, is highly sensitive to outliers (Hubert et al. 2012). Therefore, in order to help reduce the effects of outliers on the underlying pattern of the data, the Deterministic Minimum Covariance Determinant (DetMCD) estimate, proposed by Hubert et al. (2012), is used here to robustly estimate the covariance matrix of the data.

3.2 Point Cloud Segmentation

Segmentation is the process of grouping the points of a certain class that possess similar attributes. To segment the classified point clouds with similar characteristics, two methods are generally used namely, region growing and clustering. Region growing methods are widely used due to their computational efficiency; however, they are not considered as robust methods since the results of the segmentation is dependent on the selected initial seed point (Wang and Shan, 2009; Lari, 2014). Therefore, clustering methods are used in this research to provide more robust segmentation results.

Generally, there are four main clustering algorithms presented in (Jain and Dubes, 1988). In the research carried out by Milligan and Isaac (1980), the complete linkage method was shown to be more efficient than the others in identifying compact clusters. In this research, an iterative planar clustering method is proposed, using a novel robust complete linkage method, in order to robustly determine planar clusters from unorganized point clouds.

3.2.1 Boundary Detection to Ensure Surface Continuity

Using the proposed clustering algorithm, it is possible to clustered coplanar point which are spatially discontinuous. In order to enforce surface continuity within each cluster, the boundary points of each cluster is determined using the modified “convex hull” algorithm proposed by Sampath and Shan (2007). This approach ensures that the disconnected surfaces are segmented into different clusters.

3.2.2 Robust Plane Fitting

After the boundary detection, each cluster contains coplanar point clouds from continuous surfaces. All the information carried by the points within a planar cluster can hence be summarized into a normal vector and a point, which represent the plane parameters of the cluster. The robust PCA using the Deterministic MCD is used to robustly estimate the aforementioned plane parameters. The robust PCA ensures that local surface roughness due to construction errors and/or outlying data do not affect the result of the plane fitting.

3.3 Surface Intersection

As indicated in Section 3.1, most common structural elements are constructed by the intersection of planar surfaces. The method proposed above can theoretically determine the planar facets of structural
elements on a construction site. Therefore, to determine the vertices of these types of structural elements, the closest planes are required to be intersected. For this matter, the planes whose boundaries are closer than the pre-defined threshold are first identified. The line of intersection of every pair of adjacent planes is then calculated. The neighboring points on the two planar clusters are then projected on the intersecting line. The upper bound and the lower bound of the line will be determined based on the position of the projected points. For the two end points of every identified line-segment, the closest end points of the remaining line-segments (within a threshold) are determined. The closest lines are then intersected in order to refine the end points of the line segments. The resulting end points are the vertices of the object of interest.

4 EXPERIMENTS

In Section 3, a fully automated method was proposed to robustly determine the boundaries of structural elements that are constructed from the intersection of planar surfaces. In this section, two experiments designed to assess the effectiveness of the proposed method for automatic 3D as-built model generation are described.

4.1 Monitoring Technology

The benefits of LiDAR to photogrammetry in generating 3D point clouds of the surrounding surfaces were outlined in Section 2.1.2. In addition, the resolution achieved by photogrammetry may not be sufficient to accurately classify and segment the acquired point clouds”. Therefore, LiDAR is the preferred alternative to generate 3D coordinates of the surrounding surfaces (Maalek et al. 2014). The Leica HDS6100 is used in this study to capture the required data. This device has the ability to collect up to 508,000 points per second (Leica, 2009).

4.2 Experiment 1: Mechanics of Materials Laboratory

Using the Leica HDS6100, one set of LiDAR data, consisting of three scan-stations, was collected from the Mechanics of Materials laboratory at the University of Calgary (Figure 3). As illustrated in Figure 3a, the laboratory consists of many obstacles and metallic tables, which may increase the possibility of occlusions as well as loss of accuracy due to multipath reflection. Therefore, it may be considered as a fair representation of an actual indoor construction site. Approximately 30 million 3D points of the interior surfaces were recorded from the three scan-stations. The total data collection time was less than 15 minutes for all scan stations. As illustrated in Figure 3b, the lab consists of 26 different walls. The elevation of the ceiling relative to the floor is 2.7 m. The planned model suggests that the roof, floor and the surrounding walls are planar surfaces. The plot of the plan of the site represents a concave polygon.

![Figure 3: a) "Mechanics of Material" laboratory; b) plan view of the laboratory](image-url)
4.2.1 Floor and Flat Slab Ceiling Extraction

Here, a method is proposed to identify and extract the points on the floor and the flat slab ceilings without performing a robust PCA. This is especially beneficial to help reduce the calculation time of the segmentation process. It can be demonstrated that the histogram of point elevation for any room similar to the lab used in this study has the form shown in Figure 4a. As illustrated, the histogram of elevation consists of two major peaks, which represent the points of the floor and the ceiling. To determine the location of these two modes, the Median-shift algorithm proposed by Shapira et al. (2009) was used. The two modes are regarded as points Pf and Pc in Figure 4a. In order to robustly identify the points on the ceiling and the floor using the identified modes (peaks), first all the points in $\pm r$ (rc) from the mode Pf (Pc) are identified. rf (rc) is the difference of the minimum (maximum) elevation of the data set from the elevation of first (last) meaningful mode Pf (Pc). The Deterministic MCD algorithm was then applied on these specified points in order to identify the subset that complies with the majority of the dataset. The identified points with the least variation are then regarded as the points on the floor and ceiling.

![Figure 4: a) Expected distribution of the elevation of the point cloud; b) histogram of elevation of the actual point cloud.](image)

The histogram of elevation is as shown in Figure 4b, which complies with the hypothesis presented in Figure 4a. The objective is to determine the points of the floor and the ceiling, enclosed by the red ovals of Figure 4b. The results of the extracted points using the robust method described above are presented in Table 1. As illustrated, no Type II errors were detected during the extraction of the feature extraction, which indicates the robustness of the proposed method. In addition, the extracted points accounted for approximately half of the total accumulated point clouds, which suggest a significant reduction in the time of data classification and segmentation.

4.2.2 Segmentation and As-built Model

Using the methods presented in Section 3, the remaining point cloud was segmented with 94.7% accuracy. The results of the segmentation are as shown in Figure 5a, where the different colours represent different clusters. The purple colour represents the boundaries of the segments. Figure 5b shows the as-built 3D model of the site after the nearest planar clusters are intersected.

4.2.3 Automatic Registration

Here, a novel method is proposed to automatically register the generated as-built model to the planned model coordinate system. Figure 6 shows the plan view of the 3D as-built CAD model. In order to automatically determine the point to point correspondence between the as-built and the planned, two metrics are defined for every vertex (Figure 6a). The first is the angle between the vector that enters and
exits the vertex ($\theta$). The second is the average of the magnitude of the vector entering ($V_1$) and exiting ($V_2$) the vertex. The point correspondences are then determined based on the similarity of the two metrics using a one-step complete linkage clustering method. The method proposed by Horn (1987) is then used to perform a rigid body transformation and completed the registration process. The results indicated a 9.4 cm Mean-Radial Spherical Error (MRSE), which represents the potential discrepancies between the planned model and the captured data. The horizontal and the vertical dimensions of the walls were 7.5 cm and 2.4 cm different respectively.

![Figure 5: a) Segmentation results (obstacles are removed for clarity); b) as-built 3D CAD model](image)

### 4.3 Experiment 2: Graduate Student Hall of Residence

The objective of this experiment is to generate the as-built model of the elevator shaft for the Graduate Student Hall of Residence construction site at the University of Calgary. The elevator shaft is a concrete structure consisting of four perpendicular planar surfaces. The as-built dimensions of the shaft were of particular interest to the contractor since these dimensions are required to comply with the specification of the ordered elevator. A \( \pm 2 \) cm tolerance from the planned dimensions was acceptable for the contractor. The as-built model of the elevator shaft was generated using method proposed in Section 3 as illustrated in Figure 6b &c. The results of this experiment indicated a Distance Root Mean Squared of 1.8 cm, which complies with the standards presented in the project plan and the acceptable tolerance region.

![Figure 6: Mechanics of Materials Laboratory: a) Plan view of the as-built model prior to registration; Graduate Student Hall of Residence: b) Collected LiDAR point clouds from the elevator shaft; c) automatically generated as-built 3D CAD model](image)

### 5 CONCLUSION

In this study, a novel method for the automatic generation of the 3D/4D as-built model of planar structural elements was proposed without using the as-planned data. As-built models are of particular importance to the owner for renovation, maintenance as well as demolition of the existing structure. The proposed
system is a stand-alone method that can be used to assess the progress of construction activities even at times when the planned model is not available. The planned model is however, required to assess the deviations between the planned and the actual states of the project. This approach uses a novel robust PCA to first classify coplanar point clouds. The classified points are then segmented using the complete linkage clustering method. The boundary points of each cluster are determined to break discontinuous surfaces into smaller segments. The planar surfaces are then intersected to determine the vertices of the objects of desire. A novel method is also proposed to robustly extract the floor and flat slab ceilings without the need for the aforementioned approach, which can help reduce the calculation time significantly. A new method of automated registration and point to point correspondence search is also proposed. The two experiments show the effectiveness of the proposed system in automatically generating the 3D as-built model in both a highly occluded laboratory and an actual construction site environment.

INTEGRATING STOCHASTIC FUZZY-LOGIC DECISION SUPPORT WITH BRIDGE MANAGEMENT INFORMATION SYSTEM (BMIS)

Nizar Markiz¹ and Ahmad Jrade²
¹PhD Student, Department of Civil Engineering, University of Ottawa
²Assistant Professor, Department of Civil Engineering, University of Ottawa

Abstract: Over the past few years, infrastructure restoration has been backlogged with multifaceted factors that engrossed the attention of municipal and federal authorities in North America and Europe. Several successful integrations of bridge management information systems with decision support systems and computer aided engineering design solutions had significantly leveraged downstream processes of bridge maintenance operations and inspired many researchers. The subjectivity nature of evaluating bridge conditions and deteriorations is the main factor that influences bridge maintenance, repair, and replacement (MR&R) decisions. In order to overcome this shortcoming, the main objective of this research study is intended to demonstrate the viability of integrating a decision support system with a stochastic gamma deterioration model by utilizing a probabilistic fuzzy-logic strategic approach at bridges network level. Results are anticipated to be of major significance to municipal and federal authorities as well as to bridge stakeholders and considered a vital contribution to bridge management integrated technologies with probabilistic fuzzy-logic decision support strategic approaches.

1 BRIEF INTRODUCTION

Predicting bridge deterioration conditions is the main constituent of infrastructure asset management techniques. Furthermore, a decision support system based on fuzzy-logic theory that assist asset managers in making appropriate MR&R decisions is a necessity for a successful bridge deterioration monitoring program. Given the above-mentioned, a time-dependent prediction of overall bridge deterioration requires the development of a thorough, reliable, and user-friendly fuzzy-logic decision support system to assist contractors in making decisions among maintenance, repair, and replacement strategies. Towards that goal, a wider insight into integrating a fuzzy-logic decision support system capable of assisting bridge assets managers in monitoring, scheduling, and proposing a strategic solution to deteriorating bridge infrastructures based on a standard probabilistic gamma deterioration distribution and comprising independent non-negative increments with identical scale parameters is artistically and objectively being created and deployed.

2 PROBLEM STATEMENT

Economically, it has been proven that often in many situations, maintenance costs exceed annual or semi-annual preventative maintenance costs. However, it is observed that most bridge stakeholders are frequently reluctant to pay for maintenance fees rather than early preventative maintenance costs, which appear to be of no benefit or was found, from previous experience, not successful in preventing a bridge structure from deteriorating. Therefore, integrating bridge performance indicators based on bridge
beneficiaries’ perception on technical parameters with stochastic bridge time-dependent deterioration modeling may be utilized for planning maintenance and deterioration monitoring programs and subsequently prioritizing MR&R activities; such as inspection, sampling, preventative and maintenance operations.

3 MOTIVATION AND OBJECTIVES

The proposed integration is a rationalized approach that justifies most of bridge stakeholders “ineffective” spending as the scale of subjectivity in quantifying bridge deterioration is considerably reduced. Moreover, the integration contributes towards not just reliability of a particular bridge element but also to the reliability of collected data and probability of the occurrence of deterioration benchmarks such as imitation of corrosion and elemental degradations. Therefore, the main objective of this paper is geared towards proposing a fuzzy-logic decision support system based on complex quality functions and a gamma stochastic deterioration model approach, which is based on the integration of the above probabilistic models in an attempt to improve the effectiveness of bridge maintenance management systems.

4 REVIEW OF THE LITERATURE

Highway and transportation authorities have often relied upon simple deterministic deterioration curves for predicting bridge maintenance programs. Recent bridge management systems; however, have implemented Markov chains deterioration models, which are considered as a major step forward towards incorporating stochastic-natured deterioration models. Proceedings and evolutions that tailored the Markov chain approach in bridge management systems were provided in a study published by Frangopol et al. (2001). In another study conducted by Van Noortwijk et al. (2007) gamma processes and peaks-over-threshold distributions for time-dependent reliability is illustrated. In their paper, a comprehensive discussion on the evaluation of structural reliability is presented where a methodology that integrated two stochastic processes originating from a Poisson process for obtaining the temporal reliability of a particular structural component was proposed. In another study conducted by Lounis (2000), it is argued that one advantage of Markov models application is the simplicity of allowing information pertaining to existing bridge conditions and bridge remaining service life to be determined at any given time. Another study conducted by Edirisinghe et. al. (2013) present the application of gamma process for stochastic deterioration prediction of building elements derived from discrete condition data obtained from the Victorian local government infrastructure asset database. Moreover, Reddy and Ramudu (2013) analyze a numerical arithmetic-geometric maintenance model for deteriorating system subject to a random environment. Furthermore, Pandey and Van Noortwijk (2004) investigate a gamma process model for temporal structural reliability and present a relative assessment of random variable deterioration models based on the first order reliability methods and temporal stochastic modeling based on the gamma process. Van Noortwijk et al. (2005) study a gamma process model for temporal structural reliability and presented a combined computational method comprising both deterioration resistance and variable load modeled as a stochastic gamma process. On the other hand, Lounis and Madanat (2002) present a two-level decision support system that amalgamates stochastic deterioration models to enhance efficacy of bridge maintenance management systems. Hence, the majority of these studies have not considered the integration of decision support systems with gamma stochastic process models to assist assets managers in capturing economical maintenance routes and making strategic MR&R decisions. In an attempt to overcome such limitation, reliability-based deterioration models that are based on fuzzy-logic decision support system by the deployment of complex quality functions originating from the house of quality (HOQ) model, presented latter, quantitative and qualitative fuzzy logic scorings that take into account diverse parameters (i.e. technical, functional, safety, etc) are proposed. Moreover, such models are powerful in the manner that they are capable of analyzing single or multiple simple spans of complicated bridge structures of a highway bridge network that possess multiple failure modes and diverse failure consequences. Therefore, the proposed methodology towards the development of the bridge management system incorporates a fuzzy-logic decision support system complete with MR&R solutions integrated with a reliability-based gamma stochastic process models for predicting temporal bridge deteriorations.
5 PROPOSED DEVELOPMENT METHODOLOGY

The proposed development methodology comprises an innovative bridge management information system (BMIS) based on a strategic framework that is capable of integrating bridge gamma stochastic deterioration modeling with a fuzzy-logic decision support system through the deployment of complex quality functions derived from bridge beneficiary-driven parameters and symmetrical triangular fuzzy numbers (STFN’s) to capitulate bridge evaluation ambiguities. Furthermore, the developed framework possesses a unique aspect of BMIS by including several bridge MR&R strategies into a probabilistic matrix factorization to derive competitive priority ratings. An overview of the model development is illustrated in Figure 1.

Model development methodology comprises the following six main steps. At first, data related to the bridge beneficiary-driven technical parameters module components are collected and strategically arranged into a database server. Next, a decision support system that assists the user in making MR&R decisions is implemented. Then, complex quality functions that analyze bridge beneficiaries/users relative perception on the multiple evaluation criteria are incorporated towards the development of a fuzzy-logic decision support system that assist the user in evaluating the condition of a bridge element. Afterwards, a mathematical model is employed to evaluate bridge MR&R scorings and provides solutions on the analysis. Later on, a gamma stochastic temporal deterioration model is created where MR&R ranking ratings are defined and incorporated into the model for prioritization of maintenance operations. At the end, prioritization and optimization of maintenance operation results are presented. Three main modules are then categorized according to actual bridge deterioration monitoring activity sequence. The modules are as follows: 1) selection of optimum MR&R strategy that comprises an automated quality function deployment (QFD), a client-based quality management system based on product beneficiaries/users.
relative importance perception on a set of defined competitors; (2) Multi-criteria decision making approach
equipment fleet cost optimization system that includes analyses of strategies for the selection of the best
bridge maintenance operation alternative based on a specified list of technical parameters; 3) gamma
stochastic process, which contains a time-dependent deterioration model with priority rankings obtained
from the previous module automatically linked to the BMIS software technical database followed by a
report module that displays instantaneous output reports of optimum MR&R strategic solutions.

6 FUZZY-LOGIC DECISION SUPPORT

Presently, bridge MR&R decisions are mainly influenced by the scale of subjectivity involved in bridge
condition assessments. Otayek et al. (2010) have studied the integration of a decision support system
based on a proposed machine technique as part of artificial intelligence and neural networks (NN). In their
study, the authors recommend continuous and further development in decision support systems in an
attempt to assist bridge designers in selecting bridge type at conceptual phases. On the other hand,
Malekly et al. (2012) have proposed a methodology of implementing QFD and TOPSIS for bridge
selection. Their methodology is integrated in a novel oriented approach while overcoming interoperability
issues among the disperse databases. Therefore, authors of this study propose an integration prototype
of a decision support system and MR&R-related attributes. Bridge MR&R decisions are found to be
significantly influenced by each of the following seven main (WHATs) criterion: (1) technical 'W 1'; (2)
functional 'W 2'; (3) safety 'W 3'; (4) construction 'W 4'; (5) economics 'W 5'; (6) aesthetics 'W 6'; and (7)
material 'W 7'. Selection of the WHATs criteria is based on earlier studies on critical factors that
infrastructure asset managers rely upon and authors' perception on bridge criterion importance and
successive bridge condition assessments. A 9-point symmetrical triangular fuzzy logic numbers (STFN)
range from one to nine, with one being very low and nine being very important, is adopted for assisting
the user in predicting bridge beneficiaries perception pursuant to the seven main criteria listed above. The
scoring system comprises crisp and fuzzy measures when uncertainty arises. On the other hand, bridge
beneficiaries are identified in this study and classified as follows: (i) stakeholders/government; (ii)
designers ENGINEERS; (iii) contractors/builders; and (iv) public/residents. Also, the following nine common
bridge types "competitors" are identified and incorporated into the database platform for QFD analyses:
(1) beam bridges 'C 1'; (2) truss bridges 'C 2'; (3) cantilever bridges 'C 3'; (4) arch bridges 'C 4'; (5) tied-arch
bridges 'C 5'; (6) suspension bridges 'C 6'; (7) cable-stayed bridges 'C 7'; (8) movable bridges 'C 8'; and (9)
double-decked bridges 'C 9'. Upon completion of beneficiaries' scorings on the seven WHATs, perception
on relative importance ratings of the seven WHATs is determined. In this study, Chan and Wu (2005)
mathematical expressions are deployed due to their efficiency, systematic characteristics, and ease of
use in competitive analysis of bridge type selection. Crisp and STFN measure forms of relative
importance ratings are obtained in accordance with Chan and Wu (2005) Eqs. 1 and 2.

\[ \text{[1]} \quad g_{mk} = \frac{g_{m1} + g_{m2} + g_{m3} + g_{m4} + g_{m5} + g_{m6} + g_{m7} + g_{m8} + g_{m9}}{9} \]

\[ \text{[2]} \quad \tilde{g}_{mk} = \frac{\tilde{g}_{m1} + \tilde{g}_{m2} + \tilde{g}_{m3} + \tilde{g}_{m4} + \tilde{g}_{m5} + \tilde{g}_{m6} + \tilde{g}_{m7} + \tilde{g}_{m8} + \tilde{g}_{m9}}{9} \]

Where; $g_{mk}$ is a bridge beneficiary relative importance perception on a WHATs criterion in ‘crisp’ form;
k is a bridge beneficiary; $W_{ni}$ is a WHATs criterion; $\tilde{g}_{mk}$ is a bridge beneficiary relative importance
perception on a WHATs criterion in ‘fuzzy’ form. In other words, $g_{mk}$ is the average "integer" crisp scoring
value of a bridge beneficiary on the relative importance of each of the WHATs criteria and $\tilde{g}_{mk}$ is the
average "integer" fuzzy scoring value of a bridge beneficiary on the relative importance of each of the
WHATs criterion. Following the determination of relative importance ratings, bridge beneficiaries’
competitive comparison matrix analysis is developed as per Chan and Wu (2005) Eqs. 3 and 4.
[3] \( X = \begin{bmatrix} x_{mk} \end{bmatrix}_{7 \times 9} \)

[4] \( x_{mlk} = \frac{(x_{m11} + x_{m12} + x_{m13} + x_{m14})}{4} \)

Where; \( X \) is the bridge beneficiaries’ comparison matrix; \( x_{mk} \) is a bridge beneficiary assessment on \( W_m \); and \( x_{mlk} \) is a bridge beneficiary assessment of a bridge competitor on \( W_m \). Afterwards, the probability distribution of each \( W_m \) on bridge competitors is calculated using Chan and Wu (2005) Eq. 5.

[5] \( p_{mk} = \frac{x_{mk}}{x_m} \)

Where; \( p_{mk} \) is the probability distribution of \( W_m \) on bridge competitors; \( x_{mk} \) is a bridge beneficiary assessment on \( W_m \) ‘result obtained from expression (4)’; and \( x_m \) is the total of bridge beneficiary assessment of all bridge competitors on each of \( W_m \). Following the determination of probability distribution of \( W_m \), its measure of entropy, which is a quantification of the expected value of a system with uncertainty in random variables, may be obtained using Chan and Wu (2005) Eqs. 6 and 7.

[6] \( E(W_m) = -\phi_9 \sum_{l=1}^{9} p_{mk} \ln(p_{mk}) \)

[7] \( \phi_9 = \frac{1}{\ln(9)} \)

Where; \( E(W_m) \) is the measure of entropy by a discrete probability distribution for \( W_m \); \( \phi_9 \) is the normalization factor that guarantees \( 0 \leq E(p_1, p_2, \ldots, p_L) \leq 1 \); \( p_{mk} \) is the probability distribution of \( W_m \) for the diverse bridge competitors. Higher entropy or \( (p_1, p_2, \ldots, p_L) \) implies smaller variances and lesser information in a probability distribution \( p_L \). At the end, it is possible to determine bridge competitors’ priority ratings on each of the seven \( W_m \) using Chan and Wu (2005) Eq. 8.

[8] \( e_m = \frac{E(W_m)}{\sum_{m=1}^{7} E(W_m)} \)

Where; \( e_m \) is the criterion weight of \( W_m \).

7 TECHNIQUE OF PREFERENCE BY SIMILARITY TO IDEAL SOLUTION (TOPSIS)

Upon determination of the seven WHATs, a multi-criteria decision making approach, TOPSIS, is undertaken. This approach takes into account the following criteria: (i) qualitative benefit; (ii) quantitative benefit; and (iii) cost criteria. As part of TOPSIS analysis, the following two most contradicting alternatives are surmised: (a) ideal alternative in which the maximum gain from each of the criteria values is taken; and (b) negative ideal alternative in which the maximum loss from each of the criteria values is taken. Towards the end, TOPSIS opts in for the alternative that converges to the ideal solution and opts out from...
the negative ideal alternative. Prior to undertaking the multi-criteria decision making approach, a TOPSIS matrix is developed using Eq. 9.

\[ X = \left( x_{ij} \right) \]

Where; \( X \) is the bridge beneficiaries comparison matrix; and \( x_{ij} \) is an “m x n” matrix with ‘m’ criteria and ‘n’ bridge competitors that display the score of bridge beneficiary ‘i’ on criterion ‘j’. TOPSIS analysis comprises the following consecutive five steps: (i) normalized decision matrix; (ii) weighted normalized decision matrix; (iii) ideal and negative ideal solutions; (iv) bridge competitors’ separation measures; and (v) relative closeness to ideal solution as shown in Figure 2.

![TOPSIS Process Flowchart](image)

In this study, Hwang et al. (1993) mathematical expressions are deployed based on their direct applicability to ranking bridge type alternatives and proven reliability. Generating the normalized decision matrix is intended to convert various parametric dimensions into non-dimensional parameters to allow for contrasting among criteria using Hwang et al. (1993) Eq. 10.

\[ r_{ij} = \frac{x_{ij}}{\sqrt{\sum x_{ij}^2}} \]
Where; \( r_{ij} \) is the normalized scoring value of bridge beneficiaries on bridge competitors’ criteria.

Afterwards, the creation of a weighted decision matrix is obtained by multiplying the criterion weights determined from Eq. 8 by its corresponding column of the normalized decision matrix obtained from Eq. 10 through the employment of Hwang et al. (1993) Eq. 11.

\[ v_{ij} = w_i r_{ij} \]

Where; \( v_{ij} \) is the weighted normalized element of the TOPSIS matrix; and \( w_i \) is the WHATs criterion weight value. Afterwards, the ideal and negative ideal solutions are determined using Hwang et al. (1993) Eqs.12 and 13 respectively.

\[ A^* = \{v_{i1}^*, ..., v_{ij}^*\} \]

\[ A' = \{v_{i1}', ..., v_{ij}'\} \]

Where; \( A^* \) is the positive ideal solution; where \( v_{ij}^* = \{\max v_{ij}\} \) if \( j \in J \); minimum \( v_{ij} \) if \( j \in J^' \); \( A' \) is the negative ideal solution where \( v_{ij}' = \{\min v_{ij}\} \) if \( j \in J \); maximum \( v_{ij} \) if \( j \in J^' \); where \( J \) is the set of beneficial attributes or criteria; and \( J^' \) is the set of negative attributes or criteria. Afterwards, bridge competitors’ separation measures from ideal and negative ideal solutions are calculated by using Hwang et al. (1993) Eqs.14 and 15 respectively.

\[ S_i^* = \left[ \sum (v_{ij}^* - v_{ij})^2 \right]^{1/2} \]

\[ S_i' = \left[ \sum (v_{ij}' - v_{ij})^2 \right]^{1/2} \]

Where; \( S_i^* \) is the separation from the positive ideal solution; \( S_i' \) is the separation from the negative ideal solution; and \( i \) is the number of bridge competitors. Finally, relative closeness to ideal solution is calculated by Eq. 16.

\[ C_i^* = \frac{S_i'}{S_i^* + S_i'} ; \text{ where } 0 < C_i^* < 1 \]

Where; \( C_i^* \) is the relative closeness to positive ideal solution. The recommended bridge competitor or alternative is the one with a corresponding \( C_i^* \) closest to the value of unity “1”. The developed model shall be capable of assisting the user with the MR&R decisions at a bridge network level provided the circumstances given.

8 GAMMA STOACHASTIC MODEL

The general equation for a gamma distribution probability density function is as per the Eq.17.
\[ f(x) = \frac{(x - \mu)^{\gamma - 1} e^{\frac{x - \mu}{\beta}}}{\beta \Gamma(\gamma)} \quad \text{where} \quad x \geq \mu; \quad \text{and} \quad \gamma, \beta > 0 \]

Where; \( x \) is the value of a time-dependent deterioration parameter; \( \gamma \) is the gamma probability density function (PDF) shape parameter, \( \mu \) is the location parameter, \( \beta \) is the scale parameter, and \( \Gamma \) is the gamma function defined Eq. 18.

\[ \Gamma(\gamma) = \int_{0}^{\infty} x^{\gamma-1} e^{-x} \, dx \]

A standard gamma distribution is determined by substituting the shape parameter, \( \mu = 0 \) and the scale parameter, \( \beta = 0 \) and; therefore, the general gamma distribution function reduces to the Eq. 19.

\[ f(x) = \frac{x^{\gamma-1} e^{-x}}{\Gamma(\gamma)} \quad \text{where} \quad x \geq 0; \quad \text{and} \quad \gamma > 0 \]

9 MODEL DEVELOPMENT

The model is being developed through an object-oriented programming (OOP) approach utilizing ‘C#’ and implemented in a classical .NET framework. The main purpose of the model is to facilitate the interface between bridge beneficiaries, MR&R attributes, and gamma shock model functions. At first, the user inputs bridge condition assessment survey results based on the developed fuzzy logic scoring system related to bridge MR&R attributes for the four distinct beneficiaries defined earlier into the QFD module as shown in Figure 3.
Afterwards, a beneficiary comparative matrix is established where parametric weights are assigned for commencement of TOPSIS analysis.

10 SUMMARY AND CONCLUSIONS

In this paper, the viability of developing an integrated fuzzy-logic decision support system with a gamma stochastic temporal deterioration model targeted towards assisting bridge stakeholders and assets managers propose strategic MR&R solutions for deteriorated bridge structures is presented. Comparative analyses of disperse bridge beneficiary driven attributes and MR&R solutions were conducted utilizing QFD systematic approaches. The actual accuracy of the model is highly dependent upon the technical and functional constraints as well as user-defined fuzzy-logic entries. It was concluded that the model possess some limitations pursuant to complex and joint elemental bridge time-dependent deteriorations. It is necessary to mention that the model is proposed as a tool that can be used to eliminate subjectivity in bridge performance assessment and predict the most appropriate maintenance solutions for a particular bridge project. The proposal presented herein may be utilized in bridge projects that involve major degradations where evaluating elemental deteriorations would be a subject to uncertainties. This capability provides the model a great advantage over other bridge performance indicator software packages, prototypes, or models published earlier in literature. Also, results presented in this paper are anticipated to be of major significance to the bridge assets managers and stakeholders and would be a novel contribution to bridge management system approaches and assortment of MR&R strategic solutions.

TRACKING CONSTRUCTION PROJECTS PROGRESS USING MOBILE HAND-HELD DEVICES

Mohamed M. Marzouk and Mohamed M. Zaher
Structural Engineering Department, Faculty of Engineering, Cairo University, Egypt

Abstract: Recent studies have attempted to automate monitoring progress of construction projects using 3D laser scanning or image based reconstruction methods. This paper presents a new methodology for monitoring using mobile hand-held devices such as smartphones and tablet computers. This is done by proposing a new developed android application called “BIM track” that the end-user can use to record the progress of activities (actual dates, percentage complete, and actual cost) from a remote location. BIM track is cloud-based which ads in speeding up the production of construction progress reports and improves data accuracy as it’s connected with Google drive using fusion tables that make the user able to combine/edit the data on the internet. As such, it is capable to collaborate, visualize, and share data through the internet to export the results into an Excel spreadsheet from the mobile application to a remote computer. In addition, the data can be imported to the Navisworks to update the project’s 5D model. Accordingly, time schedules, cost performance (CPI) and schedule performance index (SPI) can be calculated easily. In addition, such results can be shown in 5D model using Navisworks to compare actual progress versus the planned progress. BIM track android application can have an access to any uploaded project’s 3D model using Autodesk 360 as this application is integrated with BIM track. A case study is presented below to demonstrate the use of the proposed methods to track the project and to make a comparison between the actual and the planned progress of the project.

1 INTRODUCTION

Nowadays, there is major developments in Mobile hand-held devices technologies that are highly prevailing that is no longer limited to personal use. Portability and accessibility granted the Mobile hand-held devices such as smartphones and computer tablets a great advantage that attempt recent studies to automate the process of construction site monitoring. A recent survey conducted by McGraw Hill reveals that 93% of random samples of general contractors and subcontractors are now using mobile devices on their jobsites to document workflows (Bernstein and Russo 2012). There are several aspects for improvement in productivity of onsite operations. Any onsite information management system should have the following characteristics (Bowden, et al. 2006) (Golparvar-Fard, et al. 2011) (Son, et al. 2012) (Bae, Golparvar-Fard and White 2013): 1) enable project monitoring capabilities 2) provide easy access to relevant information so that onsite resources could be managed more effectively, and 3) function in near real-time to share information and facilitate interactions among project participant. (Kim, et al. 2013) listed five different categories of studies for mobile computing of construction: 1) development of a framework or platform to demonstrate how mobile computing should be used for construction; 2) mobile computing as a toll for identification or general management; 3) mobile computing for defect management; 4) mobile computing for safety or disaster management; and 5) development of specific features of mobile computing.
As a step towards improving the productivity on site, it is required to perform beneficial reporting system to provide the opportunity for project management to detect the performance deviations. However, typical practice for progress tracking mostly depends on supervisors daily or weekly reports, which involve intensive manual data collection and entail frequent transcription or data entry errors. Field engineers and/or superintendents along with 2D as-planned drawings, project specifications and construction details to review the progress achieved by that date then study these reports. After that, they study the construction schedule to identify the work planned to be done by that date. This requires a significant amount of manual work that may affect the quality of the progress estimations (Kiziltas and Akinci 2005).

To overcome such limitations, recent researches trend moves towards improving construction monitoring through model-based assessment methods, where the expected performance is typically modeled with 4D Building Information Models (BIMs) and actual performance is sensed through 3D laser scanners (Turkan, et al. 2012) (Kim, et al. 2013) or a 3D sensing techniques called 3D image based reconstruction methods (Golparvar-Fard et al. 2009, Golparvar-Fard et al. 2011, Golparvar-Fard et al. 2012). In this paper, the proposed methodology makes benefit of the advantages of the mobile hand-held devices to develop an android application to monitor the construction projects through cloud based service. Time schedule is loaded along with the cost for each activity to generate a 5D model to calculate the planned, and actual values cost during the project. A case study is presented in which this application is deployed on a construction project to endorse its capability to track projects to compare the results.

2 DEVELOPMENT OF BIM-TRACK APPLICATION

This research aims at optimizing the built-in advents of smart phones with other technologies to provide an effective monitoring for progress on-site. (Kim, et al. 2013) listed the advents of smart phones that have become the standard of most smart phones can be classified into Global Positioning System, High-resolution color touch screen, sensors, camera, and high-speed data transfer. BIM-Track android application acquire from the aforementioned advents the High-resolution color touch screen to allow the user to read/add information through the high-speed data transfer to upload captured images integrated with its location as shown in the sections hereunder.

2.1 BIM-Track Structure

In the last few years, the trend toward the mobile computing has significantly increased in the construction management field. BIM-Track mobile application is developed using a combination of the following:

1) Primavera P6 R8.3 (Oracle 2015): P6 Professional is a comprehensive, multi project planning and control software, built on Oracle and Microsoft SQL Server relational databases for enterprise-wide project. Primavera is used to issue a time schedule using CPM (Critical Path Method) and to assign the activities cost for further cost control reports.
2) Revit 2014 (Autodesk, Revit 2015): Revit software is specifically built for Building Information Modeling (BIM), empowering design and construction professionals to bring ideas from concept to construction with a coordinated and consistent model-based approach. BIM Track used this program to create a 3D model.
3) Navisworks 2014 (Autodesk, Navisworks 2015): it is an application which allow the users to integrate the created 3D model with the time schedule and its assigned cost to produce a video that shows the 5D simulation in the project in various stages.
4) Autodesk 360 (Autodesk, Autodesk 360 2015): Autodesk 360 is service provided by Autodesk that allow to share and organize all project data, collaborate on 2D/3D model on the web or on the smart phone.
5) Fusion tables (Google 2015): It is an application similar to Microsoft Excel connected with Google drive that is able to combine the data on the web, collaborate, visualize and share. This service are used in this paper for updating the activities actual durations, actual start, actual finish, performance, and actual cost, etc. where these results can be filtered and summarized across hundreds of thousands of rows.
6) Matlab (Image Processing toolbox) (Mathworks, Image processing tool box 2015): provides a comprehensive set of reference-standard algorithms, functions, and apps for image processing, analysis, visualization, and algorithm development. Image analysis can be performed employing different
techniques including, image segmentation, image enhancement, noise reduction, geometric transformations, and image registration. This tool is used to analyze the progress of the captured images. 7) MIT App Inventor (MIT app inventor 2015) App Inventor is a cloud-based tool that can build android apps using web browser through Java programming language. This tool is divided into a group of blocks that have functions and a design interface for application designing to ease the use with the end-user.

Figure 1 illustrates the supportive applications that constitute BIM-Track” Application.

**Figure 1: Supportive Applications for BIM-Track**

### 2.2 BIM-Track Data Flow

Tracking projects process, in a form of acquiring information and capturing images, is performed by visiting the field office and construction sites. The proposed BIM-Track application provides improved accessibility of project information and site images. Before updating the project’s information, the end-user of the proposed application can obtain the basic information of the preloaded projects that is prepared in the head office. Moreover, the integrated Building Information Model to the application can save time and help in taking fast decision on site, where these benefits are based upon the level of detail of the model. The level of detail (LOD) can be categorized through system published by AIA. (Bedrick 2008) defined five categories for Level of Details (LOD); the LOD 100 as a conceptual stage, LOD 200 as an approximate geometry stage, LOD 300 as a precise geometry stage, LOD 400 is fabrication stage, and LOD 500 as as-built stage.

However, the project information needs to be updated to track the project's status, this happens through the accessible devices as shown in Figure 2. First, the 2D/3D drawings provided by Autodesk 360 have an access to add any comments on the selected element to allow for interactive drawing sharing among the application users to provide the required information and this happens through Mobile computing system. Moreover, the captured image that is assigned to a specific element in the 2D/3D drawings can be used to track the performance in the project. RGB images are converted to binary images to calculate the actual performance using image segmentation. Second, data provided from the fusion tables can be used to update the Time Schedule and the actual cost of each activity to generate an actual 5D model to
be able to compare the actual/planned progress to see the difference between the Actual Cost of Work Performed (ACWP) and Budgeted Cost of work Scheduled (BCWS) through a 5D model.

![Data Flow in BIM-Track](image)

**Figure 2: Data flow in BIM-Track**

### 2.3 BIM-Track Interface

Effective tracking of site activities requires a friendly interface for the end-user to ease the usage of the developed android application. BIM-Track start screen shows the options available to the end-users. First, a button that open a preloaded 5D model is uploaded over the internet, which is updated periodically. The 5D model visualizes the difference between the planned and the actuals on the project as detailed in the sections hereunder, where this 5D model is updated after checking username and password of the user. BIM-Track has a button that shows the essential information such as the location, description, stakeholders, perspectives, and estimated cost of the project. In the proposed BIM-Track application, two tracking methods are used; fusion tables and the 3D model to capture the images for a specific location or leave a comment to the users (see Figure 3).

![BIM-Track Screens](image)

**Figure 3: BIM-Track Screens**
3 SITE MONITORING USING BIM-TRACK

3.1 Image Analysis for Progress Monitoring

Effective tracking for construction projects can have positive results in managing the projects. The developed BIM-Track application enables the users to: 1) visualize the project in 3D, and 2) open the construction project’s drawings to minimize time of acquiring hardcopy drawings. Autodesk 360 is used in viewing the drawings for different projects. For each project, it can be loaded with the 2D/3D drawings or both as per the exported .DWFX file extension using Revit 2014. However, Autodesk 360 is not only used for viewing the drawings or visualizing a 3D model, but it is used for tracking projects as well. Figure 4 depicts that progress can be added in comments where these comments can be added to a specific element in the drawings. Such elements can have markups as pin icon on the drawing, area highlighted, and freehand. Moreover, these comments are used to describe the state of work to perform an effective tracking for construction projects. Subsequently, these captured images are imported to MATLAB image processing toolbox to track the progress of works.

![Figure 4: Tracking project using Autodesk 360](image)

Images acquisition of construction sites is a preliminary step, where such images are attached to specific element in the 3D model. However, the image quality must be fine enough to recognize the objects in the image. Autodesk 360 transfers the captured image through the cloud mobile system effectively to be available through any accessed device. Once the captured site image is downloaded to the PC, it can be processed for progress monitoring. Figure 5 illustrates the procedure of image analysis to identify construction progress for executed typical floors in an administrative building. The RGB captured image using the smart phone shows both de-shuttered slab and other shuttered elements. The image processing tool using the MATLAB is capable to identify number of slabs in the image as a horizontal shapes after reducing the noises in the captured image, where, many of steel scaffolds as an example affect identifying the progress in any captured image. To achieve better results with respect to identification of number of performed slabs any noise should be removed or any element but the slab in the image.

Zou and Kim (2007) used HSV color space as the hue is less sensitive to different lighting conditions than RGB images to differentiate between objects with different colors. They stated that in HSV image, objects of different colors tends to be differentiated from another because hue represents the dominant wavelength of the color. However, the considered captured image colors have near RGB values especially for the shuttered slab. Thus, image segmentation takes place through converting the captured RGB image to grayscale image then to a binary image. Separation the grayscale image occurs to have three different planes 1) red, 2) green, and 3) blue. This process is called image segmentation, which is followed by adding this planes to one plane after adjusting the level of each plane to reduce the noise in the binary image to be complemented. In the complement of a binary image, zeros become ones and
ones become zeros; black and white are reversed. In the complement of an intensity or RGB image, each pixel value is subtracted from the maximum pixel value supported by the class (or 1.0 for double-precision images) and the difference is used as the pixel value in the output image. In the output image, dark areas become lighter and light areas become darker to fill image regions and holes, where these processes named image enhancement. Mathworks (2014) defined image enhancement as the process of adjusting digital images so that the results are more suitable for display or further image analysis.

Image analysis can take place by measuring properties of image regions using a logical operation in the Matlab as the function ‘find (X)’ that locates all nonzero elements of array X, and returns the linear indices of those elements in vector. If X is a row vector, then f is a row vector; otherwise, f is a column vector w. If X contains no nonzero elements or is an empty array, then f is an empty array. In our study X is the white part that is valued to be ‘1’ to detect the slab region and surround them by boundary boxes for users to count and identify the slabs.

![Image analysis procedure](image_analysis.png)

### 3.2 5D Model Development

During the execution of any mega construction project, cost control process takes place to track a project to conclude some parameters such as the budgeted cost of work scheduled (BCWS) which is known as the planned value, budgeted cost of work performed (BCWP) which is also known as Earned Value, and Actual cost of work performed (ACWP). BIM-Track application tends to show the difference between the aforementioned parameters through a 5D model and determine if the project is under or over budget and schedule to make the construction managers plan corrective actions (if any), and implement this corrective actions. A case study was conducted through BIM track android application to achieve this goal, where BIM track mobile has the access to add information to update the activities to enrich the tracked project by generating 5D model using Navisworks. First, information that can be acquired in the developed android application varies such as actual start, actual Finish, progress percent complete, WBS code, and the allocation of the activities responsibility to each Engineer on site. Second, BIM-Track transfers the results through google drive, which is a cloud storage service that allows the users to store the updated information using fusion tables. Third, the actual cost of each activity and budgeted total cost can be updated offsite after exporting the updated results from the android application onsite to a Microsoft Excel comma separated value file (.CSV) through the Google drive. Finally, the final results can be synchronized through the previous update which is imported to the Navisworks.

Now that Navisworks contains the time schedule, financial cost, and the 3D model imported. The final task is to attach each activity in the time schedule to the relevant task manually, or using a function called “Timeliner Rules”. Timeliner rules can attach the tasks to items with the same name, selection set with same name, and layers with the same name this is according to the generated 3D model technique, where the process of attaching the tasks is one time process as updating the 5D model will depends only on adding the information of each activity.
4 CASE STUDY

As a verification of image analysis for site monitoring, a case study for a construction Mega project for an administrative building located in Smart Village, Giza, Egypt with total area 13,000 m2 was performed to verify the usage of BIM track android application using a Sony Xperia C smartphone with 5 inches TFT capacitive touch screen, 8 Mega pixel front camera with Quad-core 1.2 GHz Cortex-A7 processor. Using mobile 3G/WCDMA networks that enable data transfer. A Joint Photographic Experts Group (JPEG) image format was captured on April 16, 2014 for a typical floor slab to apply image processing to track the project for the concrete skeleton, as the concrete works in the similar projects shall be critical activities. As shown in Figure 6, the converted binary image in figure 6c is noisy and such noise need to be removed, and the slabs shall be clearer. A manual trial and error process takes place for some variables to: 1) choose appropriate level of thresholded color plane to integrate the sum of all planes, 2) the intensity of the filled holes in the converted binary image. For evaluation process, the progress information represented with the user visual recognition compared with the Matlab results after trying different values for the variables to validate the counted number of slabs as illustrated in Figure 6. As a preliminary result, it was found an incorrect progress due to the disruption caused by the horizontal parts of the steel scaffolds and the shuttering, wherefore filled holes value between slabs has been increased to get the result as shown in Figure 6g.

![Image](image.png)

Figure 6: Case Study Image analysis procedure.

065-7
Moreover, it shall be mentioned that it’s recommended to fix the camera in same position and level to easily identify further progress without any trail and errors for image analysis to keep sure that the whole process is automated. This place recommended to be out of reach to keep sure that the position did not change every update. Tower cranes is highly recommended for this process. Whilst for the verification of generating a 5D model for the same project and scope of concrete works, BIM-Track android application was tested for sharing the updated activities to Google drive fusion tables over the internet, where the input data were activity name, performed progress percentage, actual start, actual finish, WBS code, and the site engineers allocated to the activity. These data were used to update the time schedule on the Primavera with data date May 17, 2014 to update the previous update with data date May 10, 2014. And thereafter, the updated time schedule was exported to the Navisworks in .CSV format to synchronize it with additional data calculated with the Primavera. This data were the planned value, earned value, and the actual cost of work performed for the activities. As such, the Navisworks was able to export three 5D model for May 17, 2014 data date to 1) Monitor project, 2) visualize the updated/planned 3D model where the process of fixing the steel reinforcement is presented in red color, shuttering for columns and slab is presented in yellow color, and at the end of pouring concrete activity is presented in the model final appearance (see figure 7) and 3) Compare the final total cost. These results were used to calculate important parameters for cost control management to check if the project is under or over budget, and ahead of behind schedule using the following functions, considering Cost Performance Index (CPI), and Schedule Performance Index (SPI), respectively as shown in Figure 7. The results show that the project is under budget, and behind schedule where the estimated CPI and SPI are 1.02 and 0.94, respectively. These results need a proper immediate action to recover within the next updates that is performed on a weekly basis.

Figure 7: 5D model visualization.

5 CONCLUSIONS

Mobile hand-held devices such as smart phones, and tablet computer with other computing technologies provided a powerful system for tracking construction projects. The objective of this study was to develop an android mobile application connected with other applications to aid in tracking projects through storing the updated data over a mobile cloud computing system. BIM-Track the developed application have two method of tracking which are image analysis for progress monitoring, and 5D modeling for the planned and actual progress. The application enables project monitoring and it provides easy access to project’s information, and facilitates the visualization interaction through the 3D model. Image analysis provided
information about the captured images using Matlab, whilst Navisworks used the updated information form the fusion tables to generate the 5D models. A case study for Administrative building under construction was presented to illustrate the use of the proposed application.

References

Abstract: Today, the demand of sustainable buildings is getting higher. The main purpose of buildings is to provide a comfortable living environment to their occupants, considering different aspects including thermal, visual and acoustic comfort as well as Indoor Air Quality. Life cycle assessments are related to many issues such as environmental concerns. Decreasing carbon foot print and energy consumption rates and increasing comfort level for the building users can help to achieve environmental improvements. This comfort level is related highly to Indoor Air Quality (IAQ). This research aims at improving environmental concerns using building information modeling. As-built BIM model is developed to act as a hub to allow transformation of information to an external database, extracted from the BIM Model in COBIE (Construction-Operations Building Information Exchange) format. The database is updated in a dynamic manner to reflect external environmental changes. The environmental changes are captured using sensors that can detect variations in temperature and humidity. Also, carbon emissions and energy consumption rates are reflected back on the model. A case study is presented to demonstrate the use of the proposed framework.

1 INTRODUCTION

Green building concept has been adopted by the construction industry as a response for the global environmental challenges leading to successful results. Abbaszadeh et al. (2006) found that thermal comfort, air quality, furnishing, cleaning and maintenance achieved higher rates for satisfaction in LEED-certified green buildings compared to those non-green counter parts. On the other hand, clients are looking for the added benefits coming from applying the concept of sustainable buildings as they have to increase the capital cost invested to perform their projects Paul and Taylor (2008). Previous research concluded that the aspect of sustainable and green buildings will become the most common among people when they get sure of the benefits and financial gains achieved from their projects as a result of the occupants improved productivity (Zuo et al. 2014). This improved productivity is assigned to the comfortable and satisfying environment provided for their users. Interoperable Carbon Information Modeling (iCIM) project provides an online tool to facilitate carbon assessment of a building by informing designers regarding their decisions and impact of their decisions throughout the building life cycle (iCIM 2011). According to the norms of building automations, it was found that comfort is an important characteristic compared to the usual security and safety issues. It was found also that thermal comfort and air quality are very important and significant factors in deciding the building sustainability and the human comfort level (Singh et al. 2011, Kang and Park 2000).

According to the American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE 2013) and International Organization for Standardization (ISO) 7730, thermal comfort is defined as a
“State of mind that expresses satisfaction with the thermal environment”. Paul and Taylor (2008) performed a comparison between a green university office building and two conventional universities office buildings all located in Australia. They conducted a survey using questionnaires to examine comfort and satisfaction of users. The questionnaire included temperature, humidity, lighting, aesthetics, acoustics, serenity and overall satisfaction. The green building was having a level of thermal comfort higher than the two conventional buildings. A sustainable building is a function of comfortable and healthy spaces, reducing the generated waste, reducing the used natural resources and lower usage of energy. Kang and Park (2000) developed an integrated comfort sense system for indoor climate, three measurement environmental parameters were used in the system; temperature, humidity and air flow. ISO 7730 considered other parameters such as clothing level, activity level and mean radiant temperature. ZigBee technology-based environment was developed to monitor the indoor and outdoor environmental measurements. The procedures of thermal comfort analysis were proposed in literature (Kumar et al. 2010, Kumar and Hancke 2014-a, Kumar and Hancke 2014-b). Smart systems of thermal comfort sensing can be utilized as a practical tool for monitoring thermal comfort in homes, automobiles, office buildings, etc. (Kumar and Hancke 2014-a). Air conditioning systems can only sense air temperature as they are having obstacles in placating inhabitants in the building environment. But the technology in this area developed new methodologies and designs to achieve the demand of the best possible smart air conditioning system as it can provide the required value of comfort and control in an optimized environment (Kumar et al. 2010, Kumar and Hancke 2014-b). Ventilation is considered one of the effective systems that can improve the internal Air quality (IAQ) (Paul et al. 2010, Liu and Liu 2005), whereas, HVAC is having different control ventilation strategies. One of these strategies is called dual-mode ventilation control method it can save about 8.3-28.3% in electricity usage compared to the conventional fixed-rate controlling strategies (Chao et al. 2004). Other factors such as lighting, internal motions and activities also can play important roles in achieving the goal of occupants comfort level and would be taken into consideration.

Building Information Modeling (BIM) is considered one of the shining technologies developed to increase the efficiency of construction industry. Its function was extended to help in the facility management process by using the As-built BIM model and it is used also in monitoring the facility behavior over its life time as a way to increase the level of control on the building even in operations or maintenance. These great advantages are results of the comprehensive information stored in the model during the construction process. The functional and physical characteristics of a facility can be modeled digitally using BIM (Marzouk et al. 2010). COBIE (Construction Operation Building Information Exchange) is one of the IFC (Industry Foundation Classes) formats was developed in the aim of facility management improvement. It exports all model data in a manner that helps the facility manager to apply a high level of control, understanding all the building components, improve data quality and cut costs at projects turnover. Marzouk and Abdelaty (2014) proposed an integration between subways BIM-based models and Facility management process using a semi-automated inspection system. The system was developed using Wireless Sensor Network (WSN) inside the subway for detecting temperature and humidity. This paper presents a study that was performed on a university building located in Riyadh City the capital of Saudi Arabia. The building is a multifunction building where it has offices, laboratories and a lecture hall. The aim of the study is to evaluate the building behavior over the year regarding the Indoor Air Quality issues (temperature and humidity) and improving the occupants comfort level with respect to energy consumption rates and carbon footprint. The result may play a role in providing sustainable building and a higher convince for owners in achieving valuable benefits.

2 PROPOSED MODEL

The proposed model is developed to represent the idea of improving the IAQ in a certain facility building; the idea enhances the process of building design and management system with more data assessment for temperature and humidity taking into considerations their dynamic nature over the year due to the external environmental changes. The assessment results are used to improve the occupants comfort level inside the building with respect to the consumption and usage of energy and the carbon emissions produced. As-built BIM model is used to monitor the system behavior and weather the occupant’s comfort level is maintained or not. The model has to reflect any defects in the system behavior to the facility
 manager. Tracking the temperature and humidity changes is performed through sensors located in all the building spaces. These sensors are provided by (Dantec Dynamics 2012). The proposed model links the as-built BIM model to the assessment results through an external data base that is updated frequently with the sensors data and updating the As-built BIM model back with these data. The data are analyzed in the external database to ensure that they provide the required comfort level and notify the facility manager with any defects through the BIM model if the comfort level is out of the comfort range. The facility manager is then allowed to locate the problem and apply the required response plan immediately. The COBIE is considered one of the special information exchange tools that is designed to help in facility management. The COBIE sheet is chosen to be an external database. As such, the can manage the process easily and respond to any defects immediately to maintain the occupants’ comfort level. The designated procedure of the proposed model is illustrated in Figure 1.

![Figure 1: Proposed model procedure](image)

### 3 LOCATING SENSORS

At the model first stage, the process of measuring temperature and humidity had to be optimized by tracking the temperature and humidity behavior over the year and their effect on the IAQ and the occupants comfort level. In response to this problem, a thermal analysis was performed on the building. This thermal simulation was developed on the As-built BIM model with the help of the Revit and Ecotect software. The procedures of the analysis were first performed on the Revit as all the model spaces were defined and the model was exported in the GBXML format as shown in Figure 2. Then the Ecotect role started by importing the GBXML file. The non-defined spaces were remodeled on the Ecotect and the as-built materials were defined. Then, the building functional data were defined. Each space function was defined according to its function (office, laboratory or lecture hall) and according to the function the settings were adjusted. The thermal properties of the building were selected; the HVAC system was a Fan Coil System working on the concept of Constant Air Valve (CAV) with an assumed efficiency of 95%. Then, the thermostat range for environmental temperature range for comfort was defined, and then the lighting settings were set for each specified space. Then, the operation schedule was defined according to the hours of operations of each zone, these data were assumed according to the University working days.
After defining the space properties, the building was located on the map in its accurate location using Google Earth as shown in Figure 3. Then, the Riyadh city weather file was attached to the model and the solar path was defined according to the building orientation. Figure 4 shows monthly charts for the general effect of defined data on the building. After running the simulation, the critical spaces were identified due to their affection with external environmental changes through the year so that the analysis could be completed in an efficient way. The critical spaces were not all highest points of temperature and humidity in the building, but also lowest temperatures and humidity zones were critical so that it is possible to predict other building spaces data using interpolations and averages after receiving the actual data measured from the sensors located in the building.
4 LOCATING SENSORS

This section presents the experiment procedures and the methodology of analyzing the experiment outputs. The sensors were located in the building according to the performed thermal analysis. Ten spaces were chosen to monitor the internal air quality with respect to temperature and humidity. Three temperature probes and humidity probes were used in each space at the same time to improve the measurement accuracy Table 1. The experiment was performed in 23rd of November 2014 at 14:00 with a switched off Air Conditioning. Sample of the results are shown in Table 1. The sensors’ measurements were compared to the results of the thermal analysis that was conducted using Ecotect software. The thermal analysis was performed by applying the same experiment conditions. The thermal analysis results were approximately similar to the sensors measurements and that increased our trust in the performed thermal analysis even in defining the critical zones inside the building or in further capabilities in monitoring the indoor air quality. One of the critical spaces (named Space 5) was considered for the analysis (see Figure 2). A sample of the thermal analysis that shows inside and outside temperatures is depicted in Figure 5, taking into consideration conditions that are listed in Table 2.

5 ENERGY ANALYSIS

The energy analysis process was performed to monitor the efficiency of the building behavior in dealing with energy usage rates and carbon emissions. In this stage, the As-built model (GBXML format) was imported to Autodesk Green Building Studio software. The building systems were defined as stated before in previous stages and then the simulation experiments were conducted. The results of the simulation as shown in Figure 6 indicate the values of energy consumption due to different factors such as lighting, air conditioning, hot water and other factors. Simulation was carried out on the building by changing the internal systems to improve the energy usage and decrease the carbon emissions. The first simulation experiment was conducted to study the impact of changing the HVAC system from Fan Coil System to Variable Air Valves (VAV) system. This change improves the HVAC efficiency regarding the number of occupants in each space. The second simulation experiment was conducted to study the impact of using lighting occupancy sensors instead of manual lighting switched. Figure 7 shows that lighting efficiency and occupancy sensors can significantly contribute in more energy savings. These two extra simulations illustrated an improvement for the building behavior as shown in Table 3. The efficiency of building behavior was improved at the Variable Air Valve (VAV) simulation as the electrical and fuel usage and carbon emissions were decreased and went to their minimum rates at the second simulation.

6 UTILIZING COMFORT LEVEL

COBIE (Construction Operation Building Information Exchange) is considered one of the tools that can help in the process of facility management. It is used to provide two main advantages; the first is that the extracted COBIE sheet enables a full monitoring on the building objects and a system regarding their operations and maintenance, and the second is linking all the previous stages together to track and improve IAQ (see Figure 8). All measurements coming from sensors are imported into the COBIE sheet in a new tab in tabular form matching the COBIE format as the new tab could be linked with the Sheet using the unique element identifier. Also, the Energy analysis data are imported to the COBIE using the same procedures. The method of importing sensors measurements and Energy analysis to the COBIE is performed with the aid of Visual Basic for Applications programming language (VBA). The imported measurements are compared to the standard comfort range for temperature and humidity as stated by (ASHRAE, 2013): Temperature (22-25°C) and Humidity (31-41%) and if the sensors measurements were out of the comfort range the COBIE will reflect this back on the BIM model and give alert to the user with these out of range measurements so that the user can fix the problem immediately. Alerts would be a notification email to the responsible person. Another COBIE function is its ability to give the user alerts in case of any system expected shortage due to the end of its service life. These problems may be concerned with the HVAC system, lighting system or any system that could affect the users’ comfort level regarding the IAQ.
7 CONCLUSION

This paper presented a model for tracking IAQ using BIM. The model is performed with the aid of different tools such as Revit, Bentley AECOsim, Ecotect, Green Building Studio and COBIE to increase its functionality. COBIE is extracted from the As-Built BIM model to act as a database for different measurements conducted through the building service time such as temperature, humidity, energy usage and carbon emissions. This database is frequently analyzed to make sure that the measurements are fulfilling the occupants comfort level and reports any negative incidents to the BIM model giving alerts to the model user. The paper also proposed some optimized alternatives to the existing design such as using the Variable Air Valve HVAC system instead of Fan Coil Unit and using lighting occupancy sensors instead of manual switches. These alternatives maintained the required comfort level with decreasing energy consumption and carbon emissions.

Abstract: There has been an increase in the practice of managing multiple projects as the number of megaprojects has decreased and firms try to manage a larger number of smaller projects. The use of portfolio management is growing in the industry to allow firms to maximize the use of their limited resources. This paper reports on the outcome of a comprehensive survey, which was supported by the Construction Industry Institute (CII) and a team of 17 experts from various firms. The survey focused on identifying contemporary portfolio management practices by asking 28 questions on five topics: firm information, makeup of a portfolio, current practices, performance metrics, and implementation. The survey was designed to give an insight into what successful owners and contractors have done in implementing portfolio management. It was found that owners approach portfolio management differently from contractors. Owners generally establish strategic business objectives and select projects and form their portfolios using their available resources. On the other hand, contractors try to win projects and follow their clients’ regulations; however, they still need portfolio management to efficiently manage their projects. A major emphasis of this research effort was the list of performance metrics used in portfolio management. Owners who successfully implemented portfolio management within their firms have practiced the use of a formal project prioritization system in a portfolio. All of these firms use dashboards with performance metrics to show the performance of a portfolio. The Main indicators found on current dashboards include cost, schedule, safety, and overall success of the portfolio.

1 INTRODUCTION

The objective of the research was to identify recommended practices for project portfolio management. In this research, a portfolio is defined as a group of related or unrelated projects and/or programs managed by a single individual, hereafter referred to as a portfolio manager. This definition was decided by the research team and is different in some respects from the standard definition in the Standard for Portfolio Management (PMI 2013), which considers meeting strategic business objectives of a firm by implementing a portfolio approach. The research team consisted of the authors and a group of 17 industry experts from CII member firms.

The research goals were covered in three main stages as shown in Figure 1. The Survey is included in the “Collect Data” stage prior to interviews and case studies. The purpose of the online survey was to
help in identifying the principle drivers, metrics, tools, processes, and techniques, of successful portfolio management and also, the main barriers to successful implementation of portfolio management in various firms. Another purpose of the survey was to help in screening and identifying the most appropriate firms for in-depth face-to-face interviews. The online survey questions were designed with the help and participation of all team members. The research team finalized the 28 questions following two goals. First, the survey was designed such that respondents could complete it in 30 minutes or less. Second, the questions were organized in a logical way so that the respondents could see the continuity of questions.

![Figure 1: Three stages of the research methodology (CII RR303)](image)

The research team made a major effort to extend the data collection beyond the CII data liaisons. For this purpose, the members of Construction Management Association of America (CMAA) and Construction Users Round Table (CURT) were contacted to increase the response rate. The research team helped in identifying and introducing individuals who could contribute to this effort.

## 2 CATEGORIES OF QUESTIONS

The survey questions were divided into five categories: 1. Firm information, 2. makeup of a portfolio, 3. current practices, 4. performance metrics, and 5. implementation.

Six questions under the “firm information” category were designed to collect information regarding the firm type, industry sectors, and the name and role of respondents. The survey was intended to gather information from all types of firms, public and private, CII and non-CII, and owner and contractor.

The “makeup of the portfolio” category included six questions to get a perspective on formation of portfolios in terms of size, duration, and dollar value of projects. Moreover, other questions were asked about the availability of individuals who managed multiple projects and their titles.

The next category, “current practices,” included seven questions. These questions attempted to collect information regarding available tools on portfolio management in 13 various areas such as schedule, cost, cash flow, procurement, resource allocation, communication, quality, scope, change management, safety, risk management, issue management, and/or Key Performance Indicators (KPIs). Moreover, some questions were about using standard tools and practices, using CII best practices, prioritizing projects, and giving authorities to portfolio managers at the portfolio level.

One of the goals of the research was to identify useful applicable metrics in different areas. Six questions under the “performance metrics” category were designed to understand the available metrics in 15 areas including the 13 aforementioned areas and overall portfolio health and success. One question was about the areas that metrics could be included in a dashboard; moreover, respondents were asked about the importance of including these 15 areas in an ideal dashboard. A five points Likert scale with 1 (least important) and 5 (most important) was used to identify the importance of areas in an ideal dashboard.

Three questions were included in the “implementation” category. These questions were designed to measure the level of portfolio management success within firms, to understand the barriers in a successful application of portfolio management, and to understand any related suggestions or comments.
3 FIRM INFORMATION

The online survey was launched using the SelectSurvey™ tool provided by the CII. The survey was sent to 306 individuals in 251 firms. This included 130 CII and 121 non-CII firms. The response rate was 45% of email recipients and 36% of firms. These rates compare favorably with similar data collection efforts using the online survey tools (Nulty 2008; Hamilton 2011; Johnson and Owens 2003). Slightly over half of those interviewed were from CII firms as shown in Table 1.

</table>

* Number of Respondents ** Percentage of Respondents

The survey was designed to get a perspective on portfolio management in different industry sectors. Respondents could select as many industry sectors as they were active in. Table 2 shows the percentage of individuals responded to the survey in different firm types. More than three-fifths of those interviewed were in heavy industry sector. Several of the firms interviewed were engaged in more than one sector of the construction industry; hence the sum of percentages goes well over 100. The firms in “Other” sector were active as consultant, manufacturer, healthcare provider, software developer, and educator.

4 KEY FINDINGS AND STATISTICAL TRENDS

The analysis of responses to other four categories of questions, makeup of a portfolio, current practices, performance metrics, and implementation, are explained in this section.

4.1 Makeup of a Portfolio

Almost all firms responding to the survey have individuals who managed a group of projects. Portfolio management was practiced in 87 (96.7%) firms, and only three firms did not use portfolio management extensively. The widespread use of portfolio management indicates the necessity and relevance of the research in all industry sectors. The three firms that did not have individuals to manage multiple projects usually have very large projects managed by one person. Two of these firms still have portfolio management for small projects with a total budget of less than $5 million.

Individuals who manage a portfolio of projects have various titles. The most common title is project manager following by project director, program manager, and portfolio manager. Many firms have several titles for individuals who managed a group of projects at different managerial levels; hence the percentages do not add up to 100 as shown in Table 3. The respondents had 48 other roles in the “other” category such as senior executive, global construction manager, vice president, etc.
Table 3: Titles of individuals responding to the survey (percentages)

</tbody>
</table>

The survey asked about the extent of portfolio manager’s authority in the following four areas: 1. Budget, 2. Work force, 3. Procurement strategy, and 4. Sequence of execution (schedule adjustment). The level of authorities was different depending on the positions of respondents in various managerial levels. Contractors chose “work force” and “sequence of execution” as the top two areas where authority is given to portfolio managers. The authorities varied from portfolio to portfolio, client to client, and site to site for contractors. Owners selected “budget” and “sequence of execution” as the two top areas of authority given to portfolio managers.

The topic of formation of portfolios was investigated considering the typical duration, budget, and the number of projects in a portfolio. 54% of firms do not assign more than 10 projects in a portfolio. More than one-third of respondents do not typically allocate more than six projects to a portfolio. CII owners typically have more than 50 projects in their portfolios while the majority of other firms have less than 6 projects as shown in Table 4. CII owners were mostly active in heavy industrial sector with numerous periodic maintenance needs; therefore, the typical number of projects in their portfolios was more than 50. For other firms, less than 6 projects were dominant due to the large size of the projects. In each table, the largest figure on each row is bolded.

Table 5 illustrates that the most common portfolio budget range is larger than $100 million among various types of firms. The size of portfolios was mostly in excess of $10 million. Comparing the portfolio budget range with the number of projects in a portfolio, it could be concluded that firms typically form their portfolios either with many small projects or a couple of large projects.

</tbody>
</table>

The typical duration of projects is longer than one year for over three-quarters of respondents while majority selected 12 to 24 months. On the other hand, about one-third of respondents have projects that were typically longer than two years. Over 42% of non-CII contractors selected more than 24 months as the typical portfolio budget range.
4.2 Current Practices

The questions in this section were focused on portfolio management current practices. Three independent questions asked about using tailored, innovative, standard or customized (commercial or custom-built software) tools, and a fourth question asked about tools under development for portfolio project management. Moreover, the survey asked about the use of CII best practices for portfolio management. Then, the last two questions on this section were about the use of a formal prioritizing system for projects.

4.2.1 Tailored Tools

Almost all of the firms with portfolio management practices have tailored project management tools, techniques, and processes to manage multiple projects. Tailored tools are the customized tools, which are available in the market, adjusting with organizational processes. The graph in Figure 2 shows the percentage of tailored tools used in each area for portfolio management.

![Percentage of firms using tailored tools and processes in different areas](image)

Figure 2: Percentage of firms using tailored tools and processes in different areas

The thick dashed lines indicate that the non-CII firms had higher rates of customized tools in most of the areas except resource allocation, compared to CII firms. The thin dashed lines show that owners have slightly higher rates of using customized tools in cash flow, cost, procurement, and scope while contractors have considerably higher tailored tools in other areas.

4.2.2 Innovative Tools

In the majority of firms, 37 out of 55, use innovative tools and techniques on portfolio management. Table 6 illustrates the breakdown of respondents who used innovative tools within various firm types. CII owners used innovative tools more than other types of firms. It should be noted that the term "innovative tools" could be open to interpretation by the respondents. One person’s innovative tool can be a common practice to another. Reviewing the responses showed that most innovative techniques consisted of customizing existing off-the-shelf software, however, some firms had developed elaborate software systems for their portfolio management practice.

</tbody>
</table>
Firms mostly used customized software in the fields of cost, schedule, change order, and information management. Owners had some common processes and procedures such as outsourcing of software services, standard stage gate process, and balanced scorecard. The Microsoft Project Portfolio Planner was used only in one owner firm. On the other hand, contractors used several tools such as web based Primavera-P6, software on iPad, and the master integrated schedule tool. One of the contractors had his own portfolio management software for managing projects around the world. A comparison between owners and contractors highlighted that the use of Primavera-P6, Portfolio Contract Management, SAP portfolio management, and EVMS were common among owners and contractors.

4.2.3 Tools under Development

Several tools are being developed in firms. Two firms were customizing Unifier Portfolio Manager for portfolio management. This software is useful when a financial goal should be set for a group of projects. Other firms are planning to use server-based software such as PMWeb, repository Citrix, eBuilder, Capex, and custom access databases. Collaborated workflow using Microsoft SharePoint was also implemented to transfer information among divisions. Primavera-P6 or other ORACLE software for Portfolio Management (Oracle R12) and SAP were commonly used by both owners and contractors.

A comparison between contractors and owners show that both were trying to securely share data among their projects and define the work flows. The use of data sharing software such as eBuilder and SharePoint were common among owners and contractors while for this purpose some customized tools were being developed by owners. Owners also used Capex and Citrix for data sharing. They were working to customize software such as Oracle Unifier, Oracle R12, and SAP for managing a group of projects.

4.2.4 Use of CII Best Practices for Portfolio Management

Over two-thirds of respondents, 47 out of 70, had never adapted CII best practices for portfolio management. CII owners used more CII best practices for portfolio management compared to CII contractors. A CII best practice is a “process or method that, when executed effectively, leads to enhanced project performance” (CII Webpage).

A few firms used CII tools for portfolio management. For example, BMC (a software company) have developed some tools based on the CII best practices. The use of CII best practices on safety, PDRI, resource allocation, lessons learned, planning for start-up, team building, front end loading (FEL), and front end planning (FEP) were noted by respondents.

A comparison between the CII contractors and owners showed that the use of PDRI was common among them. One of the owners used the Independent Project Analysis (IPA) tools and processes that are similar to CII tools. Some contractors considered their clients’ viewpoints and needs to design a customized FEL or FEP process.

4.2.5 Project Prioritization within Portfolios

The project prioritization is crucial for the survival of firms to create the highest value using limited resources. 52.9% of firms did not use a formal system of project prioritization within their portfolios. The prioritization system was used by CII and non-CII owners more than contractors. The percentage of owners who used formal prioritization was higher than those who did not.

The respondents did not specify any standard prioritization method for the projects in a portfolio. Some firms have established criteria to prioritize projects, but the prioritization method was not stated. Some firms indicated simple methods for prioritization such as project deadlines, open communication with client, weekly project meeting, safety, revenue, operation improvements, turnaround date for installation, and resource requirements. Some systematic processes were also indicated using tools such as Work Load Planner, in-house risk-based system, SaaS, and StrataJazz.

Even though multicriteria decision making (MCDM) methods are available and many research reports and case studies have been published especially on Analytical Hierarchy Process (AHP) (Vaidya and Kumar
2006) and PROMETHEE (Behzadian et al. 2010), these were not widespread within the industry. Introducing the advantages of the MCDM methods to industries could motivate them to implement a formal process for project portfolio formation.

4.2.6 Standard or Customized Software

Schedule and cost received the highest rate of software usage by both owners and contractors. Procurement and Cash Flow got the third and fourth ranks for owners while Cash Flow and Resource Allocation had similar rank for contractors. Issue and Risk Management had the lowest software usage among owners; and Scope and Issue Management software for contractors. The two most common software in 7 different areas of project management are listed in Table 7. The term “Internal” means the software was developed in-house and could be based on off-the-shelf software.

4.3 Performance Metrics

Six questions were included in this section. The intent was to identify the metrics that firms used and what information could be included in an ideal dashboard. The questions focused on measuring portfolio performance in 13 areas, improving metrics on these areas, visualizing the portfolio performance on a dashboard, weighting the importance of different areas on a dashboard.

4.3.1 Portfolio Performance

More than 81% of firms have metrics to measure and monitor the performance of their portfolios. Over half of the CII firms who were using portfolio performance metrics were owners. The percentage of non-CII owners using portfolio performance measures was also higher than contractors, 37.5% compared to 34.4%. The top five areas to measure portfolio performance have similar ranks among both parties. Cost, schedule, cash flow, change management, and safety were the five areas that had similar ranks among owners and contractors. Figure 3 depicts the number of respondents selected each of the areas to measure portfolio performance.

![Figure 3: Frequency of metrics selected in various areas to measure portfolio performance](image-url)
### 4.3.2 Improving Metrics in Various Areas

Owners and contractors have different needs regarding developing metrics in various areas. Less than half of respondents expressed their needs to improve metrics for the 13 areas. The highest needs to metrics improvement were respectively on resource allocation, schedule, and cash flow for owners; and schedule, resource allocation, and KPIs were identified for contractors. Figure 4 depicts the number of respondents interested in having improved metrics in various areas to measure the portfolio performance. The rank of various areas differs for owners and contractors; however resource allocation and schedule are the top two areas that need improved metrics.

![Figure 4: Frequency of areas that need improved metrics to measure portfolio performance](image)

### 4.3.3 Dashboards

59.1% of firms use some sort of dashboard to visualize the portfolio performance. A higher percentage of CII owners and contractors have a dashboard compared to non-CII owners and contractors. Table 8 depicts the statistics of respondents using a dashboard.

<table>
<thead>
<tr>
<th></th>
<th>Yes</th>
<th>No</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>#</td>
<td>%</td>
</tr>
<tr>

</tr>
<tr>
<td>Non-CII Owner</td>
<td>9</td>
<td>29.0</td>
</tr>
<tr>
<td>Non-CII Contractor</td>
<td>6</td>
<td>19.4</td>
</tr>
</tbody>
</table>

Cost and schedule were the top two areas that owners and contractors include in their performance dashboards. Besides cost and schedule, contractors chose change management as the third top area, while owners selected safety and cash flow as third and fourth top areas. In this paper due to space limitations, a short list of metrics is shown in Table 9 for the five major areas that performance metrics are mostly used. A complete list of metrics for 9 areas (schedule, cost & cash flow, safety & environment, change management & scope management, resource allocation, procurement & supply-chain management, quality, risk management, and client satisfaction) is available in CII document IR303-2.

Safety, cost and schedule were the top three areas that owners and contractors chose in an ideal dashboard. Therefore, an ideal dashboard should at least cover these three areas.

4.4 Implementation

The survey asked about the level of success in implementing portfolio management by the firms. They were also asked about the barriers in implementing portfolio management. Almost half of firms, 42.6%, rated the portfolio management success as “Average” in their firms, while less than two percent rated the implementation of portfolio management in their firms as “Best in Class.” The barriers based on the respondents’ ideas are listed in Table 10.

</tbody>
</table>
5 CONCLUSIONS

Portfolio management is used by almost all of the firms that participated in this survey. The majority of firms are utilizing software tools to better manage their portfolios. The survey has identified various areas where these tools are used, with the top three areas being schedule, cost, and procurement. Primavera-P6 and MSP are the two major tools in the area of schedule while SAP and internally developed tools are used for cost. SAP, Smart Plant, and internally developed software are used in the area of procurement for portfolio management. In all of the areas except schedule, firms have tailored existing tools or developed custom-built software to better adjust with their processes.

Firms use a combination of KPIs to track and measure the performance of their portfolios. The most common KPIs on dashboards are in the areas of cost and schedule. Change management is important for contractors as the third KPI and safety and cash flow for owners. The ideal dashboard should include at least three KPIs, cost, schedule, and safety.

The survey showed that even though portfolio management has been practiced in firms for more than 30 years, it still has some barriers such as standardization of processes, centralization of databases, prioritization systems, customization of dashboards, and generalization of concepts, justification of benefits to cost of implementation. Removing these barriers, which may be the subject of future research, can assist firms to improve the efficiency of their resources while pursuing their strategies.

Abstract: Design coordination and conflict detection are the most common and highly valued uses of Building Information Modeling (BIM). The process is essential as critical design decisions are often made in this stage. BIM promises to support automatic evaluation of building design, rather than the manual, iterative and time-consuming evaluation of CAD drawings. However, we have observed that current BIM tools are unable to identify many types of design coordination issues and that these issues are particularly challenging to manage and resolve. This research is based on ethnographic field studies of two building design coordination processes, examining how practitioners identify, resolve and document design issues during design coordination process. We coded and analyzed over 60 meetings to investigate the characteristics of BIM design coordination issues, and developed a framework based on prior research and our own observations to classify design coordination issues. We classified design coordination issues into seven categories of spatial, clearance, physical, inquiry, systematic design errors and missing information. We also observed and analyzed design issues' frequency of occurrence, and investigated the resolution rate of design issues. We believe our characterization of design issues can help practitioners better identify, categorize, resolve, and document design issues, as well as re-using generated knowledge of resolving same type of issues throughout design coordination.

Keywords: BIM, Design Coordination, Design Issue, Errors, Clash Detection, Collaboration, Interactive Workspaces, Design Artifacts, Building Systems, MEP coordination.

1 INTRODUCTION

In complex building projects, design coordination is a critical and challenging task. It involves the detailed layout and configuration of the various building systems such that it complies with design, construction, and operations criteria (Tatum and Korman 2000). Recent advancements in Building Information Modeling (BIM) tools have had a significant impact on the efficiency and efficacy of the design coordination process. Studies have shown that design coordination and conflict detection with BIM is one of the most frequent and valued uses of BIM in the construction sector (Bernstein and Jones 2012). Communication of project information through paper-based information representations limits the team’s ability to work together, to solve problems and make decisions during design meetings (Fischer et al. 2002). In contrast, teams using BIM tools for Mechanical Electrical & Plumbing (MEP) coordination are
found more likely to be satisfied with the meeting process and spend less time arguing over issues compared to paper based design coordination meetings. (Liston, Fischer, and Kunz 2000).

BIM supports the automatic evaluation of building design, rather than the manual, iterative and time-consuming evaluation of CAD drawings (Lee, Park, and Won 2012). However, we observed that not all design coordination issues are identifiable using state of the art BIM tools, specifically the design issues that are not geometrically identifiable (using the geometry of building components to automatically detect conflicts). Prior research (e.g. Tabesh and Staub-French (2006), Wang and Liete (2014)) have addressed many aspects of design issues including their context and classification. However, they focused on design issues that are geometrically identifiable (e.g. conflicts between two components), rather than non-geometrically identifiable (e.g. inquiries, and missing model components).

We conducted two ethnographic case studies of complex building design coordination processes using state of the art BIM tools. We characterized the design issues practitioners identified, resolved and documented throughout design coordination, through developing a framework for classifying design issues based on prior studies and our own observations, analyzing their frequency of occurrence in both case studies, and investigating the resolution rate of the design issues in one of the case studies. We found that the case study in early construction stage, involved more design issues of constructability and incorrect design details whereas the one in late construction stage faced more design issues of inquiry, and as-built missing components.

2 MOTIVATING CASE STUDIES

We performed two ethnographic field studies of design coordination processes to gain a better understating of the current practice and identify its shortcomings. Over the course of design and construction, BIM was used extensively to coordinate designs involving different consultants and sub-trades. In both projects, the meeting participants consisted of representatives from the different trades involved in the project, including the owner, the construction manager, architect, engineering consultants and construction sub-trades. The meetings always had at least six active participants and in most cases the MEP coordinator and the BIM navigator were present. On some occasions, when a participant was not present, he/she participated remotely through conference calls or online video conferencing tools.

Case study A: The newly constructed Pharmaceutical Sciences Building (Figure 2) at the University of British Columbia, Vancouver campus is a 18,000 m² facility, providing a variety of teaching and learning spaces from lecture halls and seminar rooms, to a pharmacist clinic and three floors of research laboratories. The project had considerably complicated MEP systems along with a unique architectural design, which made design coordination and constructability the key concerns for this fast track project. Since the beginning of construction, weekly meetings were held in our BIM Trailer (Figure 1) on the construction site. The BIM Trailer was equipped with two large-screen touch displays, connected to separate computers displaying 2D and 3D digital information. Construction of the project started in June 2010 and the building was delivered on time for occupancy in September 2012. Most participants were the ones creating the BIM for trades, so they had considerable experience with BIM. However, few participants were less familiar with interactions with BIM and digital tools.

Figure 1: Meeting environment from a design coordination meeting in case study A.
Case study B: currently under construction (early construction stage), the Royal Alberta Museum (Figure 3) building project involves the construction of a 25,349 m² building located in downtown Edmonton, Alberta on a site measuring 20,024 m². The project, in its current state, was initiated in 2011 under a design-build procurement mode. The total budget for this project is $340M while the construction budget alone is $260M. The project is scheduled to be completed in June of 2016. In terms of level of expertise with BIM, most project participants have no experience (35%) or consider themselves as beginners (35%) while 22% consider themselves advanced BIM users. We remotely participated, recorded and observed participants conducting design coordination, as well as observing and analysing various design coordination issues participants identified, resolved and documented throughout design coordination.

2.1 Design Coordination Issue Resolution Process

Based on our observations, we have come to understand that resolving a design coordination issue using BIM involves a cycle of three interconnected steps: Issue preparation (identification) issue resolution and issue documentation (Figure 4). Each of these design coordination steps shown in Figure 4 are comprised of smaller (micro) steps that shape the current practice of identifying, resolving and documenting BIM design coordination tools. This section attempts to better illustrate the micro steps involved the process as well as highlighting the observed challenges practitioners face throughout design coordination process. We elaborate this by showing how one particular issue which we observed was identified, resolved and documented in a case study.

Figure 4 - BIM design coordination process

Figure 5 - image 1 shows an issue the BIM navigator picked among hundreds of geometrically identified issues. He examined it in detail, and communicated it with project coordinator. In the same figure - image 2, shows how the coordinator zoomed out to inspect the issue. He then communicated it with different building systems representatives and found the need for a group discussion. He prepares another view (Image 3) to better outline the issue and the systems involved prior to issue resolution meeting.
To better show the remaining steps involved in resolution of above design issue, Figure 6 – images 1 and 2 shows how that issue was presented, shown and discussed in the coordination meeting as well as how participants interacted with the design artifacts. In image 3, the architect sates that the issue needs to be further discussed as input from other project stake holders are required. At this stage the coordinator determines that the issue needs to be documented for future follow-ups.

In terms of issue documentation, once the discussion on a certain issue reached an end (e.g. resolved, required further input from a different source, or needed follow up in the future), depending on the importance of the issue, the coordinator documented the details of each issue including its status, location, involved systems, snapshot(s), entry and solution dates, proposed solution and details of how it could be resolved in a spreadsheet containing all issues (Figure 7). In both projects A & B, the same documentation format, and details were used to document the issues. However, in project A, participants kept all resolved and non-resolved issues in a single file, and in case study B they used multiple files.

Figure 7: Design Issue Documentation
2.2 Limitations of Current Practice

Although the current process of identifying and preparing Issues seem ad-hoc, often when two building systems are integrated using state of the art BIM tools, thousands of design conflicts are detected, including numerous false ones. As Table 1 shows, the issues involved in design coordination sometimes go beyond simply geometrically detected design issues. Such design issues involve practitioners' knowledge and expertise to be able to be identified. In prior research this is often called practitioner’s rationale (Tommelein and Gholami 2012), which requires deep understanding of different construction systems, requirements and the codes.

While attempting to classify the issues observed in both case studies, we were unable to classify observed issues using the current points of departure in the field. Although previous studies (e.g. Tabesh and Staub-French (2006), Tommelein and Gholami (2012), Wang and Liete (2014), and Lee, Park, and Won (2012)) have effectively addressed major geometrically identifiable design coordination issues (e.g. a mechanical duct conflicting with structural column caps), few research characterized issues that are more complex in nature and are not identified through model based automatic clash detection (we call these non-geometrically identifiable). Design issues such as inquiries about maintenance and installation, or wrong dedicated openings in different systems (Table 1) have a significant impact on the design coordination process.

Most researchers (Inc. Tabesh and Staub-French 2006, Tommelein and Gholami 2012, Wang and Leite 2012) have focused on geometrically identifiable design issues, however, we believe there is a need for a wider framework that can address and classify both geometrically and non-geometrically identifiable BIM design issues. We believe having access to such framework can improve design issue identification and documentation for BIM based design coordination processes. We envision having a framework combined with a central repository for design issues for classifying design issues can help practitioners classify design issues from the beginning of issue identification, track issues throughout their resolution and help with issue documentation throughout the BIM design Coordination process.

3 RELEVANT LITERATURE

This research has built on findings of past research as a foundation of the framework we have developed in section 5.1. although different researchers have used different terminologies (including design errors, conflicts and MEP clash) for referring to what we call BIM design coordination issue (design issue in short) in this article, there are notable similarities between their research and ours that helped us
significantly to build the framework. In this section we aim to address these points of departures briefly and highlight what we have built on:

As one of the pioneers of design coordination issue characterization, (Korman, Fischer, and Tatum 2003) classified design issues into three main categories of design criteria, construction, and operations issues. They also identified design issue attributes as geometric characteristics (component dimensions) and topological characteristics (spatial relationships). This work later on became a foundation to which (Tabesh and Staub-French 2006) built on to further classify design issues as tasks of conceptual reasoning (i.e., design validation, detailing, and sequencing), spatial reasoning (i.e., layout, routing and positioning) and underlying reasons behind the constraints identified in each discipline (i.e., tolerance, productivity, space, performance, access, safety and aesthetics).

Other researchers such as (Wang and Liete 2014) attempted to address design issue resolution knowledge capture, they attempted to provide a formalized representation schema for MEP coordination to present factors involved in cash analysis, clash resolution and management. Similar to this study their schema was developed based on literature review and findings of two case studies. On the other hand, they solely focused on geometrically identifiable issues, covering clash description, clash context, clash evaluation, and clash management items. In another attempt, while proposing a structured method for analysing BIM’s return on investment other research (Lee, Park, and Won 2012) classified design issues in terms of their cause, likelihood of identification, impact on schedule, impact on quality and impact on direct cost.

Previous research mainly focused on characterizing geometrically identifiable design issues for BIM building design coordination meetings. Most issues identified in the previous research focused on the components itself. These included highlighting BIM’s capabilities and strength for visualization of design issues (Tabesh and Staub-French 2006), representing geometrically identified clashes (Wang and Liete 2014), and formalizing knowledge representation for clashes (Tommelein and Gholami 2012). BIM design coordination issues are comprised of both non-geometrically and geometrically identified design issues. Non-geometrically intedentified issues are mostly manually identified, often comprising of multiple geometrically identified design issues. Although the current research has provided a good point of departure for characterizing and classifying design issues, our findings suggest that there is a need a for a better design issue classification framework that can address all design issues in BIM design coordination processes.

4 METHODOLOGY

We observed (in-person and remotely) and video recorded weekly design coordination meetings from the early stages of design through construction of the building systems, recorded over 43 design coordination meetings of which 32 meetings were held in our BIM trailer on case study A, observed the design coordination process in case study B through design and early construction of building structures, and analysed design coordination meetings in both case studies A & B. We conducted a qualitative assessment of the meetings initially to determine our focus area for a detailed analysis. We had access to construction documents, BIM files, site progress, design issue spreadsheets and some of the communication between project participants.

In particular, we investigated how design issue were identified, communicated among project coordinators and navigators, presented and resolved issues, their documentation approach and their future follow-up regarding each issue. We considered each issue first and tracked how that issue was identified through checking the BIM files of each meeting, how it was resolved through observing specific segments of the meeting related to that issue and by analyzing participants’ notes and issue documentation spreadsheets regarding each issue. This methodology enabled us to conduct most of our research qualitatively, rather than the quantitatively.

In addition, in order to investigate issue identification process in detail, we conducted a think-aloud observation (Lewis, 1982) while a BIM Navigator performed issue preparations on a high-rise multipurpose facility in Vancouver, BC. We asked the navigator to say whatever he was looking at,
thinking, doing, and feeling as he performed task. This enabled us to see first-hand the process of task completion. We observed how the navigator performed 3D model integrations and clash detection, distinguished between true and false clashes, communicated with the project coordinator to discuss each issue and prepared the coordination meeting agenda. This observation method helped us to better capture how design issues are identified and how participants communicate and work together prior to meetings.

Throughout this study, we have aimed to build our research methodology based on recommendations of (Green, Kao, and Larsen 2010). We are following their research protocol to continuously compare collected data and search “for resonance with conceptual ideas derived from ongoing literature searches”. Figure 8 shows our adaptation of methodology for their suggested methodology for generating theory through ethnographic case study. This methodology has allowed us to continuously improve our findings as we studied the literature.

5 CHARACTERIZATION OF DESIGN COORDINATION ISSUES

5.1 Design Issue Classification Framework

As discussed above, through observation and characterization of design issues in both case studies A & B, we found essential points of departure to help us better shape our understanding of issue classification. In Table 2, we have shown various design issues we observed along with their identification (detection) method, category, sub description, example of an actual issue that we captured, as well as a snapshot of that issue, to better elaborate our classification of the design issues. We also have identified the design issues previously identified by each key point of departure. The key points of departure used in the framework are respectively (Korman, Fischer, and Tatum 2003),(Tommelien and Gholami 2012),(Wong and Lelle 2014), and (Lee, Park, and Won 2012).

To elaborate further on what we have built on in terms of classification of design issues from the existing knowledge, we have adopted he most common classification of design issues: hard (actual) and soft (extended) ((Korman, Fischer, and Tatum 2003) and (Tabesh and Staub-French 2006)). As well as the time clash which refers to constructability and order of components being installed (Tommelien and Gholami 2012). We also built on (Lee, Park, and Won 2012)’s identification design issue causes: illogical design, discrepancies between drawings, and missing items. These classifications are explained below.

5.2 Analysing Design Issues in Case Studies A & B

We have classified the observed issues in both case studies A & B based on our developed framework (Table 2). The issues in each case study were investigated independently based on what the practitioners have documented and our own observations of the meetings. Having two case studies helped us to validate and evaluate the framework. During the analysis of the issues, the framework was re-iterated multiple times, revisiting issue categories, terminology and examples multiple times to ensure all design issues in both case studies could be classified using the developed framework. Also, having two case studies helped us achieve a wider generalizability for the developed framework. In total we analysed 98 issues from case study A and 120 issues from case study B (Figure 9). The figures show each design issue sub-category using different colours, as well as their frequency of occurrence in relation to total number of issues in each case study in a percentage format.

As Figure 9 shows, both projects nearly equal proportions of issues due to systematic design errors, these include illogical design, trade design conflict, and multiple systems conflicts. However, due to the stage of each case study the design issues handled by each team differ.

</tbody>
</table>

Since, case study A was in the handover phase whereas case study B only had its major structure built at the time of this study, it is not surprising to see case study A’s time design issues (constructability) twice the size of design issues in case study A. On the other hand, we can see more inquiries in case study A, which could be due to the final stages of the project where multi project stake holders require different things.

In addition, it is not surprising to see no design issues relating to as built models, since there were little mechanical components installed at the time of design coordination. However, it is noticeable that incorrect design detail issues (e.g. wrong opening sizes) were almost 3 times higher in case study B. this could reflect the miss-coordination between different system prior to construction phase. In addition, missing model components contributed to an average of 7% of design issues in both case studies, which can emphasis on the importance of having every discipline meeting the coordination deadlines.

5.3 Analyzing Issue Resolution Rate

Classifying the design issues in the previous section, we found that in some issue resolution meetings, participants identified and resolved more issues than others. Also, towards the end of construction on case study A, a large number of design issues remained un-resolved on the documents. Therefore, we conducted an issue resolution rate study to better understand how often design issues were added, resolved and how many of them remained unresolved by the end of each meeting. We performed this study by tracking and analyzing issues of 12 consecutive design coordination meetings (Figure 10). These 12 meetings were the last design coordination meetings for case study A.

Furthermore, it is surprising that 20% of the design issues remained unresolved by the end of design coordination stage (final days of construction). We believe some of these issues could have been resolved on site, or they were not on the priority to-do list. Also, we observed that participants often spent
Finally, in terms of design issue documentation, we observed when design coordination meetings were poorly documented, the result had a direct influence as to preparations of the next meeting. For instance, in one occasion, the meeting coordinator could not attend the meeting and no other participant was in charge of the meeting documentation and task assignment, as a result the first 30 minutes of the next meeting was dedicated to revise prior progress and the meeting ended early as the necessary models were not prepared by responsible trades for design coordination.

6 CONCLUSION AND FUTURE WORK

We have conducted two ethnographic field studies to understand how participants identify, resolve and document design coordination issues in BIM based building design coordination processes. We developed a framework to classify both geometrically and non-geometrically identifiable design coordination issues, analyzed two case studies based on developed framework, investigated design issue resolution rates, and highlighted the role of documentation on issue preparations of subsequent meetings. Our characterization identified the non-geometrically identifiable design issues that were rarely identified in the previous research.

We believe further validation strategies are required at this stage in order to highlight the shortcomings of the developed framework. In particular we envision conducting feedback sessions with practitioners to ensure that the developed framework resonates with their knowledge. Other strategies could include performing industry workshops, in order to capture insights of other practitioners specifically not those in Feedback Sessions to achieve wider generalizability.

Abstract: This paper describes the development of a constraint programming (CP) model for schedule optimization to satisfy both deadline and resource constraints in large-scale construction projects. Unlike many meta-heuristic methods in the literature, the CP model is fast and provides near-optimum solutions to projects with hundreds of activities. The IBM ILOG modeling software and its CPLEX-CP solver engine have been used to develop the proposed CP optimization model for solving the multi-mode resource-constrained project scheduling problem. The model takes many constraints into account, including project deadline, penalty (liquidated damages), incentive, and multiple resource constraints. The paper compares the CP results with the results of other methods, such as heuristic and genetic algorithm optimization, on case studies from the literature to prove the practicality and usefulness of the CP model. The paper also reports the results of CP optimization on larger projects of 1,000 to 2000 activities, which is common in construction practice, and is too large to be solvable by other methods. This research contributes to developing a practical decision support system for resolving real-life constraints in construction projects.

1 INTRODUCTION

Optimizing construction schedules has concerned many researchers in the past decades. In the literature, a broad category of schedule optimization models are referred to as multimode resource constrained problems, when each activity has more than one mode of execution with different resource requirements and costs. In the multimode problems, the main optimization objective has been either:

(a) Minimize the total project duration, while not exceeding resource limits. This problem has been referred to as (Multimode resource constraint scheduling problem, or MRCSP), or

(b) Minimize the total project cost, while not exceeding resource limits or a deadline constraint; which is referred to as (Multimode resource constraint time-cost trade-off, or RC-TCT).

While both cases involve multi-modes and resource constraints, case (b) is more general as it considers both cost and time in its formulation. Despite the extensive research in the literature in both aspects, no commercial software includes any time-cost trade-off (TCT) heuristic to help meet deadlines, let alone any procedure to resolve both deadline and resource constraints. One of the main contributing reasons, perhaps, is that both of these problems are known to be nondeterministic polynomial-time hard (NP-hard), which are very difficult to solve, particularly for large-scale problems.

In the literature, there is a large body of knowledge related to resolving either the RC-TCT or MRCPS problem. Each problem by itself is considered a large-scale problem that has a large number of possible solutions, even when few activities are considered. In general, however, each of these problems has been addressed by three types of techniques, as follows: (1) traditional mathematical (exact), (2)
heuristic, and (3) metaheuristic (artificial intelligence-based). Good surveys of the exact, heuristic, and metaheuristic procedures for the MRCPS P and the RC-TCT problems are found in Peteghem and Vanhoucke (2010), and in Menesi and Hegazy (2014), respectively.

To the writers' knowledge, none of the literature efforts of the three solution types have addressed large-size problems. Most efforts discussed small demonstration examples of 10 or 20 activities and the few efforts that handled medium-size problems (a few hundred activities) required an unreasonably large time to provide a solution. Kandil and El-Rayes (2005), for example, reported a GA processing time of 55 h for a case study of 360 activities, which was reduced to 9.3 h using a system of parallel computing with 50 processors. One of the latest efforts to handle large-scale problems is the heuristic model of Hegazy and Menesi (2012) for resolving the RC-TCT problem. Their case study of 360 activities required 32 minutes to be solved, which is much faster than GAs, for the same size problem. However, even this heuristic method is expected to take many hours in the case of much larger problems than 360 activities, thus the key drawback of these methods is that finding near optimal schedules for large scale is very time-consuming and solution quality greatly degrades with problem size (Hegazy and Menesi 2012; Menesi et al. 2013; Ling and Fang 2011). The primary objective of this paper, therefore, is to introduce a new model using constraint programming (CP) to provide fast near-optimum solutions to much larger-scale multimode optimization problems, thus providing a practical approach to optimize construction schedules.

2 CONSTRAINT PROGRAMMING

Constraint programming (CP) has been successfully used to solve complex combinatorial problems in a wide variety of domains (Chan and Hu 2002; Heipcke 1999) by combining operations research and logic programming techniques. To facilitate the use of CP algorithms in scheduling problems, IBM developed a powerful software library, called IBM ILOG CPLEX Optimization Studio (Beck et al. 2011). It incorporates a CP engine (with IBM ILOG CPLEX CP Optimizer) that has specialized syntax for modeling scheduling problems and other combinatorial problems that cannot be easily linearized or solved using traditional mathematical programming methods. The CPLEX-CP optimizer defines the scheduling problem by: a set of time intervals representing activities to be completed; a set of constraints that apply during these intervals or between intervals; and an objective function. Once the model is coded using the modeling language of the IBM ILOG tool (as discussed in the next section), the problem is solved by the CPLEX-CP solver engine using two techniques to find a solution: constructive search and constraint propagation (initial and during search). The initial constraint propagation removes the possible variable values that will not take part in any solution, thus reducing the search space. The constraint propagation during the search, on the other hand, removes all values that violate the constraints. The CP optimizer then uses a constructive search strategy to guide the search for a solution in the remaining part of the search space. The CP optimizer engine continues to search using constructive search and constraint propagation until a solution is found. In the literature, various researchers reported the advantages of CP in scheduling problems. Efforts include Liess and Michelon (2008) for solving the resource-constrained project scheduling problem; Liu and Wang (2008) for solving resource-constrained project scheduling problems considering cash flow; Liu and Shih (2009) for construction rescheduling optimization; Liu and Wang (2011) for optimizing overall profit and satisfying various resource constraints; and Menesi et al. (2013) for time-cost-resource optimization in large-scale projects.

3 CP MODEL FOR SCHEDULE OPTIMIZATION

3.1 General activity representation

Consider a construction project with \( n \) activities, each activity \( i \) has a set of associated construction methods \( (M_i) \). Each method \( k \) (from 1 to \( M_i \)) represents a construction mode or a way of carrying out activity \( i \). Associated with this method \( (k) \) is a specific duration \( (d_{ik}) \), cost \( (c_{ik}) \) and resources \( (r_{ik}) \). Naturally, these construction methods vary from cheap-and-slow to fast-and-expensive, thus offer ways to speed the activity, if needed. Based on these construction options, the planned duration \( (D_i) \) and direct cost \( (C_i) \) of each activity \( i \) can be expressed as a function of which method is used, as follows:
Where, \( X_{ik} \) is a binary variable that indicates which method \( k \) is planned for activity \( i \). Thus, if \( X_{ik} = 1 \), then method \( k \) is the one used for activity \( i \), while \( X_{ik} = 0 \) for all other methods. To make sure only one mode of construction is used for each activity, one constraint is needed for each activity, where the sum of the method indices \( X_{ik} \) s should equal to 1.

\[
\sum_{k=1}^{M_i} X_{ik} = 1 \quad i = 1, 2, \ldots, n \quad (3)
\]

**Network Logic Constraints:** The network logic is defined in a set of hard constraints. The logical relationship between any activity \( i \) and its immediate predecessor \( p \), is expressed as:

\[
SS_i - SF_p \geq 0 \quad p = 1, 2, \ldots, NP \quad (4)
\]

Where \( SS_i \) is the scheduled start time of activity \( i \); \( SF_p \) is the scheduled finish time of the predecessor activity; and \( NP \) is the number of immediate predecessors for activity \( i \).

**Resource Constraints:** The project resource constraints are expressed in the model as follows:

\[
\sum_{i \in S_t} r_{ikl} \leq R_{lk} \quad l = 1, \ldots, L; \quad t = 1, \ldots, T \quad (5)
\]

Where, \( S_t \) is the set of eligible activities in time period \( t \), \( r_{ikl} \) is amount of resource \( l \) required by construction method \( k \) of activity \( i \), \( R_{lk} \) is the amount of resource \( l \) available in time period \( t \), \( L \) is number of resource types, \( t \) is the time period \( (t = 1, \ldots, T) \), and \( T \) is project completion time.

### 3.2 Problem-specific formulation

**Case of MRCPSP problems:** Objective Function is to minimize the project duration \( T \), as follows:

\[
\text{Minimize } T \quad (6)
\]

Where \( T = \) Maximum scheduled finish time \( SF_p \) among all activities

**Case of RC-TCT problems:** At the project level, the direct cost of the project is noted as \( PDC \) and the indirect cost as \( PIC \), thus, the total project cost \( (TPTC) \) can be expressed as:

\[
TPTC = PDC + PIC \quad (7)
\]

Where, the project direct cost is the summation of the activities’ direct costs in Eq. 2, as follows:

\[
PDC = \sum_{i=1}^{n} C_i = \sum_{i=1}^{n} \sum_{k=1}^{M_i} c_{ik} X_{ik} \quad (8)
\]

The project indirect costs, on the other hand, are project-duration dependent; the longer the project duration, the more indirect costs are incurred and vice versa. The relationship between \( PIC \) and the project duration \( (T) \) can be expressed as:

\[
PIC = IC_0 + IC \cdot T \quad (9)
\]

Where \( IC_0 \) is the fixed indirect costs (e.g., permits, mobilization cost, temporary hookups, temporary facilities, purchase advances), and \( IC \) is the indirect cost per time period (i.e., daily expenditures), and \( T \) is the total project duration. To consider practical scheduling situations, the model adjusts the total project
cost considering penalty and incentives amounts. If the project schedule is delayed beyond a defined
deadline, the delay cost \( C_{pd} \) is expressed as:

\[
C_{pd} = Y \times C_d \times (T - \text{deadline duration})
\]  \hspace{1cm} (10)

Where: \( Y \) is a zero-one variable representing if a project delay occurred (i.e., \( Y = 1 \) if the project duration \( T \) is greater than the deadline duration), and \( C_d \) is the cost of project delay per day (i.e., delay penalty).

On the other hand, if the project is scheduled to finish before the deadline, the incentive for early completion is expressed as:

\[
IN = Z \times B \times (\text{deadline duration} - T)
\]  \hspace{1cm} (11)

Where \( Z \) is a zero-one variable representing if the schedule is completed earlier than the deadline (i.e., \( Z = 1 \) if project duration \( T \) is less than the deadline duration), and \( B \) is the incentive per day saved.

**Project Completion Constraint:** The project completion constraint is expressed as:

\[
SF_e \leq \text{Deadline Duration} \quad E = 1, 2, \ldots, NE
\]  \hspace{1cm} (12)

Where: \( SF_e \) is the finish time of ending activities, \( NE \) is the number of ending activities.

Objective Function is to minimize the sum of the costs described above, formulated as follows:

\[
\text{Minimize } C = TPC + C_{pd} - IN
\]  \hspace{1cm} (13)

### 3.3 Multi-objective CP Model

In addition to the above single-objective multimode model in which the objective was to minimize the total duration or cost, another bi-objective multimode model was developed to include a secondary objective to minimize the fluctuations in the resource usage (resource leveling). The resource leveling problem itself is also a NP-hard problem and aims at achieving the most efficient resource utilization by reducing the peaks and valleys in the resource usage profile, without increasing project duration (Ponz-Tienda et al. 2013). One of the benefits of CPLEX-CP is that it has an internal function staticLex that can define an objective function with multiple objectives, with the first objective being most important, and so on. Utilizing this function, a multi-objective version of the CP model was developed with two objectives: (1) minimize project duration for MRCPSP problems or minimize project total cost for RC-TCT problems; and (2) minimize the peak resource demand. This is based on the fact that reducing the peak use of resources results in a more levelled resource profile.

### 4 IMPLEMENTATION AND RESULTS

Both of the proposed single-objective and multiple-objective CP formulations have been modeled in IBM ILOG CPLEX Optimization Studio, as shown in Figure 1. The figure shows a portion of the CP code and the ILOG modeling environment. Once developed, the CP models were applied to literature case studies.

#### 4.1 Experiments on the MRCPSC problem

The developed CP models for MRCPSC was applied to a 10-activity project reported in Zhang (2012) who compared the solutions among three metaheuristic methods, and thus can be readily compared with those of the CP model of this paper. Each activity in the project has up to three modes of execution and one type of renewable resource. The project network and the three modes for each activity are shown in Figure 2. The available amount of resources is limited to 5 resource units per day.

#### 4.2 Single-Objective Experiments on Small Projects

The results of single-objective CP optimization were compared with the results of three metaheuristic methods for the case study reported in Zhang (2012): ant colony optimization (ACO); particle swarm optimization (PSO); and genetic algorithm (GA). The comparison of results shows the superior performance of the CP model in terms of solution quality and processing speed. Repeating the
experiments several times for this 10-activity case, the ACO algorithm could achieve the best result (14 days) only 81% of the time, which is better performance than PSO and GA. The CP solution, on the other hand, achieved the 14-day optimum solution in all experiments. To verify the CP solution, the resulting activities’ start and finish times were entered into Microsoft Project Software, as shown in Figure 3a. The figure verifies that project duration is shortest, non-critical activities are not crashed, and that the resource-loaded schedule does not exceed the resource availability limit.

![Figure 1: ILOG CPLEX Optimization Studio](image1)

![Figure 2: Project network and activity modes for a 10-activity case study project](image2)
Single-Objective Experiments on Medium and Large Projects: Experiments on medium and large-scale projects were carried out. The 10-activity project of Zhang (2012) was used as the basis for creating larger projects with 100, 500, 1,000, 1,500, and 2,000 activities. The results of three experiments for the case of 100 activities experienced processing time of 1 s, 1 min, and 3 min, respectively. In the 3-min case, CP reached the optimal solution and, thus, its deviation from the optimal solution is zero. Also, for a 500-activity project, the CP model was able to reach a solution with a duration deviation of only 4.6% within 10 min. The quality of the CP solution for the same 500-activity project was then greatly improved when the processing time was extended to 30 min, reaching a deviation of 2.57% from the optimal solution. Therefore, for medium-size projects, the CP model can reach within 3% from the optimal duration, without violating resource limits, within a reasonable processing time (can be much faster if experiments were done on a desktop machine). For the 1,000-activity case, increasing the processing time to 2 h reduced the deviation from 18.9 to less than 5%, whereas in the 1,500-activity case; the deviation was greatly reduced from 21.0 to 7.3% when the processing time was increased from 1 min to 2 h. For the 2000-activity case, which is extremely large, the deviation remained at about 9.6% even with a processing time of 3 h. This result is considered practically reasonable. A deviation of 4.78 or 9.61% from optimum in the cases of 1,000 and 2,000 activities are not high. Without optimization, solutions are expected to be much worse or cannot be achieved. Figure 4 summarizes CP solutions for different problem sizes. Based on these results, the CP model proved to provide good solution quality with
reasonable processing time (20 min), thus, proving the practicality of the CP model in handling large-scale projects.

![Figure 4: Solution quality and processing time for different sizes of MRCPSC problems](image)

**Multiple-Objective Experiments:** The bi-objective model was then tested on the 10-activity case study and was found to work extremely well and does not require additional processing time. The resulting resource profile of the bi-objective optimization for the 10-activity project (Figure 3b) shows a much better resource profile than the single-objective solution in Figure 3a. The bi-objective model was also tested on the 1,000-activity case, with a processing time of two hours. The optimization reduced the solution deviation to 5%, with a standard deviation of daily resource usage being 1.018 (as compared with the single objective case that produced a 4.78% solution deviation and 1.030 standard deviation of resource usage). This shows the ability of the CP model to correctly trade-off among the objectives used.

### 4.1 Experiments on RC-TCT problem

**Single-Objective Experiments on Medium and Large-Scale Projects:** The case study of Chen and Weng (2009) was used as the basis for creating larger-size projects (1000, and 2000 activities). The base case study project consists of ten activities having up to 4 discrete options that use varying amounts of one limited resource. The experiments using the CP model and the heuristic method were performed for the base case of 10 activities and for the projects of 300, and 2000 activities. Table 1 presents the optimization results for each experiment, including the solution’s total cost, project duration, processing time, and deviation from optimum solution. As shown in Table 1, the CP solution for the 10-activity project (involving 38 variables and 51 constraints) reached the optimal solution in one second. For large-size projects with 2000 activities, which is extremely large, the deviation remained at about 6.5% even with longer processing time (up to 2 hours). This result is considered practically reasonable and the CP model proved to provide good solution quality with reasonable processing time (30 minutes), thus, proving the practicality of the CP model in resolving the combined schedule constraints in large-scale projects. This result represents a benchmark for further research to improve upon.

5 CONCLUDING REMARKS

Project managers usually have different options to complete activities with different resources and different production rates. Widely used scheduling software, such as Primavera P6 and Microsoft Project, do not have an option to enter more than one construction method or mode for an activity. In other words, using these software systems, project managers have to manually enter one option at a time in order to see the impact of using different activity modes on the project completion date. Currently, more owners are asking the contractors to submit and use resource-loaded schedules to manage their projects. While resource loading schedule may be a difficult exercise, it enables management to assess the amount of resources available and avoid risks early in project planning. If the resource-loaded schedule alerts decision makers that the available resources will not suffice to execute the work on time as planned, management can begin negotiating for additional resources early in the project.

This paper presents a fast and powerful tool for project managers based on constraint programming to perform what-if analysis for large-size projects and enables them to efficiently utilize their resources. Although it is possible to load the activities modes automatically into the CP process, a full automated process is not yet developed. This process automation is currently an ongoing task by the authors to fully link the CP model with Primavera P6 or Microsoft Project software, which are the industry most-used scheduling software systems. Another limitation of the current CP model is the fact that it is designed to optimize the schedules before construction starts. Serious modifications are therefore needed to modify the model so that it accepts actual progress information and then produces an optimized corrective action plan that does little disturbance to the already selected modes for the activities. This is in addition to considering other constraints related to cash flow and other requirements, during the optimization. One final note is that despite the fact that the CP modeling tool is easily programmable, requiring the scheduling expert to have computer programming skills is a serious obstacle to implementing CP models, until full automation is achieved. The encouraging results of this paper, therefore, may motivate the producers of industry standard software systems to incorporate some optimization features into their tools, so that optimization becomes a mainstream tool in the industry. The focus of future work in this area should then be on introducing efficient methods to handle practical size problems. Tweaking existing methods to achieve minor performance improvement on small problems has less practical value.

DESIGN CHANGE MANAGEMENT USING A BIM-BASED VISUALIZATION MODEL

Abstract: Building projects frequently experience a number of changes in design development to satisfy owners’ space and functional needs within allocated budgets. These iterative changes, while necessary, individually and collectively have ripple effect on what appears to be the unchanged scope of projects work, with varying impacts on project delivery time and cost. Efficient management of design changes requires scope rendition and minimization of time and cost impacts of these changes. This paper presents an automated model, developed to help design professionals and owners visualize the ripple effect of contemplated design changes. This visualization covers those design changes requested by owners after completion of the design phase and before commencement of the construction phase. The developed model is expected to help owners and their agents to better grasp the ripple effect of design changes and consequently, to make better decisions as to approving or rejecting contemplated changes. The model is also able to calculate the impact of changes on projects cost and time. The model is developed on the basis of comparing the original model of a building to its revised model, which incorporates the introduced changes. The changes included in the developed model encompass addition, deletion as well as changes in quantities and specifications of building components. The model is then integrated with Building Information Modeling (BIM) to provide visualization and documentation of the design changes. The use of BIM provides significant benefits in coordinating changes across different views in the model, thereby enabling users to study the ripple effect of a change from different views, such as plans, elevations and 3D views. The model is capable of illustrating the ripple effect in architectural, mechanical, electrical and HVAC systems. For evaluation purposes, the model has been applied to a case study.

1 INTRODUCTION

Owners of construction projects have become more and more demanding, continuously changing their project’s design to suit their evolving needs, particularly in non-traditional project delivery systems. They may request changes at any phase of a project to respond to new market demands (Ibbs, 2012). Almost 20 years ago, studies had revealed that 20-25% of the construction period was lost as a result of inadequate design (Undurraga, 1996). In addition, lower-quality construction was attributed in 78% of projects to percentage of design changes (Koskela, 1992).

A change is any additional work added to the scope of a project that causes the project to incur delays and/or additional costs to the original contract. As such, a change can take many forms. However, it is owner-initiated change that must receive more attention than any other types of change, as this sort of change could present a risk to both the owner and the contractor. A change may be simple in an owner’s
mindset, but that perspective (most likely) does not consider the multiple affects that one change can have on many other areas of a project. Each change could add to the cost of the original contract and/or cause a delay in the project’s execution, even though there could be cases where a change does not add to a project’s cost and time. Some changes can even be beneficial to both owner and the contractor, but that situation is rather rare. A system that can manipulate changes would thus be a valuable tool in the construction industry. Owners should be involved in their projects, and the role and responsibility of an AEC (Architectural, Engineering, and Construction) team is to provide guidance, giving the owner all the required information about the requested change and its impacts on the project. If this new system could visualize the change and illustrate its impacts, then the owner would be able to see the ‘big picture’ and make an informed decision. This system should avoid unnecessary conflicts and disputes between the owner and the contractor, and thus greatly reduce the recourse to lawsuits.

A successful management system for applying, visualizing, analyzing and organizing change orders requested by owners would clearly be beneficial. Dealing with change orders in the traditional fashion, using paper-based printouts of 2D drawings, is no longer adequate, as it does not allow all of the ramifications of a change to be discovered. Moreover, with projects becoming increasingly complex, the ripple effect analysis of design changes is becoming much more challenging and time-consuming. This problem is being addressed by the development of Building Information Modeling (BIM) to provide real-time dynamic databases. BIM makes it possible to apply a change to a building model and to determine the impacts of that change in the design model, in every view and in real time. In other words, it can self-adjust a model’s database whenever a new change is applied. However, the user is only able to see a change, and the newly-affected model, but not the ripple effect of that change. BIMs only visualize the new model design; they do not highlight the components that are affected by the changed component(s). This limitation illustrates the need to develop a BIM-based change management system to provide effective management of a multi-disciplinary model through the dynamic procedure of building design. This study presents an integrated BIM-based automated model for design professionals and owners. It is designed to improve the visualization capabilities to help in analyzing a change’s ripple effect and in tracking the consequences, and to help owners and designers to communicate with each other in selecting beneficial changes that respond to the owners’ desired criteria, prior to the construction phase.

2 BACKGROUND

Understanding the meaning of change management is as important as knowing its process. Voropajev (1997) defined it as “an integral process related to all project’s internal and external factors influencing project changes: any possible change forecast; the identification of already-occurred changes; planning preventive impacts; to the coordination of changes across the entire project” (Voropajev, 1997). Tiog (1990) said, “a change order management system should be established for the ultimate benefit of owners” (Tigon, 1990). Sun et al. (2006) stated “the aim of project change management is not to seek the elimination of all project changes, but to minimize the negative impact of necessary changes and to avoid unnecessary ones” (Ming Sun A. F., 2006). Mirshekarlou (2012) reported that “by implementing a project change management system, a project’s involved parties would be able to reduce deleterious changes and encourage beneficial changes. Also, the project’s work performance and its chance of success should increase” (Mirshekarlou, 2012).

A change order process can be qualitative or quantitative, and sometimes a system can be a combination of both. Both systems would help the project participants to have a bright outlook on the possible changes and their impacts. Qualitative methods focus on how to process change orders once a change request is made, and how to make it beneficial for both the owner and the contractor. All the available best practices, guidelines and change management process steps can be classified as quantitative methods. These steps guide the change management process from the time the change is initiated to the completion of the project. However, there is no guaranty that a project will benefit, as none of these qualitative methods can identify the ripple effect of the changes that result from a single change. Current industry practice uses this type of change management process. To identify a changes’ ripple effect, experts must go through the all of a systems’ 2D printouts to see if the change could cause ripple effect in other parts of the project. This is very time-consuming and requires a number of highly-experienced
experts to use their knowledge to identify the change consequences. On the other hand, there are many quantitative methods that can be used to study the impact of changes. Quantitative methods concentrate on the impacts of the change order on time, cost, quality and/or productivity, and calculate everything numerically. All of the theoretical models and information models can be utilized in the quantitative change management system.

The first leaders in quantitative models were Leonard et al. (1991); utilizing the data from 57 different construction projects, they developed a regression model to quantify the impact of change orders on productivity (Leonard, 1991). Mokhtar et al. (1998) implemented an information model to help project participants coordinate design information when design changes occur by using a central database that of active building components. The model can transit design changes, track past changes, plan and schedule future changes and improve design change management (Mokhtar, 1998). Hanna et al. (2002) presented a new methodology, an integration of statistical regression and fuzzy logic, to quantify the cumulative impact of change orders on construction projects. The output of a fuzzy membership function would be the expected loss of labor productivity and its standard deviation (Awad S. Hanna. P. M.-J., 2002). Moselhi et al. (2005) developed a neural network model for quantifying the impact of change orders on labor productivity. The model is integrated with four other models, developed by others, to make a prototype software system that evaluates the percentage loss of labor productivity due to change orders (Osama Moselhi, 2005). Zhao et al. (2010) developed a change order prediction model as a beneficial tool for project management teams to manage changes proactively and efficiently. The model uses an activity-based dependency structure matrix (DSM) to identify the ripple effect of changes. It uses Monte Carlo simulation to analyze the change probability of activities involved in construction projects (Zhen Yu Zhao, 2010). Langroodi et al. (2012) evaluated existing BIM tools through a case study to determine if how BIM could be capable of aiding change management during the design and construction of fast-track projects. An ontology for change was developed in order to provide a common understanding of change characteristics for those when using BIM to manage changes (Behzad Pilehchian Langroodi., 2012). Most of the current quantitative models are designed to calculate the impact of change on productivity. Some of them are only applicable to the mechanical and electrical aspects of projects. These do not have any computer implementation and their limited number of variables reduces their practical utilization. None of them is able to visualize the ripple effect of the changes.

3 PROPOSED METHODOLOGY

This paper introduces a BIM-based model to support design change management; particularly to visualize the ripple effect of design change. Integration and automation methods were applied to the model development process to support change management. The main purpose behind the developed model is to provide decision makers with a tool to visualize the ripple effect of owner-requested design changes.

The process of project design change management begins when the owner requests design changes after completion of the design phase and before commencement of the construction phase. The design change is divided into four different categories: adding, removing and modifying one or more components in the original model, as well as any combination of these categories. These changes have their unique ripple effect on a project.

The developed model consists of three main frameworks, utilized for change management and owner decision-making. The first is a data acquisition framework, the second is a data analysis framework, and the third is a reporting framework as it is illustrated in Figure 1.

3.1 Data acquisition framework

For data acquisition, the project 2D drawings are needed in order to generate the original 3D BIM model. For the purpose of change impact analysis, project systems, such as architectural, structural, electrical, mechanical, piping and plumbing and HVAC should be part of the BIM model. The other required data are the owner’s design change requests. All requests are presented in a meeting with design team who applies them in the developed model in order to visualize their impact and share that with the owner. Meanwhile, the changes are introduced to a copy of the original 3D BIM model, which results in the creation of the 2nd model. The analysis is performed to trace the ripple effect of that change can begin.

3.2 Data analysis framework

In the data analysis framework the purpose is to visualize the ripple effect of an owner’s design changes in all of a project’s systems. By the time that a component has changed, the change may affect the other components that are connected to that first-changed component. Current BIM tools can update the whole model according to the first change. This means that when a change is happening in the attributes of a component, all the other components’ attributes related or connected to the first-changed component will be adjusted automatically. The problem with this model fixation is that it is not easy to follow or to use to evaluate a subsequent improved design change analysis. This process gets even more complicated when a project is more complex, as there will be more components and attributes.

The developed model should be able to trace the relationship between the changed component and the other components that are connected to it, which means finding the change path or the change sequence. For example, a wall is attached to a window, a door, the roof, floor, etc. The component not only has a connection to the other architectural components, it also has a connection to the components of other systems, such as mechanical, electrical, HVAC, piping and plumbing.

Therefore, determining these relationships and connections is the main step involved in discovering the ripple effect of a change. In this model, work breakdown structure (WBS) is defined at a micro level in the scheduling, which means that every component in the model has its own data information. Having a micro WBS will ease this process. When a change occurs at a component level by having micro-level WBS, the model will detect the area that a changed component is located in. It will then detect all the components that are connected to the changed component to discover if there are any other changes occurring based on the first change, which is the main source of impact. This action will continue until there are no longer any changes being found in the other components in the architectural system or any other systems.
available in the model. The same procedure also occurs in the other areas that are connected to the area where the main change is located.

The proposed model begins the analysis of all the ripple effect by a comparison method, which means that the model starts to compare the original BIM model with the modified BIM model. The analyzing procedure is based on a component-by-component comparison between the two BIM models. Every component in both models has an ID, which simplifies the comparison, and the procedure will provide an immediate result. The comparison model will detect the following:

- If the components are found in one model but not in the other. This detection will be for those types of design changes where the owner decides to remove one or more component from the original model.
- If the components are found in both models, but the components’ specification have changed in one model. This type of detection covers those types of design changes where the owner changes the specifications of one or more components in the original model.
- If the components are found in both models, and they have not changed from one model to the other.

3.3 Reporting framework

After the proposed model has visualized the change ripple effect, the next step is to provide a report to the user to assist in the change decision-making process. This model produces a report that shows all the affected components with their newly-assigned specifications such as length, height and width. The report also includes information about the original components, so that the user can see the differences between the original and the changed components. This report should be opened in the BIM interface and provide the visualization of the project model simultaneously, in a different window.

4 CASE STUDY

The proposed methodology is implemented and applied via BIM technology an actual project. In this study, the BIM platform is defined in Autodesk Revit 2014. The Revit.NET Application Programming Interface (API) allows users to program with any.NET compliant language, such as VB.NET and C#, as a way to add extensions to the originally generated BIM model. The developed model is merged with plugins that are coded in Microsoft Visual C#.Net programming language, which is in compliance with Revit APIs. The developed Revit add-In is named “Check Change”. Check Change provides the user with a change order ripple effect visualization of the owner-requested design change(s). At the same time, it also provides a report of the change ripple effect and a list of all the components that would be changed as a result of the owner’s change request(s).

In the data acquisition part, the BIM model is developed from the project’s architectural drawings; this model is called the Original model. After generating the Original model, the user opens the second model, which is a copy of the original model and is called the Copy. The user then modifies the Copy model according to the owner’s design change requirements. Both models will be shown in the same interface. Thus, the user can see both the Original and the Copy models in the Revit interface, as shown in figure 2. The program is designed so that the user cannot open more than two models at the same time.
Figure 2: Architectural System Data Acquisition

The Revit program also provides the ability for the user to see the Original and the Copy models from different viewpoints, such as plan, elevation, and section and 3D views. Having this access to the different views improves and facilitates the visualization process and a more complete understanding of the design changes. After uploading the models in the Revit interface, the next step is to click on the Check Change add-In to visualize the change ripple effect, visualized when the coded Revit add-In starts to compare the Original and the Copy models to detect the differences between the two models’ components. Clicking on Check Change tells the system to start the component-by-component comparison between the two models, as illustrated in Figure 3.

The visualization procedure is shown in Figure 4. At this stage of the model development, all of the visualization is shown in one color. Part of this study plan is to define different colors for the different results of the comparison between the two models.
For example, the components that stay the same in both models after applying the owner’s design changes appear in one color, and the components that exist in both models, but whose specifications are changed in the copy model, are indicated in another color. The components that are in the Original model and not in the Copy model are visualized in another color in the Original model.

The add-In can also provide a report of the changes detected after the component-by-component comparison. After the user applies the Check Change command, the model provides the change ripple effect visualization as well as a report. The report presents its information side-by-side; one side is for the Original model, and the other is for the Copy model, modified according to the design change requirements. The comparison model provides a report that shows all of the components that are changed due to the first source of change, the owner’s design changes. The components that have some modification in their specification will get a check sign in the report. By looking at the report, the user can observe that the reason for a change in a component could be due to a change in the height, width, length or a change in the material of that component. A sample of this report is given in Figure 5. The report and the visualizing process do not yet work together; the user would get either the report of the impacted components or a visualization of the change ripple effect. This study proposes to make a connection between the report production and the ripple effect visualization, so that the user would be able to see both at the same time and in the same interface after applying the Check Change command. In addition, the user would be able to click on a component in the report to highlight that component in every view of the model: plan, 3D, elevation or section. The user (and other interested parties) would thus be able to understand and appreciate the implications of the change ripple effect much easier.
5 CONCLUSION

Design changes initiated by owners are common and they can impact project’s cost, time, quality and overall performance. A single change in one location in a project can easily cause a series of changes in other parts of the project. Finding the sequence of change or change path via 2D drawings is time-consuming and demanding, and the result might not be accurate enough. This paper presents an automated BIM-based model to visualize the ripple effect of owner-requested design changes as they are applied to a project after the design phase has finished and before the construction phase has started. The developed model uses a component-by-component (ID-to-ID) comparison technique between the original model and the modified model to extract the list of affected components and highlight them in the Copy BIM model. The model is expected to allow project owners to make better decisions after being presented with the ripple effect of their requested changes in the architectural, mechanical, electrical and HVAC systems of the project.

Abstract: Canadian Water and Wastewater Association (CWWA) estimated the cost to replace 112,000 km of water mains in Canada to be 34 billion Canadian Dollars. Reliability analysis of water distribution networks (WDNs) is an important aspect in planning and operation of a WDN and hence plays an important role in the efficient use of allocated budget. In general, reliability analysis is classified into mechanical reliability and hydraulic reliability. Mechanical reliability is defined as the ability to function even when some components are out of service or there is any mechanical break. Hydraulic reliability is concerned with delivery of the specified quantity of water to a specific location at the required time under the desired pressure. This paper introduces a methodology for evaluating mechanical reliability of WDNs using the minimum cut set approach. The methodology involves the computation of mechanical reliability at the component (pipe, hydrant etc.), segment (collection of pipes and components) and network levels. An illustrative example is worked out to demonstrate the use of the developed methodology.

1 INTRODUCTION

Water distribution networks (WDN) are complex interconnected networks consisting of sources, pipes, and other hydraulic control elements such as pumps, valves, regulators, tanks etc., that require extensive planning and maintenance to ensure good quality water is delivered to all customers (Shinisthe et al., 2002). These networks are often described in terms of a graph, with links representing the pipes, and nodes representing connections between pipes, hydraulic control elements, consumers, and sources (Ostfeld et al., 2002). They are vital part of urban infrastructure and require high investment, operation and maintenance costs. The main task of WDN is to provide consumers with a minimum acceptable level of supply (in terms of pressure, availability, and water quality) at all times under a range of operating conditions. The degree to which the network is able to achieve this, under both normal and abnormal conditions, is termed its reliability. (Atkinson et al., 2014). Hence, reliability is considered as an integral part in making decisions regarding the planning, design, and operation phases of WDNs.

Many researchers defined reliability based on different conditions. Al-Zahrani and Syed (2005) defined reliability of WDN as its ability to deliver water to individual consumers in the required quantity and quality and under a satisfactory pressure head. Kalungi and Tanyimboh (2003) defined reliability as the extent to which the network can meet customer demands at adequate pressure under normal and abnormal operating conditions. In general reliability of any network refers to its ability of performing a mission placed on it, adequately under stated environmental conditions and for a prescribed time interval.
No network is entirely reliable. In every network, undesirable events, i.e. failures, can cause decline or interruptions in the network performance (Ostfeld 2004). Reliability of WDNs relates to two types of failure, (1) mechanical failure of network components and (2) hydraulic failure caused by changes in demand and pressure head. Mechanical reliability reflects the degree to which the network can continue to provide adequate levels of service during unplanned events such as mechanical failure (e.g., pipe bursts, pump malfunction). Hydraulic reliability reflects how well the network can cope with changes over time, such as deterioration of components or demand variations (Atkinson et al., 2014). Some authors (Islam et al., 2014; Gupta et al., 2012) have also argued about water quality reliability which is assessed with respect to a predefined level or range of selected water quality parameters (e.g., residual chlorine concentration). If the water quality parameter is within the prescribed range, the WDN is considered reliable, otherwise it is considered unreliable for water quality. However, the scope of this paper is limited to the evaluation of mechanical reliability of WDN and its components.

According to Su et al. (1987), reliability of components in a WDN such as valves, hydrants, controls etc. has an effect upon, and must be used to determine, the overall network reliability. However, no model has been found in the literature evaluating reliability of components. In this paper, a methodology is developed to assess the reliability of components in a WDN, and using reliabilities of these components, segment reliability is evaluated. Then the overall network reliability is assessed using minimum cut set method.

2 BACKGROUND

A review of the literature reveals that there is no universally acceptable measure for the reliability of water distribution networks. It gained considerable research attention over the last few decades. This research has concentrated on methodologies for reliability assessment and for reliability inclusion in optimal design and operation of WDNs. This section provides a summary of these efforts.

As reliability is not a network property that can be measured directly, it should be assessed based on other characteristics of the network that can be directly measured or calculated. Ostfeld (2004) categorized reliability assessment methods into (1) connectivity/topological, (2) hydraulic and (3) entropy as a reliability surrogate. The reliability which is based on the concept of connectivity refers to measures associated with the probability that a given network remains physically connected by taking into account the topology of the network. This type of measure mainly serves the purpose of evaluating mechanical reliability. Shamsi (1990) and Quimpo & Shamsi (1991) incorporated the use of node pair reliability (NPR) as the network reliability measure. The NPR is defined as the probability that a specific source and demand nodes are connected. This definition corresponds to the probability that at least one path is functional between the source node and the demand node considered. Yannopoulos and Spiliotis (2013) focused on topology of network as a measure for analyzing mechanical reliability. They developed a methodology based on adjacent matrix of graph theory in order to determine connectivity among different nodes. Measures used within this category do not consider the level of service provided to the consumers during a failure. The existence of a path between a consumer and a node is only a necessary condition for supplying its required demands (Ostfeld, 2004).

The second category of reliability assessment i.e., hydraulic measure is concerned with the conveyance of desired quantities and qualities of water at required pressures to the appropriate locations at the appropriate times. Xu and Goulter (1999) used a probabilistic hydraulic approach, based on the concept of the first-order reliability method (FORM), to determine the capacity reliability of the water distribution network, which is related to the hydraulic and demand variation failures, and is defined as the probability that the nodal demand is met at or over the prescribed minimum pressure for a fixed network configuration under random nodal demands and random pipe roughnesses. Shinistine et al. (2002), coupled a cut-set method with a hydraulic steady state simulation model that implicitly solves the continuity and energy equations for two large scale municipal water distribution networks in the Tucson Metropolitan Area. The measure of reliability was defined as the probability of satisfying nodal demands and pressure heads for various possible pipe breaks in the water distribution network at any given time. Zhuang et al. (2011) presented a methodology for reliability and availability assessment of a WDN based on an adaptive pump operation. In response to a pipe break, pump operations were adapted using
various sizes of pump combinations. In their method, they evaluate hydraulic reliability in terms of available water to fulfill desired demand.

Entropy, as a surrogate measure for reliability is the third category which has been used by several researchers for reliability assessment during recent years. The fundamental idea is to use Shannon’s (1948) entropy measure of uncertainty that quantifies the amount of information contained in a finite probability distribution, to measure the inherent redundancy of a network. In this regard, entropy is more related to the category of connectivity/topological analysis than to that of hydraulic reliability. It is assumed that distribution networks, which are designed to carry maximum entropy flows, are generally reliable (Ostfeld, 2004). A WDN with higher entropy is expected to cope better with simultaneous multi-pipe failure (Gheisi and Naser, 2014). Prasad and Tanyimboh (2008) used Flow Entropy, a statistical entropy measure for WDNs to show that surrogate reliability measure can be used effectively to improve reliability of multi-source networks. Tanyimboh et al. (2011) used statistical entropy and other surrogate measures such as network resilience, resilience index and modified resilience index, for the reliability assessment of WDN to assess the effectiveness of surrogate reliability measures in relation to more rigorous and accurate hydraulic reliability measures.

Among the most well-defined processes to determine the topological/mechanical reliability of a network is the process of minimum cut-set (Yannopoulos and Spiliotis, 2013). Tung (1985) discussed six techniques for WDN reliability evaluation and concluded that the cut-set method is the most efficient technique in evaluating the network reliability. The minimum cut-set approach is usually applied in order to investigate the topology of a WDN and the detection of its critical elements the failure of which will affect the network operation. The minimum cut-set is a set of network components which, when failed, causes failure of the network; but if just one component of the set has not failed, no failure of network occurs. Following the cut-set method, an estimation of mechanical reliability of the WDN can be achieved.

2.1 Identification of minimum cut sets

To identify the minimum cut sets of a network in a reduced computational time, a method generally used in power transmission networks for the same purpose has been adopted (Zhou et al., 2012). It involves 1) finding all possible paths from the source node to the demand node, 2) Constructing a path matrix and 3) getting minimum cut sets from the path matrix.

A path is a connection between a source node and a demand node. This model considers a node to be adequately supplied as long as there is at least one link connecting it to the rest of the network which means that the network is not considered as failed even if there is a single path from the source node to the demand node. After finding all possible paths, a path matrix is constructed in which, number of rows is equivalent to the number of paths from source node to demand node under consideration, and number of columns is equivalent to the number of segments (or combinations of segments) in a network. This matrix is a zero-one matrix with 1 as its entry if the segment is present in the path to the demand node, and 0 as its entry if it is not. For example, there are 3 segments A, B and C in a network and the possible paths from the source node to the demand node are AB and AC. Then the path matrix is expressed as

\[
[1] P = \begin{bmatrix}
A & B & C \\
1 & 1 & 0 \\
1 & 0 & 1 \\
\end{bmatrix}
\]

Once the path matrix is constructed for the demand node under consideration, the network is analyzed for minimum cut sets. First order cut set is a single segment which when fails, causes the failure of entire network. Similarly, second order cut set is the combination of two segments, the combined failure of which causes the failure of entire network. If any column in a path matrix contains all elements as 1, then the segment corresponding to that column is recorded as a first order cut set. For example, all the elements of the first column are 1 in the matrix 1. Hence segment \{A\} is recorded as a first order cut set. To find the second order cut sets, create all combinations of 2 segments and construct a new path matrix by merging the elements as per the combinations. For example, combination of 2 segments for the above example network are \{A, B\}, \{B, C\} and \{C, A\}. New path matrix would be
From the matrix 2, combination of B and C results in a column with all elements as 1. Hence \( \{B, C\} \) is recorded as second order cut set. Note that, any combination with A is neglected because A is already a minimum cut set. The same procedure is followed for finding third and higher order cut sets with combinations of corresponding segments.

3 METHODOLOGY

This section discusses the various computing measures adopted to develop the methodology.

![Network reliability flowchart](image)

Figure 1: Network reliability flowchart

3.1 Failure rate

Most researchers have chosen failure rate as the primary indicator of reliability. Quantitatively, it is defined as the number of breaks per year per unit length. Breaks are considered one of the significant factors contributing to water losses and require substantial human effort and cost to repair such failures. As the number of breaks increases, the reliability of a WDN decreases. The most often applied formulae for estimating the pipe failure rate have been obtained using simple regression models on the available pipe failure data from a limited time period. In this paper, the pipe failure rate or breakage rate is
computed using a regression model based on age of pipe, being developed in an ongoing research work at Concordia University. According to this model, the failure rate can be expressed as

\[ \lambda_{\text{pipe}} = 6 \times 10^{-6} X^2 + 0.0004X + 0.0026 \]

Where X is the age of pipe in years and \( \lambda_{\text{pipe}} \) is the failure rate of pipe expressed in number of breaks per year per unit length of pipe.

The failure rate of other components (hydrants, valves, controls) can be expressed as

\[ \lambda_{\text{component}} = \frac{N_f}{\text{Length of segment}} \]

Where \( N_f \) is the number of failures per year and \( \lambda_{\text{component}} \) is the failure rate of component expressed in number of failures per year per unit length of segment.

### 3.2 Component reliability

After determining the failure rates of pipes and other components, the reliability is assumed to follow negative exponential distribution which would mean that reliability decreases exponentially as the failure rate increases with time, and can be computed as

\[ R_c = e^{-\lambda t} \]

Where \( R_c \) is the reliability of a component or pipe and \( \lambda t \) is the failure rate of a component or pipe.

### 3.3 Segment reliability

A segment is a single water main pipe or a group of connected pipes (along with all the associated components) which are usually located between two nearest intersections at which isolation valves may exist (Salman A., 2011). According to the definition, the segment reliability can be expressed as

\[ R_{\text{seg}} = \sum \lambda \]  

The above equation represents segment reliability where components have the same weight which is not true. Each component has its relative importance in a segment. To be more specific in determining segment reliability, a relative weight component (\( w_i \)) is included in equation 4 to adjust it.

\[ R_{\text{seg}} = \sum_{i=1}^{n} R_c w_i \]

Where \( i \) is the water main component, \( n \) is total number of water main components and \( w_i \) is the relative weight of component.

The relative weight of component (\( w_i \)) is the ratio of weight of component under consideration to the total weight of components in that particular segment. The weights of components are obtained from Salman A. (2011).

\[ \text{Relative Weight } (w_i) = \frac{\text{Weight of component}}{\text{Sum of weights of all components}} \]
### Table 1 Component Weights (Salman A., 2011)

### 3.4 Network reliability

The procedure for determining the network reliability of a WDN based on the minimum cut-set method is as follows.

#### 3.4.1 Probability of failure of segments

Quantitatively, the probability of failure of a segment is the complement of the reliability of a segment. It can be expressed as

\[ Q = 1 - e^{-kt} \]

These segment failure probabilities are computed so that they can be used later for determining network reliability using minimum cut set method.

#### 3.4.2 Identification of minimum cut sets

As described earlier in the literature review, all the minimum cut sets have to be identified to serve the purpose of evaluating network reliability.

#### 3.4.3 Mechanical reliability of WDN based on Minimum Cut Set

According to Shinstine et al. (2002), for \( n \) components (segments) in the \( i_{th} \) minimum cut set of a WDN, the failure probability of the \( j_{th} \) component (segment) is \( Q_j \), which can be obtained by Eq. 7. The failure probability of the \( i_{th} \) minimum cut set is

\[ Q(MC_i) = \prod_{j=1}^{n} Q_j \]

Where \( n \) is the number of segments in corresponding minimum cut set.

Assuming that the occurrence of the failure of the components within a minimum cut set are statistically independent. For example, if a water distribution network has four minimum cut sets, \( MC_1, MC_2, MC_3, \) and \( MC_4 \), for the network reliability, the failure probability of the network \( Q_N \), is then defined as follows (Billinton and Allan 1983):

\[ Q_N = Q(MC_1 \cap MC_2 \cap MC_3 \cap MC_4) \]

By applying the principle of inclusion and exclusion, equation 9 can be reduced to:
[10] \( Q_N = Q(MC_1) + Q(MC_2) + Q(MC_3) + Q(MC_4) = \sum_{i=1}^{M} Q(MC_i) \)

Where \( M \) is the number of minimum cut-sets in the network.

Finally, the mechanical reliability of the network can be expressed as:

[11] \( R_N = 1 - Q_N = 1 - \sum_{i=1}^{M} Q(MC_i) \)

### 4 CASE EXAMPLE

The hypothetical network shown in figure 3 is utilized for the demonstration of the developed methodology. The network consists of 8 segments named alphabetically and 7 nodes named numerically. Node 7 is a source node while the other nodes are demand nodes. Assuming the repair data for the network as shown in table 2, reliability of each component, each segment and whole network can be calculated. To calculate the reliability of presented hypothetical network using minimum cut sets method, network should be analyzed for the identification of minimum cut sets.

![Network model of case study](image)

Figure 3: Network model of case study

Let us consider node 3 as the demand node. The possible paths for the water to reach demand node 3 from source node 7 are found to be ABD, ACFED, ACFGH, and ABEGH and there are 8 segments. Therefore the path matrix can be constructed as

\[
[3] P = \begin{bmatrix}
A & B & C & D & E & F & G & H \\
1 & 1 & 0 & 1 & 0 & 0 & 0 & 0 \\
1 & 0 & 1 & 1 & 1 & 0 & 0 & 0 \\
1 & 0 & 1 & 0 & 0 & 1 & 1 & 1 \\
1 & 1 & 0 & 0 & 1 & 0 & 1 & 1 \\
\end{bmatrix}
\]

The elements in column A of matrix 3 are all 1. Hence \( \{A\} \) is recorded as a first order cut set. Note that, while finding second order cut sets, combination of segment A with other segments is not needed. Because the failure of A, alone causes the failure of network. It does not need combination of any other segment to cause failure of network.

To find second order cut sets, combinations list of 2 segments out of 8 segments is generated using WOLFRAM MATHEMATICA 10.1. Total number of combinations are found to be 28 and are listed in table 3. Hence the new path matrix contains 5 rows (No. of paths) and 28 columns (No. of combinations of segments) and can be constructed as

\[
[4] P = \begin{bmatrix}
A+B & B+C & B+F & C+D & D+E & D+G & D+H & E+F & G+H \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 0 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 0 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 & 1 \\
\end{bmatrix}
\]
(All the combinations with segment A are not needed and hence they are neglected. Dotted columns
represent that there are few combinations that are not shown here because it's a large matrix and could
not be fit to page.)

</tbody>
</table>

It can be observed that the elements in columns of matrix 4, representing combinations of {B, C}, {B, F},
{D, G} and {D, H} are all 1. It means that combined failure of these segments can cause failure of network
and hence {B, C}, {B, F}, {D, G} and {D, H} are recorded as second order cut sets. Note that, while finding
third order cut sets, any combination containing first order cut sets and second order cut sets are
neglected. Because they don’t need more segments to cause failure of network.

Same procedure is repeated for finding third order cut sets with combinations list of 3 segments. Total
number of combinations are found to be 56 as listed in table 3. Hence the new path matrix contains 5
rows (No. of paths) and 56 columns (No. of combinations of segments) and can be constructed as
As we can see, elements in columns of matrix 5, representing combinations of \( \{B, E, G\}, \{B, E, H\}, \{C, D, E\} \) and \( \{D, E, F\} \) are all 1, which means that the combined failure of these segments can cause failure of network and these are recorded as third order cut sets. The same procedure is repeated for each and every demand node in the network and all the cut sets are recorded. Note that any cut set is recorded only once. If the same cut set is identified while performing network analysis considering another demand node, it is not recorded as a cut set again.

Finally, the minimum cut sets after analyzing the network for all demand nodes are listed in table below.

### Table 3 Possible combinations of segments that can cause combined failure

<table>

</tr>
</tbody>
</table>

Hence the reliability of the presented hypothetical network can be calculated as

\[
R_N = 1 - Q_N = 1 - \sum_{i=1}^{M} Q(MC_i)
\]

\[
Q_N = Q(MC_1) + Q(MC_2) + Q(MC_3) = 0.0107
\]

\[
\therefore R_N = 1 - Q_N = 0.9893
\]

### 5 CONCLUSIONS:

Mechanical failure of pipes in water distribution networks has been studied by numerous statistical models in the past. But none of these models focused on mechanical failure of other components of water distribution networks which may also affect the reliability of the whole network. This paper presents a
methodology to evaluate mechanical reliability of water distribution networks along with its components, using minimum cut set method. The accuracy of a developed model depends on the accuracy of the data used to build it. The proposed model requires very detailed historic break data of all the components including pipes. But many municipalities are not equipped to collect such detailed data. In this paper, the failure rate of pipes is based only on a single parameter i.e., age of the pipe and the failure rate of other components is obtained using a more general formula. Consideration of as much parameters should lead to more realistic failure rate predictions. Research should be extended to also predict the failure rate of components other than pipe. Municipalities are required to collect detailed break data of all the components of water distribution networks. The availability of such data would assist in evaluating reliability more accurately.

SHIFTING LOGICS OF CONSTRUCTABILITY AND DESIGN: A STUDY OF EMERGING AEC INTEGRATED PRACTICES FOR ENERGY PERFORMANCE

Christopher Monson1,2, Laura Osburn1, Carrie Sturts Dossick1, Heather Burpee1, and Gina Neff1
1 University of Washington, U.S.A.
2 cmonson2@uw.edu

Abstract: In this paper, we analyze the practices of translation and synthesis for energy performance in building design. We use grounded theory method to collect and analyze qualitative interview and observation data to examine the difficulties of knowledge sharing and problem solving between builders and architectural and engineering designers. Extending the theory of disciplinary specific “institutional logics,” we show that designers and builders integrate their work in three ways: 1) by addressing gaps in their own knowledge that require information from a knowledge domain different from their own, 2) by synthesizing design and construction issues holistically, and 3) through integrating construction and design work practices. These insights offer evidence of shifts in the institutional logics that structure the construction and design disciplines.

1 INTRODUCTION

In the traditional model of architecture, engineering, and construction (AEC) practice, architects and engineers prepare documents for builders to construct buildings in a temporally linear relationship. The “hand-off” between disciplines at the time of bidding establishes professional boundaries with significant cultural differences between the disciplines of design and construction, and transferring knowledge across these disciplinary boundaries is difficult and resistant to easy technological fixes (Neff et al., 2010). Like all industries, AEC industries follow what sociologists have called institutional logics, “the socially constructed, historical pattern of material practices, assumptions, values, beliefs, and rules” which act as “a set of assumptions and values, usually implicit, about how to interpret organizational reality, what constitutes appropriate behaviour, and how to succeed” (Thornton, 2004:69-70). For AEC industries, this means the different cultures of architecture, engineering, and construction are shaped in large part by a set of social logics that are larger than any one company or individual. For example, people on projects have conflicting obligations to company, scope or profession, and to the building project (Dossick & Neff, 2010). These emerge out of different sets of institutional logics at work within the AEC industries.

In this paper we examine work practices of translation and synthesis of energy performance design to examine the difficulties of knowledge sharing and problem solving in integrated AEC teams. We use the notion of institutional logics to help explain the challenges that designers and builders have in collaborating and communicating across the gaps in their professional knowledge. Our findings suggest that designers and builders integrate their work in three ways: 1) knowledge gaps that require accessing builder or designer domain knowledge, 2) holistic thinking that requires synthesizing design and builder
knowledge, and 3) integrated construction and design work practices that occur within and between
designer and builder firms. Together, our insights offer evidence of incremental shifts in the institutional
logics that structure the construction and design disciplines as they develop new work practices.

The worldview and decision-making processes of designers and builders are shaped by institutional
logics such as professionalism and market that overlap, intersect, and sometimes contradict one another.
Builders and designers often employ or evoke certain logics depending upon the type of activity taking
place and the social, cultural, and organizational context of the actors engaged in these tasks. For
example, builders are often expected to evoke the logics of market and cost; they analyze building
elements, turn design documents into cost estimates, view their work processes through quantification
and linearity, and consider themselves business people engaged in the capitalist market. Comparatively,
designers are often expected to evoke logics of professionalism; they synthesize across building
elements, turn ideas into form and documentation, view their work processes through qualification and
ambiguity, and consider themselves as professionals mandated to serve the public.

Closer collaboration between builders, engineers, and architects has benefits both for project efficiency
and for improving the quality of building outcomes (Kent & Becerik-Gerber, 2010), particularly for high
performance buildings (Reed, 2009). However, builders and designers have very different ways of talking
and thinking about their work which often frustrates good collaboration (Carrillo & Chinowsky, 2006). One
of the substantive challenges to contemporary integrated AEC work practices is the translation and
interpretation necessary for interdisciplinary teams to communicate and share domain knowledge. To
realize the benefits of integrated work practices, collaborative teams need to bridge across their
disciplinary differences in two parallel directions; builders need to engage the logic of design and
designers need to engage the logic of constructability.

2 LITERATURE REVIEW

Institutional logics include such things as the demands of the market, needs of a company or practice,
and commitment to a profession. These conflicting obligations can be described using the theory of
institutional logics (Thornton, 2004; Thornton et al., 2013). On all building projects, "conflicting obligations
push people away from as well as towards good collaboration" (Dossick & Neff, 2010:463). These
obligations include legal, professional, and ethical responsibilities for the scope of work and sense of
professionalism to a specific role on the project (e.g., structural engineer, lead architect), a “tentative
temporary alliance to the project,” and “a more permanent obligation to their company” (Dossick & Neff,
2010:466). AEC team members must routinely bridge the knowledge boundaries among the different
design and building disciplines. In these settings, different institutional logics can be used as justifications
for actions or cause conflicts among different members of the team. For example, new skills can offer
value, efficiencies, and increased authority but change the way that people collaborate and rely on
institutional logics to guide or justify their behavior (Smets et al., 2012). Because communication practices
are central to how institutional logics are constructed and changed (Green et al., 2008), how people talk
within integrated teams—whether through coordinating, translating, sense making or theorizing—has the
power to make and reshape these institutional logics (Ocasio et al., 2015).

Integrated AEC projects ask collaborating team members to manage gaps in their own knowledge with
information gained from other disciplines. This process requires that connections be continually made and
unmade between an individual’s domain of expertise and the expertise of other team members.
Integrated project practices encourage AEC professionals to acknowledge, interpret, accommodate, and
adopt the approaches of people from other AEC disciplines. Theories of “conflicting obligations” and
“institutional logics” seem to suggest that these connections are where we might expect to see
incremental shifts of institutional logics and predict why some integrated projects are more successful
than others.

To test this we conducted a qualitative study to see how people on integrated AEC projects talk about
different institutional logics on these projects to suggest ways these shifts are occurring with the rise of
integrated practice.
3 METHODS

3.1 Data

The data used in this study derived from three interviews (one engineer and two contractors) and twenty-one hours of field observations of participant meetings and work sessions between energy consultants, architects, engineers, and builders across four months and 12,978 words in written field notes. Our interview questions focused on collaboration, communication, translation, and synthesis of energy modeling data, including respondents' collaboration strategies and best practices for increasing team integration. Our observation data consist of conversations about new construction projects, renovation projects, and the submission of design-build proposals where energy performance was a key issue. This select dataset emerged from a larger dataset focused on issues of knowledge and translation and synthesis for energy performance in building design (10 interviews across the U.S., 19 projects, 195 hours of field observations, 141,000 words of written field notes). From a grounded theory analysis of this large data set, we found patterns in our smaller set of interview and observation data that opened up questions of shifting logics of constructability and design.

3.2 Qualitative Open Coding of Themes

Our data analysis relies on coding the team interactions that took place in our observations and in the detailed stories told during interviews. These interactions and stories reflect a stated desire for disciplinary knowledge that research participants imagined other professionals have or that they wish that they could access in the moment. We used a modified grounded-theory approach for open coding (Strauss & Corbin, 1990) for themes where designers and builders engaged in logics of “professionalism” and “market” evidenced in these interactions. For example, we coded for moments when someone expressed the desire for builder knowledge, raised questions about the constructability of a design, or acknowledged or engaged in discussion of specific construction methods or constructability costs.

We clustered themes found in our qualitative data around three key concepts showing the shifting institutional logics brought about by integrated practice: 1) designers using ideas about constructability, 2) builders using ideas from design, and 3) the evolution of builders’ thinking.

4 FINDINGS

4.1 Designers engaging the logic of construction

Our data suggests that designers engage in the logic of construction when they encounter gaps in their knowledge connecting design to construction, where they see holistic thinking that synthesizes design and construction issues, and where domain knowledge acts to link design and construction. In some cases, designers may request or suggest receiving a contractor or builder’s input to come to a shared resolution on a constructability issue. In other cases, designers appear to engage in the logic of construction during interactions where they demonstrate their ability to cross into the knowledge domain of construction and incorporate concerns of constructability into their design.

4.1.1 Gaps in knowledge connecting design to construction

At times, designers realized that input from a builder would assist in problem definition and would provide details that could help make decisions among design options. These moments frequently occurred when the contractor was not yet working with the design team, but the team anticipated gaps in their knowledge or expertise that the contractor could fill.

While working on design development, designers will direct their staff to detail elements to engage constructability issues. For example, an engineer working on a design-build contract for a renovation project pointed out to a new employee how to use a ductulator to transcribe duct measurements onto floor plans in Revit. The engineer advised the staff member that he shouldn’t use “weird dimensions. Six inches is the limit, anything else confuses contractors.” He then advised the staff member to “try to think
like a sheet metal guy. Ask, is it easy to make?” (Field Note 140808). The engineer told his staff member to anticipate questions, expectations, and concerns in the design work.

In one example, a design team was having a conversation about an ongoing HVAC assessment in an older building. This assessment would culminate in a final report advising what would need to be replaced or fixed on each floor along with cost estimates. They realized that changing out the dampers would be difficult. During this conversation, one of the participants realized that the entire design solution rested on a consideration of the repair and installation process by the contractor—an activity not fully understood by the design team—and suggested getting feedback from a contractor:

*Engineering Consultant:* I have a feeling this is a lot more challenging to change out than the [dampers] downstairs.

*Client Representative:* I agree. They’re not easy to get to.

*Consultant:* How do we handle the pricing on this? . . . We need a mechanical contractor’s input. It would be a real Rube Goldberg to fix these and to get these from the inside. We need feedback. It’s not clear what the approach is. (Field Note 141107)

Here designers tried to imagine conditions of constructability in the absence of builder input. Designers frequently arrived at these boundaries of domain knowledge as a consequence of their design efforts. However, these moments were also highly unpredictable, and questions of constructability appear to arise out of many different types of design conversations. In these design process contexts where constructability questions impacts the definition of the design problem and its potential solution, having immediate access to construction domain knowledge—as in the case of integrated project practice—can be of significant importance in terms of knowledge exchange.

### 4.1.2 Holistic thinking synthesizing design and construction

Designers and builders are trained to think differently about problem solution processes. Where the knowledge management strategies of builders could be characterized by processes of quantification, designers have more general knowledge management strategies that could be characterized by qualification. The design methodology of qualification can be seen where designers focus on performance metrics and outcomes that could be answered by any number of potential solutions. Sometimes, conflicts between quantification and qualification can lead to poor building performance where building elements that the design team intended to work together are compromised by builder choices and value engineering.

One architectural group and its energy consultants coined “bundles” to get around this problem by joining building elements as a performance package. The bundle protected building elements designed to work together from being cut individually from the final design. This was an effort by the design team to protect interconnected system choices for operational efficiencies and energy savings. This strategy required builder logics to move from building element quantification to building system qualification. This represents an institutional logic shift by builders from quantification to qualification. Another way of defining this shift is a move to synthesize design and construction issues through more holistic thinking.

Designers are not always convinced that this type of holistic team thinking is possible or available from builders. The design team was split on the idea that they needed the contractor to provide an initial review and cost for the first proposed bundle on a large hospital project. The architect suggested that the design team present the energy bundle options to the client as well as an economic analysis of each bundle. The energy modeler responded that it could be difficult to do an economic analysis for the client before having internal discussions with other team members, including the contractor. The architect suggested that the energy modeler has the knowledge expertise to “put numbers on things.” The energy modeler disagreed: “I would want to discuss that in a larger meeting with a contractor. I would want them to at least look the numbers over and put their blessing on it or note what they don’t like about them” (Field Note 141219).

The fear the architect had was that the contractor would be unable to think qualitatively and would start picking apart the constituent elements in the proposed design bundle using cost as a weapon. In turn, the energy modeler was accepting the challenge of holistic team thinking and anticipating that the
contractor’s cost estimates could act as a “blessing” for the entire bundle of strategies, a potential resolution.

Later in the same meeting, one of the energy modeler consultants noted that certain systems that they might use to increase building performance also cost less, and that there is a need to “rethink how comfort systems work and move things from one [budget] pot, like mechanical, to another. So [the owner] would not pay more to save more, but pay less to save more” (Field Note 141219). An engineer challenged this assertion, suggesting that a contractor’s domain of expertise and normative institutional logics are stuck in categories of budgeting that make it difficult to design holistically: “The challenging aspect is getting the right baseline and accurate pricing. The contractor won’t be billing to go beyond the cost per square foot.”

4.1.3 Domain knowledge linking design and construction

Our data showing benefits to builders in domain knowledge links between design and construction are slightly more robust than the benefits seen to designers. For builders, construction knowledge is now included in design activities early in integrated projects and thus builders participate more closely with design work. Compared to this general phenomenon for builders, we saw fewer new design-construction knowledge links for designers. One mechanical engineer explained how valuable it was for his own design knowledge base to take a job in a collaborative environment focused on construction: “My career didn’t take off... or, I didn’t understand things until I became a design-build engineer. [Until I] became a... I actually started working as a mechanical contractor.” (Field Note 141114). We have found some initial evidence that this kind of cross-disciplinary hiring—designers hired by contractors or builders hired by designers—is associated with firms invested in integrated project delivery.

4.2 Builders engaging the logic of design

We have found in our initial data that builders engage in the logic of design in ways that are parallel to how designers engage in the logic of construction. For builders, this occurs when they encounter gaps in their knowledge connecting construction to design, where they are asked to think holistically and synthetically between construction and design issues, and where domain knowledge between construction and design link the two disciplines.

4.2.1 Gaps in knowledge connecting construction to design

We saw examples in the data where builders often want to know more about the design performance requirements of building elements than is typically provided in traditional design-bid-build. This includes new problems like the lack of design intent in specification documentation which reduces the efficiency of constructability reviews. One builder noted:

What we often get is specs... where it’s “we’re using this light fixture.” And we don’t know if that light fixture is chosen because the owner likes the way it looks, or if it provides the right lumen output, if... you know, it’s the only one that’s available, or they think that’s available in the time that we have in order to procure. So, we get a product package that’s kind of ambiguous. And, so, if we’re going to go back to the team with seven recommendations, we’re going to pull some information from that product spec that may or may not be right. (Field Note 141111)

Here we see that traditional methods of contract document production through specifications by the design team are creating a knowledge gap for the construction team when faced with collaborative activities like iterative cost comparisons. This suggests a need for greater knowledge exchange between builders and the design team.

Another long-time construction director called these design intentions created by the design team the “whys” of a building project. He noted how understanding design intentions would allow his construction team to be “self-adjusting.” He said,
We don't know the “whys” enough . . . “Whys” are great. “Whys” would be helpful for everybody. And a lot of people don’t even know what the “whys” are. But that would be good too, right? To know where you are so you could self-adjust . . . ” (Field Note 141107)

Later, he pointed out in concrete terms how design performance knowledge helps builders be leaders on integrated project teams with architects. He said that knowing “why the data is the way it is”—what the design intentions were—“that's really super important if you’re going to lead . . . be a leader amongst that [integrated] team.” (Field Note 141107)

Builders see the usefulness of design intentions as a tool for bettering their own efforts, and that they have a desire for greater knowledge exchange with designers on integrated teams. Given that design intentions are often qualifications rather than quantifications, it suggests that builders may need to integrate more ambiguous information into their problem solution processes than traditional construction work practices may have required.

4.2.2 Holistic thinking synthesizing construction and design

Through the evolution of construction delivery processes, new modes of working have created challenges to the traditional domain boundaries between design and construction. As building information modeling (BIM) has become more widespread among construction teams as a tool for management, we find some instances where BIM has encouraged builders to find ways to have input early in schematic design to reduce subsequent problems during construction.

One large construction firm realized that it was very inefficient to wait for MEP details to be complete before they could do clash detection, and that a better proposition was to reserve spatial volumes through the building for systems development, a strategy they called “internal space planning.” This idea leveraged the 3D capacities of the BIM model produced by the design team but was actually modeled by the construction team. This effort on the part of builders is wholly dependent on their understanding of the full arc of the design effort and their capacity to integrate design activities within construction domain knowledge.

A particularly powerful aspect of holistic thinking on the part of builders is seen in design activities that are dependent upon cost information. This is an important contribution in situations where designers are less focused on cost. An engineer who had moved to a position as a mechanical systems specialist for a large contractor had a particularly clear viewpoint: “Engineers inherently are going to design the best system possible. Period. Without regards to cost. That’s just the way that they’re wired” (Field Note 141114). Another builder explained the improved benefits between “rules of thumb” costs by designers and actual cost estimates and scheduling information from their collaborating builders:

We find the engineer of record is kind of using more rules of thumb, like “oh that’s, we've typically see that would be ten percent more, and the lead time is generally six weeks.” Well, if we change that one little piece, a condenser, it can go to ten weeks . . . . You know, so when we’re involved in a more integrated process we can . . . we can talk a little bit more intelligently about that. (Field Note 141111)

By being able to offer highly accurate costs, this builder sees the benefits of integrating design and construction knowledge and a holistic engagement with the problem solving processes of both.

This same builder told us how his firm was able to offer more value to design processes by leveraging design information through a constructability lens. When asked to provide add-alternatives to a project, he explained how his firm puts this deliverable into the language of qualifiers and performance metrics aligned with the project’s design intentions found in the project program, its sustainability goals, or its life-cycle assessments. This builder uses services like life-cycle and energy calculations and operations and maintenance information—typically considered to be the responsibility of the design team—to contribute value to these iterative project development activities.
4.2.3 Domain knowledge linking construction and design

In certain construction markets, the increasing demand for preconstruction services and integrated project design early in projects makes having construction staff with design capabilities a necessity. This is a function of how building projects are contracted and how collaboration is advanced in the particular market. One mechanical engineer working as this kind of design specialist for a large contractor said of his market: “Here, if you don’t have, like, thirty people on your staff designing, you’re not even going to be in business” (Field Note 141114). This suggests that the change toward integrated design and construction practice is being taken seriously within the field.

A sustainability director for a large contractor was blunt about how builders can integrate the domain knowledge between design and construction:

So the people you’re seeing doing integrated design well from the construction perspective are the people who saw the benefits of it before there was a title. And, so they’re the frontrunners. I think you’re going to see everybody... they’re going to try to follow... And they’re going to have to learn it. Or, they’re going to hire somebody who already knows it. (Field Note 141111)

In many ways, this shows us how builders who saw the market changes coming to AEC practice found ways to complement their construction skills with those of design—suggesting how they deal with the shifts of institutional logics. The implication is that they are able to contribute more fully and operate with more authority and value in contemporary integrated project environments. Looking more closely at these evolving institutional logics may illuminate how it is accomplished and what new work practices it entails.

4.3 Evolving institutional logic of builders

We have interviewed a number of AEC practitioners who have exhibited integrated practice logic that is emerging as characteristics of a new kind of builder: the synthesizer. This kind of builder sees the role of a builder as a synthesizer of building elements and systems, acting as a translator between the design issues of form/systems and constructability. Synthesizers advocate for building performance with cross-disciplinary domain knowledge and an interdisciplinary knowledge management style. Among our study participants, one builder in particular stands out as an exemplification of this logic. His responses to our interview offer some substantive issues that could be thought of as potential foundations for the evolving institutional logic of contemporary builders in integrated project practice. Our synthesizer-builder used this kind of holistic thinking to explain, in his experience, that co-location works because it is

... a back and forth conversation. That smooths the process out a ton, because we don’t need a lot of specifications because everyone involved understands the design intent. And the design intent is developed collaboratively. The subcontractors said “Well, what about this? Does this meet your budget?” Eh, it doesn’t quite meet our efficiency. What about this?” It’s like, “well, yeah, it’s close to your budget, but it doesn’t meet your schedule” right?... It’s like, it’s almost a real-time conversation... that’s really developed early on. (Field Note 141111)

Our synthesizer-builder was encouraged by his leadership team to offer environmental design services more typically provided by design professionals such as sustainable design, storm water and habitat restoration. His firm saw this as a good business practice in their market: “[My firm] wanted my expertise to be on the table, whether that was related to schedule or cost or constructability or not. ...we want to get that information in front of the client” (Field Note 141111).

At some point, integrated design practices may push more construction firms to accommodate other holistic thinking that synthesizes construction and design domain knowledge. Ultimately, this evolution of the institutional logic of this particular construction firm recognized the strong value proposition in being a company with a proven integrated project track record and a demonstrated capability to realize sustainable building performance: “Of course we can meet the budget, of course we can meet the schedule, of course we can get this thing built for you. But, you know, the way in which we’re going to do that is slightly different; we’re going to participate in the conversation rather than do what you otherwise normally would...” (Field Note 14111).
All of these challenges to the existing institutional logics of construction as they move more toward design were wrapped up in our synthesizer-builder’s imagined future for integrated AEC teams:

If I could walk into a room in an integrated design project meeting and not know anybody, I shouldn’t be able to tell the difference between the contractor and the architect. . . . And, that is okay, or it needs to be okay in an integrated design process in order for that process to work smoothly. (Field Note 141111)

5 DISCUSSION AND CONCLUSION

There are parallels in how architects, engineers, and builders in integrated AEC projects attempt to incorporate their disciplinary realms and work toward problem solutions. This occurs when designers and builders encounter gaps in their knowledge that require different domain knowledge, synthesize design and construction issues holistically, and link construction and design work practices. We see incremental shifts of institutional logics when people connect their domain of expertise with that of other team members. This occurs when collaborative communication processes bridge different disciplinary expertise.

We saw this in case of the synthesizer-builder where cross-disciplinary knowledge allowed him to translate between design and constructability issues. The synthesizer-builder allowed shifts from construction to design logics whenever it seemed to be efficient, effective, or brought capabilities necessary to solve the problem at hand. He could engage in a productive and authoritative interdisciplinary knowledge management style that took advantage of the ability to synthesize qualitative and quantitative forms of domain knowledge. When our synthesizer-builder reported how his firm’s management encouraged him to offer design strategies to clients “whether that was related to schedule or cost or constructability or not,” we see a change to the firm’s construction logics by an inclusion of new domain knowledge and ambiguous design problem solving—a direct move toward an incorporation of some of the institutional logics of design.

Our study shows how these design and construction logics can impact builder and designer roles, knowledge management, and domain knowledge. Institutional logics shape the context of professional norms and values in which builders and designers act, and they guide how people perceive project problems and solutions through the lens of their disciplinary domains. However, integrated AEC work practices are creating new professional and social contexts where institutional logics can be challenged, shifted, and adapted. In these contexts, communication processes centered in collaboration are the means by which domain knowledge and expertise are shared. These changes might suggest that builders working in integrated AEC projects pay attention to and test the institutional logics of designers while at the same time become aware of the constructs pushing builders to adopt new institutional logics of design. Conversely, designers in integrated projects might be encouraged to engage in more of the institutional logics of construction through more rigorous attention to constructability and cost issues in the earliest phases of project design.

This study uses a small interview sample of builders and designers from the Pacific Northwest, a region where there is an increasing market in integrated design. To draw more generalizable conclusions, we will need to conduct more interviews with AEC professionals working in other parts of the U.S. and North America. This study also draws from observation data within firms that regularly use integrated design and construction project delivery. Future research could involve observations in firms that are less involved in integrated project delivery allowing for greater comparison between the institutional logic shifts of builders and designers. Still, there is much to be learned from studying leading-edge work practices in a rapidly changing industry. In larger scale studies, we expect to see evidence that evolving dimensions of AEC domain knowledge between builders and designers will be associated with attention to and the testing of institutional logics.

Abstract: Lack of adequate visualization of project construction operations often causes project parties to struggle with large amount of data. 3D Building Information Modeling (BIM) is a static model, built for representing the geometry of a constructed building and its respective information. However, construction processes are dynamic and require dynamic representation. 4D BIM is gaining more momentum in construction research and in industry. There are commercial packages that can generate 4D BIM and numerous researchers have used 4D BIM in their research. However, related literature does not disclose the methodology used or the know-how of creating 4D BIM. This paper presents an automated methodology and describes how to construct a 4D BIM. The automated methodology maps the 3D BIM objects to project schedule activities through a newly added attribute to each 3D BIM object. As such, different groups of objects within the 3D BIM are assigned to different activities. For each group, a series of decisions are made to classify whether it belongs to completed activity, activity in progress or activity to be executed in the future. The developed methodology was implemented in prototype software. Autodesk Revit has been customized so that the integration between 3D BIM and project schedule be applied using Revit Application Programming Interface (API). The developed automated methodology and software were applied to a construction project in Montreal area to demonstrate its use. The developed methodology is straightforward and easy to use. It is expected to facilitate the utilization of 4D BIM in research and in practice.

1. INTRODUCTION

Construction Industry Institute (CII) studies showed that the cost of rework could range from zero to 25% of the installed cost of construction. However, the use of visualization representations such as 3D models by management team can reduce that amount of rework by 65% on average. The efficient use of space on a construction site is a site-specific, difficult task and is often left to the intuition of construction managers. Poor spatial planning has been deemed one of the major sources of productivity loss (Thabet and Beliveau 1997). On large construction projects, project management teams often suffer from not being able to mentally visualize a project complexity. Thus, they are frequently not able to make the best decisions to mitigate risks. Visual representation is one way to overcome this problem. Visual models represent the spatial aspects of schedules and communicate schedules more effectively than traditional methods such as bar charts (Kang et al., 2007). Building information modeling (BIM) is gaining momentum in the architecture/engineering/construction (AEC) industry, especially since owners such as the US Army Corps of Engineers (USACE) implemented initiatives requiring future projects involving the design and construction of facilities include BIM. In 2005, the United States General Services
Administration (GSA) announced that starting 2006, AEC firms would be required to provide a building information model with their designs (McCuen, 2008).

By themselves, 3D models do not have the ability to show the exact status of a project at a specific point in time, and so are of little help in progress control. In order to create a construction schedule from 2D drawings, planners have to visualize the sequence of construction in their minds. This is an extremely difficult task since workspace logistics and resource utilization are highly dynamic by nature. Most site organizations plan their works based on conceptual site layout and drawings, which are rarely updated during the project execution. Thus, site managers have not fully benefited from recent advancements in visualization-information technologies (Chau et al., 2005). 3D models have some basic knowledge that results from shapes, sizes and locations. This is the geometric database, where each element has geometric attributes. In addition to the geometric attributes, which describe the physical 3D model, each element in the model can have any number of non-geometric attributes associated with it. One non-geometric attribute might be the construction method or specifications (Aslani et al., 2009).

The goal of adopting a BIM is to provide a comprehensive view of the building by including (drawings, specification, details, etc.) in a single-source model (Krygiel et al., 2008). BIM databases contain physical and functional characteristics of a structure since a BIM model is composed of smart objects rather than lines, arcs, and text. All of these characteristics are mainly due to BIM’s capability to realize the building through all of the stages in the form of a database (Fu et al., 2006). BIM users can obtain information about any single element, or for all elements in a project, to inform decisions about the project. Examples of data included with an element are material quantities, costs of elements, time considerations related to the element, building performance, operations and maintenance, and several other items essential in the lifecycle of a constructed facility (McCuen, 2009 and Motamedi and Hammad, 2009). Montaser and Moselhi (2012) developed an automated methodology utilizing BIM and tablet PC for progress reporting in construction jobsites. They added the data taken from BIM database to RFID tags attached to the components. The idea of making components data readily available on the tags provides easy access for project and construction managers through real-time connection to a central database or a portable device.

With its potential to assemble the whole project virtually before any actual construction begins, BIM adds a level of accuracy to both quantity and quality issues. Building materials can be demonstrated in real time scenarios rather than requiring manual analysis. By drawing building elements only once for a project in a plan view, the projections of all elevations and sections are generated automatically. One of the direct benefits is the reduction in drawing time; therefore, designers can mainly focus on other design issues (Krygiel et al., 2008). 3D BIM model is a static model, built to represent a building. This could be seen as a shortcoming for the construction process/operation since it is a dynamic process and merits a dynamic presentation. 4D BIM is a visual representation that combines an object oriented 3D BIM model with time. 4D BIM is information visualization that is easier to understand than traditional methods. Traditionally, project managers use 2D drawings, bar charts, and sketches to clarify the construction design, but these visualization methods do not integrate the temporal or spatial dimensions. 4D BIM models are a form of visual representation of a project that also takes into consideration the temporal aspect of how project teams plan to actually build a project, according to construction schedules. 4D BIM could be used strategically by on-site management for visualization (Hartmann et al., 2008).

Moreover, 4D BIM can assist site personnel in brainstorming sessions and discussions about access, storage and sequencing of works. Better visualization facilitates team collaboration in removing illogical relationships among activities in construction operations. Owners of the constructed facilities may have little experience in construction, and are often unable to truly participate in the development of construction plans unless a simple method of visualization and communication is made available to them. 4D BIM visualization seems to be an effective way of enhancing the many different types of human perception and it can help anticipate potential construction conflicts during the operational stages (Chan et al., 2004, and Staub-French et al., 2008). However, related literature does not disclose the methodology used or the know-how of creating 4D BIM. This paper presents an automated methodology and describes how to construct a 4D BIM.
2. DEVELOPED METHODOLOGY

4D BIM integrates the building project 3D model and its construction schedule. A realistic project baseline schedule should be developed, including project activities and their early start (ES) and early finish (EF) dates. The 3D BIM model, first, imports the planned data directly from scheduling software, in database format. Figure 1 depicts the flowchart of the procedure used to link the 3D BIM model to project schedule. It then maps the 3D BIM model objects to project schedule baseline activities. As such, different groups of these 3D BIM objects are assigned to its respective activities. Figure 2 shows the flow chart for manipulating 4D BIM for visualization purposes and the template creation process. For each group and according to current date, a series of decisions are made to classify whether it belongs to a finished activity, an activity in progress or an activity to be executed in the future. The automated procedure compares the current date to the ES and EF dates of each group, and controls each group’s visibility accordingly. Future activities, those that have not yet started, are hidden from the developed 4D BIM. For finished activities, the 4D BIM checks if each group has been inspected and checked as being finished, or if according to the as-planned schedule it is finished but not yet checked or inspected. The 4D BIM makes the finished and checked activities visible in their final forms, and displays unchecked finished activities in a red highlighted form. The activities currently in progress are displayed in yellow. The activities displayed in red and yellow are divided spatially among identified zones. To facilitate data storage, fusion and processing a relational database was developed. The database has six entities; interconnected with one-to-many, many-to-one and many-to-many relationships. Due to space limitation, the Entity Relationship (ER) diagram is not included. For more details about the developed database, please refer to Montaser (2013).

Figure 2: The process of 4D BIM model visualization
3. DEVELOPED SOFTWARE

The developed methodology was implemented in prototype software. BIM models are capable of recognizing building objects in its fixed asset hierarchy (Family - Type - Object) while being user-friendly for creating a building's indoor and outdoor zones. It links those objects to the zone that hosts them by relating an object's ID to a zone's ID. Different software developers such as Autodesk, Bentley and CATIA have applied the BIM concept. None of these systems' providers, however, describe any BIM web application. All of them are standalone applications installed on the user computer that could be connected to internet. Each has its pros and cons; however, Autodesk Revit customization capabilities have been significantly extended over the past few years. Revit Application Programming Interface (API) allows users to program with any .NET compliant language such as VB .NET and C# .NET. Revit has thus been selected here to be customized so that the integrated tablet PC data acquisition system be applied in its API and utilized as add-In.

This section presents the developed automated tool, which was developed using the "Visual C# .NET" in Revit's API. Revit was selected to be customized and the developed software was implemented to the Center for Structural and Functional Genomics (CSFG) at Concordia University in Montreal as a proof of concept and for testing the developed software. The building consists of basement floor, ground floor, first floor, second floor, mechanical floor and roof. The total built up are is 6000 m². The building is a reinforced concrete structure, except the mechanical and fire escape stairs, which are of steel structures. The contractual budget was $20 million with contractual duration of 12 months. The Architectural and Structural plans provided by Concordia University were in the form of 2D CAD drawings, and there was no BIM model for the building. A 3D BIM model was created as a part of the developed methodology. The BIM model was developed using the project 2D drawings. Revit Autodesk software was used to develop the 3D BIM model. The 3D BIM model has all of the parameters and attributes for building zones and objects. Each parameter and attribute is associated with a unique ID to avoid conflicts when dealing with data exchange and scheduling software, which is Microsoft Project 2013. The generated 3D BIM model feeds the developed software with data, such as the number of spaces, the area of each space, the object families and family types, in order to identify objects inside each space, and later facilitate integration of the 3D model with the construction schedule.

In addition to the unique ID that each object has, BIM objects also have two important characteristics that are family and type. Family represents the main description of objects such as wall, door, window, etc. While, type represents specific kind of a family object such as internal wall 1 hour fire rated or wooden door single flush panel. The developed software utilizes these two aspects of BIM objects to categorize the whole building. The software should be utilized by users, who are familiar with the project 3D BIM model and the construction schedule of the building being modeled such as project managers or project schedulers. The user is responsible for linking the Microsoft Project file to the 3D BIM model of the project and maps the 3D BIM objects to project activities through utilizing the control visibility options. Visibility options have three different use-cases that are show by activity, show and hid activities manually and show activities by date. “Show activities by date” use-case is considered the 4D BIM model that was customized in Revit. The visibility options given to the user facilitate the process of modifying or changing activities objects in case of any design modification or introduced change orders.

The user first activates the developed add-in menu in the Revit screen and subsequently selects from a pull-down menu “Set MS Project File” and completes the process depicted in Figure 3. The software closes the file explorer dialog and inserts the selected file path into displayed writable textbox. The user presses the “Done” button so, the developed tool checks if the file exists, which is part of the verification process. Then, it saves the new MS project path into the system configuration file to use it as default MS Project path and closes the change MS Project form. The second step, performed by the user, is to map 3D BIM objects to its respective activity. In creating group of elements, the user can link one object or a set of objects to one activity as diagrammatically shown in Figure 4. Prior to that linkage, MS Project schedule must be activated and verification is performed to make sure that the schedule has more than one activity. If the MS project file have list of activities, it displays two buttons “Finish” and “Close”. Then, the system allows the user to select multiple objects from the 3D Revit model and link them to one of the activities being displayed. After selecting multiple objects, the user selects the MS Project activity from a
pull-down menu “Choose Group Name” and completes the process depicted in Figure 4. Upon completion of the linking process, the object(s) inherits the attributes of the associated activity such as activity name, early start and early finish, which are then used for generating the 4D BIM model. This process is repeated until all 3D Revit objects are mapped to associated MS Project activities.

Each object in Revit, referred to here as element, has a set of attributes such as ID, family, type. These attributes vary from object to another and they are either generic or specific. A new attribute was added to all Revit objects to facilitate the linking process, as shown in Figure 5. It is referred to it as “Group”, which represents one object or a set of objects. The user selects a set of objects such as supported deep excavation piles, as shown in Figure 4, then; the name of “Group” is made identical to the activity name. The sequence of this process was designed and implemented to be from outside to inside and from top to bottom. Upon finishing one group, objects of that group will be hidden to provide access to the other objects. The mechanics of linking identified objects to relevant scheduled activities are performed interactively as shown in Figure 6.
Figure 4: Mapping 3D Revit objects to project activities (part 2)

Figure 5: The added attribute “Group” to Revit object
Figure 6: Assigning MS Project activity to Group name

Controlling visibility of activities is crucial in the developed automated tool. Therefore, three different options were developed to identify which activities are visible and which are hidden. To activate the visibility controls, the user activates the add-in menu and selects “Show/Hide Groups”. Then, the automated tool checks that at least one activity is linked to the 3D Revit objects. Otherwise, the system pops up an error message instructing the user to map the 3D Revit objects to the MS Project activities first. If this check is false then the system displays “Group Visibility Control” form. The form contains three different options, as shown in Figure 7. The user has to select one of the three options. If the user selects “Show/Hide Based on Activity” then it shows under that option a drop down list with all activities that were linked to 3D Revit objects. The user selects one activity that required to be displayed. It displays the selected activity on the current view and hides all other activities.

If the user selects “Show/Hide Based Manual” then the automated tool displays a form containing all displayed activities under the visible list and all hidden activities in other list. The user selects the needed activity to be displayed and press move or select the needed activity to be hidden and press move. In addition, the user could select to move all activities from one list to the other and vice versa. The user presses done button to apply the above actions to Revit current view. Showing specific activity or activities become very handy to the experienced user specially, in the cases of design modification or change orders. Therefore, the user can isolate the activity objects, modify it, and link it again to the MS Project activity. The third option is to show/hide activities by date, as shown in Figure 7. This option represents the methodology for applying the 4D BIM concept inside Revit without the need for third party software. When the user selects s the option of “Show/Hide Based on date”, two calendars appear. The first calendar to specify the start date and the second calendar for the end date. The automated tool applies the algorithm explained earlier for showing and hiding activities on specific date range. Figure 8 shows pictures from the generated 4D Revit visualization.

4. CONCLUSION

Lack of adequate visual representation often causes construction managers to struggle with large, amounts of data. Such limitations of traditional tools on one side and the advances in visualization-information technologies on the other have stimulated various research and development efforts to advance new innovative construction visualization techniques that depict sequence of construction operations. Traditionally, project teams use 2D drawings, Gantt-charts, and sketches to provide the necessary details of construction sequence simulation. However, these tools do not provide the
information required to generate 4D visualization of project progress. 4D BIM is the solution for this problem, which is generated by integrating the 3D BIM with project schedule. It allows a three dimension (3D) simulation of a building and its components that is called 4D BIM. This simulation goes beyond demonstrating how different building assemblies can be put together in the project. It can assist in predicting problems, show the construction variables associated with different building designs, and calculate material quantities. However the literature and current practice do not reveal a clear methodology or procedure to create a 4D BIM. Additionally, most of the work done in this area is through integrating 3BIM and schedule using third party software. This paper presents an automated methodology to create 4D BIM models. The methodology is generic, straightforward and easy to use. It is expected to facilitate the use of 4D BIM in research and in practice. The methodology has been implemented in a prototype software and was applied to a case study to demonstrate its use.

Abstract: Tracking and control of construction projects depend primarily on the accuracy, frequency and time required to collect actual onsite data of construction operations. Automated site data acquisition has received considerable attention in recent years to circumvent the limitations of manual data collection. Outdoor operations represent significant portion of construction operations, particularly in heavy civil engineering projects. This paper presents an automated methodology to track outdoor activities in near real time through 4D Building Information Modeling (BIM), Global Positioning System (GPS) and Tablet PC. The integration of 4D BIM, GPS and tablet PC provides platform for automated progress reporting that supports visualization, localization and automated data acquisition, respectively. The developed methodology was applied to a construction project in Montreal area to demonstrate its use. NavisWorks Autodesk was used to generate 4D BIM model through linking project schedule with the objects of the 3D BIM model. The tablet PC has barcode reader, Radio Frequency Identification (RFID) reader, Wi-Fi, Bluetooth, camera for images and videos and a speaker microphone for voice recording, which add more automated data acquisition capabilities. The used tablet did not have GPS. So, mobile GPS was acquired for outdoor localization. The tablet PC and the mobile GPS communicate and exchange data via Bluetooth standard communication protocol. Near-real-time automated data acquisition of onsite operations facilitates early detection of discrepancies between actual and planned performances and supports project managers in taking timely corrective measures. This methodology is expected to enhance traditional tracking and progress reporting procedures.

Keywords: Automated Data Acquisition, Progress Reporting, 4D BIM, GPS, Tablet PC

1. INTRODUCTION

Accurate and timely collection of information on the status of project resources and activities is necessary to support managers in effective assessment of project progress and in making timely decisions during the execution of work onsite (Abdelrehim, 2013). Effective tracking and control system requires collecting accurate data form construction site in timely manner with cost efficient methods. Ineffective tracking and control system can result in costly delays, rework and additional costs (Jang and Skibniewski, 2008). Tracking and control process is a challenging task in view of the dynamic change of onsite operations including material delivery and utilization (El-Omari, 2008). Traditionally, project teams use 2D drawings, Gantt-charts, and sketches to provide the needed information of measuring project progress. These tools, however, do not provide the information required to generate 3D visualization of project progress (Chan et al., 2004). Building Information Modeling (BIM) is gaining momentum in the architecture/engineering/
construction (AEC) industry by owners such as the GSA (General Services Administration) and the USACE (US Army Corps of Engineers) embraced its use on their constructed facilities (McCuen, 2008). 3D BIM model is a static model, built for representing the physical building geometry and its related information. However, construction process is a dynamic process and needs a dynamic presentation (Staub-French et al., 2008). 4D visualization requires integration of project schedule and the spatial data of the project utilizing BIM. 4D BIM is a concept, which combines an object oriented 3D model with project schedule. It is a kind of information visualization that is easier to understand than traditional methods. The literature reveals that project managers have already applied 4D models on a number of projects (Hartmann et al., 2008).

Current approaches for capturing, storing and managing construction jobsites data are mostly manual and labour-intensive methods. Data collected using manual methods are not reliable or complete, as they are dependent on the motivation, judgment and skills of the site personnel for data collection. Furthermore, data collected through these methods are typically transferred and stored in paper-based format, which is difficult to search and access, and which makes processing them into useful information expensive and unreliable (Montaser et al., 2012). Tablet PC capabilities have been enhanced considerably in recent years, in addition to its traditional advantages which, is durability mobility, expressivity of display and ease of use. Currently, it integrates various automated data acquisition technologies such as, barcode readers, RFID readers, wireless communication (Wi-Fi and Bluetooth), GPS and camera for video clips and digital images (Montaser, 2013). Recent technological advancement in data acquisition systems has made the consistent management of construction projects and their information more feasible. Bar coding and RFID are used to automatically identify, track and facilitates generating status reports (Cheng and Chen, 2002, Shehab et al., 2009, Razavi et al., 2012 and Montaser and Moselhi, 2012). Using cameras for data collection can enables the user to capture a broader perspective of construction activities and operations. The camera captured images can reduce the time needed for inspection by allowing this task to be done remotely. The captured information can be transferred to project management team via internet connection (Brilakis, 2007).

GPS has proven to be a suitable technology to locate the assets position for the outdoor operations with accuracy of centimeters (Navon and Goldschmidt, 2002). GPS is at present fully Global Navigation Satellite System (GNSS). However, GPS signals can be affected by several sources of error during transmission. Therefore, a real time data correction is performed to eliminate or minimize those errors. Differential GPS (DGPS) correction should be applied to the captured GPS data. DGPS requires one or more additional receivers, called base stations or reference stations, which are located at known points. Data collected at base stations is used to determine GPS measurement errors and compute corrections to these errors. Errors are corrected with DGPS either in real time or during post-processing (Blewitt, 1997). GPS data at a point is in the form of latitude (Φ), longitude (λ) and height (h), which is mainly a form of astronomical observations (Satellite reference coordinate system). Hence, this data needs to be converted into the Universal Transverse Mercator (UTM) coordinate system, which is a geodetic coordinate system (X, Y, Z). It comprises a standard coordinate frame for the Earth (the datum or reference ellipsoid). Further transformation is performed to transform the captured data into the 3D local coordinates system. This is done through calculating the vector 3D transformation matrix, refer to the procedure described in Leick (1995).

GPS technology has attracted researchers looking for effective ways to track the outdoor location of construction labor and equipment on jobsites (Navon et al., 2002). The construction industry has already embraced the use of GPS in control of site surveying and earthmoving operations. GPS can be used to track the location of equipment over a wide range of geographic and geometric scales. The use of GPS for earthmoving operations has reported to lead an increase of 22% in productivity and 13% in cost savings for short haul distance projects. Also for long haul distance, the advantages were less, a productivity increase of 5.57% and cost savings of 4.79% (Han et al., 2006). Caldas et al. (2006) developed a system integrating GPS and Geographical Information System (GIS), in which GPS was used to track the position of pipe spools on a construction project. Montaser and Moselhi (2014b) developed a new web-based model for the tracking and control of earth moving operations. Their model uses spatial technologies, including GPS and GIS, to facilitate automated data acquisition. This paper presents the proposed methodology that integrates 4D BIM, GPS and tablet PC automated site data.
acquisition capabilities to support tracking and progress reporting of outdoor construction operations. A recently constructed building is utilized as a case study to demonstrate the application of the developed method and to illustrate its capabilities.

2. PROPOSED METHODOLOGY

The proposed methodology integrates 4D BIM visualization, GPS localization and tablet PC automated data acquisition technologies to improve progress reporting procedures. Tablet PC is used as integration media in the developed methodology for 4D BIM model for the project being considered, GPS data and automated site data acquisition technologies. Outdoor construction areas are divided into exclusive zones which stored in the project 3D BIM model. The user has the tablet PC that incorporates the 4D BIM model and adjusts the model to the current date to have a planned visualization that represents current project status. The GPS identifies the location of the site personnel who is collecting onsite data. Based on the location identified, the zone can be retrieved from the 4D BIM. The user while, walking outdoor, collects the as built progress data utilizing the automated data technologies capabilities of the tablet PC to capture ongoing progress data in various formats such as RFID data and barcode data. The user can take snapshots with the tablet PC’s camera and write comments and notes about the onsite activities being monitored. These comments and notes are entered directly on the tablet PC screen and stored in the database. In addition, the user fills progress templates related to his current zone. The user utilizes the templates for data input for some activities in cases where the use of the above mentioned technologies is deemed costly and/or technically impossible. For example, if the bar code is not accessible or taking a picture in a dark zone is not useful.

After finishing the first zone, the user move to the next zone for data collection. The data collected in each zone is attached to the developed database with new attributes of time stamp and zone. This procedure is designed to facilitate data storage and retrieval. Project managers can analyze these data for different purpose such as safety or taking corrective actions. These steps are repeated until all zones are covered, as shown in the procedure outlined in Figure 1. This data collected is used to represent actual progress, which is then compared as planned baseline progress using earned value analysis (EVA) to measure the project performance. The analysis and processing of the captured data is depends mainly on the data source and its type. For example, RFID can be utilized for material localization and tracking, for more details please refer to (Montaser and Moselhi, 2014a). Regarding images and videos, image processing can be used to capture colors, edges and texture for finishing activities. The results of the reported progress are used afterwards to update the project schedule, which will detect any experienced delay. It will also facilitate early detection of discrepancies between actual and planned performances and, accordingly, support project managers in taking timely corrective measures. Organizing collected data is very important as it facilitates future retrieval of this data, which can help not only in progress reporting but also in management of claims and in the production of as-built 3D BIM. To facilitate data storage, fusion and processing a relational database was developed. The database has ten entities; interconnected with one-to-many, many-to-one and many-to-many relationships. Due to space limitation, the Entity Relationship (ER) diagram is not included. More details about the developed database can be found in Montaser (2013).

3. CASE STUDY

Field studies were conducted during the construction of the Center for Structural and Functional Genomics (CSFG) at Concordia University, as shown in Figure 2. The project is located at the corner of Sherbrook St. West and West Broadway St. in Montreal. It forms an expansion to the existing Science Complex. The building consists of basement floor, ground floor, first floor, second floor, mechanical floor and roof. The total built area is 6000 m². The building is of reinforced concrete framing, except for the mechanical and fire escape stairs, which are of structural steel. The contractual budget was $20 million with contractual duration of 12 months. Initial visits to the jobsite of the project were made and the blue prints released for construction as well as the construction schedule in MS project were reviewed to get familiar with the various aspects of the project. More than forty (40) jobsite visits were made. The Architectural and Structural plans provided by Concordia University were in the form of 2D CAD drawings,
and there was no BIM model for the building. A 3D BIM model was created as a part of the developed model. The BIM model was developed using the project 2D drawings. Revit Autodesk software was used to develop the 3D BIM model.

---

**Figure 1: Proposed methodology**
All construction data, such as objects' materials as well as their specifications were extracted either from available related documents or directly from observations during site visits. Since, the developed objects have parametric relationship with each other, then the sections, elevations, and perspectives were generated automatically. The model consists of 7450 parametric object. NavisWorks Autodesk was used to link the project schedule with the objects of the project 3D BIM model. The 3D Revit model objects were exported to Navisworks along with the construction schedule. Once the Microsoft Project schedule and 3D model were imported into Navisworks detailed relationships were developed to link each scheduled activity to its corresponding objects of the model. The software automatically simulates the construction sequence as per the project schedule, as shown in Figure 3. Different colors were assigned to objects in the developed 4D BIM model to express their respective status of progress. At any given time, the 4D model can reflect the time schedule in a visual manner. Objects with user selected colors indicate that they are already executed, while those highlighted in green indicate that the activities they belong them are in progress. At the top left of the simulation screen the date and the name of the activities being executed along with their exact durations.

Tablet PC is considered one of the most important components in the developed methodology. This is because it houses the captured data and the generated 4D BIM. The tablet PC used in this research is a rugged Panasonic Toughbook®H2 handheld tablet PC, as shown in Figure 4. It has 10.1" sunlight-viewable LED screen, fast Intel® Core™i5 vPro™ processor and 1.7GHz with Turbo Boost up to 2.7GHz Intel®. In addition, it has 40 GB hard drive, Smart Cache 3MB, 4GB SDRAM (DDR3-1333MHz), twin batteries (6.5 hours with both batteries), ports such as USB, serial and Ethernet and IP65 sealed all-weather design (Panasonic, 2015). GPS could be embedded in the tablet PC. However, the tablet used in this research did not have GPS. So, Trimble GeoXT mobile GPS was acquired for outdoor localization. The tablet PC, mobile RFID reader and mobile GPS communicate and exchange data via Bluetooth standard communication protocol. It was used to identify site personnel location in outdoor zones. It is a high performance GPS receiver combined with a rugged handheld computer with a powerful 520 MHz processor, 128 MB RAM, and 1 GB of onboard storage, as shown in Figure (5-a). TerraSync software was installed on the handheld GPS. It collects and updates geographical data, as shown in Figure (5-b). Differential GPS (DGPS) correction should be applied to the captured GPS data. DGPS requires one or more additional receivers, called base stations or reference stations, which are located at known points. Data collected at base stations is used to determine GPS measurement errors and compute corrections to these errors. Errors are corrected with DGPS either in real time or during post-processing (Trimble, 2015). Both methods were performed in this paper.
Figure 3: 4D BIM NavisWorks© mode

Virtual Construction @ Different time

Figure 4: The used tablet PC
For real-time DGPS correction, the base station calculates and broadcasts the error for each satellite as each measurement is received, which enables corrections while the user is in the field collecting data. Real time DGPS corrections are generated and broadcasted in real-time by privately or self-owned GPS base stations, or by a wide range of government agencies. Real-time DGPS sources include external beacon and radio sources, as well as Satellite Based Augmentation Systems (SBAS) such as VRS networks in Canada. VRS networks use multiple base stations to calculate the DGPS corrections that are then delivered to the user from a Geostationary satellite (SBAS) or from a radio or cellular phone. For example, corrections generated by a VRS network are commonly broadcasted over an internet server. A VRS network uses data from several base stations to provide corrections that are generally more accurate than corrections based on a single station. Factors that affect real time DGPS accuracy include how often the corrections are updated, how far the user is from the base station, and whether the coordinate system used by the correction source matches the coordinate system used by the GPS receiver (Can-Net, 2015). VRS base station was 50 Km far from Genomics building jobsite. Therefore, cellular connectivity was added to the Trimble GeoXT GPS handheld via the TDL 3G cellular modem, which was acquired with the GPS, as shown in Figure (5-c). It was connected to the GPS via wireless Bluetooth (Trimble, 2015). TDL 3G provides continuous network/internet access to real time VRS corrections. The authors acquired the VRS corrections license service for one-month to experiment with it through TDL 3G cellular modem.

For post-processed DGPS correction, the collected GPS data is transferred to the tablet PC via wireless Bluetooth. Since, the construction jobsite was in Concordia University Loyola campus, wireless Wi-Fi connection was available. Measurements from the base station were downloaded and GPS data processed through GPS Pathfinder Office software version 4.10 that was earlier installed on the tablet PC, as shown in Figure 6. Typically, post-processed DGPS uses only one base station (Trimble, 2015). The GPS Pathfinder software provides the functionality needed to manage and process data collected using GPS. It provides the tools needed to correct, view, and edit GPS data collected in the field, and to export it in a format suitable for GIS, CAD, or database. Both the wireless Wi-Fi and GPS PathFinder software were available on the tablet and the GPS PathFinder converted the data into Microsoft Access database format, as shown in Table 1. Therefore, the data is first transferred wirelessly from the GPS to the tablet PC and then processed through GPS PathFinder software installed on the tablet PC. Accordingly, this method was integrated with the developed 4D BIM model using NavisWorks Autodesk Application Programming Interface (API). Then, the user’s outdoor location is visualized on the 4D BIM model, as shown in Figure 7. The user in the same location can capture many data such as sound, video, image, hand written note, barcode and RFID scan. The data collected, in different formats, have two new
main attributes, time and location. This procedure facilitates data analysis and retrieval for progress reporting as well as for the remote monitoring of the project status.

4. CONCLUSION

This paper presents an automated methodology for data acquisition and progress reporting to support time and cost tracking of construction projects. The developed methodology integrates project visualization, localization and tablet PC automated site data acquisition. Project visualization is achieved by utilization of 4D BIM that integrates 3D BIM model and project schedule. Localization was done through GPS. Automated site data acquisition technologies were utilized through tablet PC enhanced capabilities that integrates RFID, barcode, wireless communication and camera technologies. It also utilizes 4D BIM to provide visualization capabilities to the process of data acquisition. Data is collected on site and stored in a database for processing to generate progress reports. With the continual development of automated data acquisition sensors and its integration, a significant amount of data can be collected on site. Near real time control of on-site operations, facilitates early detection of discrepancies between actual and planned performances and supports project managers in taking timely corrective measures. A case study of a construction project was utilized to illustrate the features of the developed methodology in collecting data required for tracking and control.

Abstract: Demand forecasting plays an integral role both in planning and managing urban transportation infrastructure. Analyzing travel demand is an integral part of any transportation system. Different types of demand forecasting models are being used by transportation industries not only to plan for renovation and expansion but also to evaluate several policy scenarios associated with the particular infrastructure system. The traditional demand forecasting models that exist mostly focus on individual transportation sectors such as air-transportation, highways, etc. and not much attention is given to consider the interdependencies and complexities among the various components and thus many-a-times ignore the emergent behaviors. To overcome this deficiency, the research study applied a system-of-systems approach to forecast the overall public transport demand considering all the different sectors of the transportation network of an integrated public transport system. However, forecasting the public demand for each transportation mode is a major challenge as it depends on several uncertain factors such as population growth, GDP growth of the country, traffic congestion on roads, average annual income of population, ticket prices, travel types and others. System dynamics modeling approach was adopted to represent the information and physical flows among the different components / entities within a system at an aggregate level with high degree of accuracy. These types of models would help the decision makers in evaluating several policy scenarios by altering the model variables and developing investment strategies for future transportation infrastructure planning. This research paper developed a conceptual framework to assess the public demand for individual transportation modes in an integrated transportation network using Abu Dhabi’s surface transport expansion and integration project as a case study.

1 INTRODUCTION

Abu Dhabi is undergoing a rapid and visionary transformation to get established as a world-leading city and the Abu Dhabi Surface Transport expansion and integration project is the core for such an infrastructure expansion involving multimillion dollars of investments. The “Plan Abu Dhabi 2030” Urban Structure Framework Plan attempts to envisage the year 2030 and provide the basis for future growth accordingly. The Surface Transport Master Plan (STMP) commissioned in February 2008 developed the conceptual transportation strategy into a detailed Master Plan and an implementation program based on the outline provided in Plan Abu Dhabi 2030. The plan addresses the regional transport needs of the Emirate as a whole, while focusing particularly on metropolitan Abu Dhabi. The challenges in this plan are the current congestions, which are swiftly approaching to full capacity, as well as the drastic increase in demand owing to increasing population. The population increase is mostly due to an estimated 400% increase in gross area of the city, six million additional office space leading to huge economic growth, and
a four-fold increase in the number of regional and international visitors (Abu Dhabi DoT 2009). Currently, private passenger car mode of transport is involved in around half of all daily person-trips while public bus transportation is approximately one percent. Reliance on private cars and taxis is the main reason for congestion. As growth continues, a multi-faceted, multi-modal transport system will be vital to creating a vibrant, sustainable world-class city (Abu Dhabi DoT 2009). By 2030 the integrated public transport network is expected to comprise of a high-speed rail service to Dubai; some 130 km of metro railway, regional rail connections; over 340 km of tram lines served by bus feeder services and a passenger water transport network. The system will also include all of the supporting Intelligent Transport Systems (ITS) and unified automatic fare collection systems (Abu Dhabi DoT 2009). Forecasting the demand on the overall network as well as its components is an essential task to facilitate proper design and management of the transportation system in order to meet its objectives.

The major objective of this paper is to develop a framework that would eventually foster the analysis of how the interdependencies between components of an integrated public transport can affect the overall demand based on the demand fluctuations of the individual modes of transport. The demand for individual modes of transport is extremely uncertain as it depends on GDP, population, roads congestion, price, level of service of each mode, and congestion of each transportation mode all play an important role in determining the overall demand on the public transport network as well as the demand on the individual modes. The System Dynamics model framework developed based on a SoS approach would allow to forecast the passenger demand for an integrated transport network based on the demand on individual modes once the real data is available. This would also provide a platform to the decision maker to test a combination of policy scenarios designed to suffice the overall objectives of a Transport Integration Project. The following sections of the paper provide a description of the research objectives, a brief summary of the reviewed literature, model development methodology, model framework and finally a discussion on the framework developed and conclusion.

2 BACKGROUND: SYSTEM OF SYSTEMS & SYSTEM DYNAMICS IN TRANSPORTATION DEMAND

A system-of-systems (SoS) is defined as a “set or arrangement of systems that results when independent and useful systems are integrated into a larger system that delivers unique capabilities” (Office of the Deputy Under Secretary of Defense for Acquisition and Technology 2008). A SoS can be differentiated from a monolithic system based on several aspects such as autonomy, belongingness, connectivity, diversity, and emergence (Boardman and Sauser 2006; Liu 2011). Other advantages as offered by SOS approach include operational and managerial independence of the components, geographic distribution, evolutionary behavior, emergent behavior and consideration of heterogeneity of the system components (Maier 1998; Delaurentis 2005). However, the two most important advantages as mentioned above are “operational independence” and “managerial independence” of the components. These aspects specify that in a SoS the sub-systems are “useful in their own right and generally operate independent of other systems”.

System Dynamics (SD) modeling is one of the tools used for studying dynamic problems arising in complex systems, such as social, managerial, economic, or ecological systems. As defined by Richardson (2011), SD is the use of informal maps and formal models with computer simulation to uncover and understand endogenous sources of system behavior“. Like some other modeling approaches, most notably Agent-Based Modeling, SD is also a bottom up system modeling approach that aggregates representations of component processes and their relationships that helps to understand the underlying structure of the system (North and Macal 2007). SD can be further used to trace this behavior over time at discrete points and to analyze how a change in a specific part of the system can affect that behavior (Martin & Forrester 2001). According to Richardson (2011), the SD approach involves defining problems dynamically, in terms of graphs over time; focusing inward on the characteristics of a system; considering dynamic behavior of a real system and formation of loops, feedbacks and circular causality; identifying independent stocks or accumulations (levels) in the system and their inflows and outflows (rates); formulating a behavioral model using a computer simulation model expressed in nonlinear
equations; getting the outputs, deriving understandings and applicable policy insights from the resulting model; and finally implementing changes.

System Dynamics (SD) has been used repeatedly in modeling surface or air transportation networks for studying, inter alia, the effect of a set of identified factors on the demand on the said networks and others. Selected examples from the literature include the works of Wang, Lu, and Peng (2008), Haghani, Lee, and Byun (2010), Suryani, Chou, and Chen (2010), Yevdokimov (2002), Wang et al., (2005), and Stave (2002). All the aforementioned research studies have treated the transportation network from a single mode perspective without recognizing that it is in fact composed of a group of interconnected systems. This research builds on the aforementioned studies by viewing the surface transportation network from a system-of-systems approach through recognizing the managerial and operational interdependence of each transport mode whilst considering the interconnections and interdependencies between the SoS components. It is worth mentioning that Agusdinata, Fry, and DeLaurentis (2011) in their work followed a SoS approach to take into account the complexity of a multimodal transportation system in assessing the carbon emission impact of on-demand air service and automobiles.

3 MODEL FRAMEWORK DEVELOPMENT PHASES

The System Dynamics model framework based on System-of-Systems (SoS) approach was developed in two phases namely definition phase and abstraction phase. A description of each of these phases are provided below:

3.1 Definition Phase

The definition phase encompasses identifying constituents of the SoS, mapping traits of the SoS and categorize the network levels by utilizing the established SoS lexicon.

3.1.1 Constituents of the Systems of Systems

The integrated multimodal surface transport system of Abu Dhabi is solely targeted to provide an efficient and pleasant mode of transportation to the public that might include a number of modes of transport in a single journey. The total demand on the integrated transportation system would be thus dependent entirely on the availability and convenience of the individual modes of transport. In order to suffice this motivation, the two major criteria that should be taken into account are a comprehensive planning from macro level ensuring that all the individual modes of transport are effectively coordinated with each other and incorporation of Intelligent Transport Systems (ITS) such as automatic ticketing, travel planning, updates of departure and arrival times, etc. The individual modes of transport, referred here as components of the transportation systems-of system (SOS) include roadways, high-speed regional train, metro network, tram network, bus service, ferry and water taxi service.

3.1.2 SOS Traits Mapping and Design Principles

The SOS traits and design principles needed to establish the Integrated Public Transportation System of Abu-Dhabi as a system of systems comprising of different individual modes are identified in Table 1 (Maier 1999 and DeLaurentis 2005).

### 3.1.3 SOS Lexicon and ROPE Table

The following ROPE (Resource, Operations, Policy, and Economics) table (Table 2) shows the Abu Dhabi Integrated Public Transport Network in SoS lexicon and taxonomy terms. This is considered to be an important initial step in development of our model framework. Based on nature of the research problem described hereunder, the scope of the proposed model will tentatively be restricted to the Resources, Operations, and Policy elements of the β and the γ levels. As highlighted in the ROPE table, our focus is mainly to study the interaction between the different modes of the transport system and how their interaction affect the overall transportation system of Abu Dhabi. Each mode is an independent system and thus their interaction is expected to reveal some of the interesting emergent behaviors for the overall system, i.e. from a systems-of-systems perspective. This research covers both the vertical and horizontal interactions within the boundary specified in the above ROPE table.

3.2 Abstraction Phase

Abstraction is the most important step in developing a framework for a model. Its main purpose is to identify the key entities of actors, effectors, disturbances, and interdependency networks. Lewe and DeLaurentis (2004) identified four categories of entities such as explicit, implicit, exogenous, and endogenous. Entities are further classified as Endogenous-Explicit (Resource Network), Endogenous-Implicit (Stakeholder Network), Exogenous-Explicit (Disruptors), and Exogenous-Implicit (Drivers). Using the same approach, the following sections provide a description of the entities identified for our integrated public transport network model.

3.2.1 Resource Network

At the beta (β) and the gamma (γ) levels of the transportation system, the resource network can be viewed as a set of interconnected entities, each represented by a transportation mode, all having the common goal of reducing congestion and providing quality and convenient services to the public. The major modes considered in modeling Abu Dhabi’s surface transport network include highways, private transport (private vehicles and taxis) and public transport (rail, metro, bus, tram, and water ferries) systems. The attributes of these modes are assumed to be (1) average speed of the mode; (2) accessibility and range; (3) operation cost; (4) fare; (5) capacity; (6) delay time; (7) intermodal capability and (8) connection time. It is noteworthy that each transportation mode has its own unique set of attributes that differentiates it from the other modes and makes it a more favorable to a certain group of users (i.e. passengers). Figure 1 shows various transportation modes that are interconnected at the beta (β) level forming the gamma (γ) level that comprises Abu Dhabi’s integrated public transport network. The transportation network of Abu Dhabi is further connected to that of other states within the United Arab Emirates forming the UAE’s national surface transportation system but it is not in the scope of this research. Interactions and communications between the resource-network entities are expected to occur both horizontally (between the different modes as well as between the UAE states) and vertically (in a hierarchical sense) for management and coordination between the system components on technical,
economic, policy, and administrative aspects. Such interactions and communications take place through the various federal and governmental bodies as described below in the “Stakeholders” section.

3.2.2 Stakeholders

Similar to any public transportation system, there is a wide range of stakeholders in Abu Dhabi integrated public transport network. As the project is in planning stage, several entities are being acknowledged as stakeholders of the transport network but not yet fully established. Users can be considered as primary stakeholders in the transportation network. They are the ones who create the demand on the transport modes and their attributes would determine the most preferred mode of transportation on the beta (β) level. Each user has his/her special travel pattern, car availability, trip purposes, and personal preferences; however, only the aggregation of these alpha (α) level attributes will show on our model as an aggregation. At the country level, federal institutions such as National Transport Authority (NTA) in United Arab Emirates are responsible for development and implementation of transport policy of the entire country. At the state level, Department of Transport (DoT) is the main institution with responsibilities of developing general transport strategy, implementing the emirate’s air, land and sea transport policy, making recommendations to the government on setting up corporations in the related sectors, legislation, privatisation and tariffs. Now, modeling the attributes and behaviors of such stakeholders through a System Dynamics approach can prove to be a challenging task due to the limitations of such modeling technique. However, the directed nature of this System-of-Systems, as mentioned above, and by assuming that all stakeholders of relevance to our research problem, described herein, work together to achieve one single goal—rather than competing goals—made such modeling task feasible.

3.2.3 Drivers

Driver entities affect the behavior of the stakeholders and these can be categorized as economic, societal, and psychological (Lewe, DeLaurentis, & Mavris 2004). These drivers play an instrumental role in creating the demand on one or more of the transportation modes as well as in determining several transportation policies such as the tariff structure. Examples of drivers in our model include the following: (i) Population growth is deemed to be one of the core indicators of total demand on surface transportation network; (ii) GDP growth is of pivotal importance because population and demographics are directly affected by a change of GDP in Abu Dhabi which subsequently impacts demand on the network and its components; (iii) Passengers’ behavior: Abu Dhabi government has declared its ambitions of convincing residents to change their behavioral patterns and choose public transport for many of their daily trips in an attempt to reduce congestion and gas emissions from vehicles.

3.2.4 Disruptors

Disruptors are entities that are unfavorable and can affect the efficiency of the system. In the surface transport network, disruptors can directly result in the decrease of demand on the entire network or on one of the modes, each with a unique degree of effect. Examples of disruptors include (i) natural disruptors such as inclement weather. Abu Dhabi is known to have a hot arid climate throughout the summer and during the hot season the demand on transportation modes that may require short walks between nodes (between metro stations) or waiting time in an open space (bus station) will decrease causing a mode shift by users and (ii) artificial disruptors such as financial crisis. A financial crisis will directly result in a decreased number of expatriate workers and tourists, which will eventually decrease the total demand on the transportation network as the workers and tourists are believed to be the main potential users of the transportation network upon its completion.

4 MODEL FRAMEWORK

As highlighted earlier, total demand on the transportation network as well as individual demands on various transportation modes is believed to be influenced by several factors such as population, demographics and economy. To that end, the framework of our System Dynamics model is in form of a causal loop diagram that is composed of multiple interconnected sub-models. The sub-models as shown in Figure 2 are: (1) population sub-model; (2) migration sub-model; (3) GDP sub-model; (4) car ownership
The sub-models are connected by means of feedback loops. Each feedback loop has either a reinforcing or a balancing effect. For example, a population growth (out of the population sub-model) increases the congestion; on the other hand an increased fare for a transport mode will most likely result in decreasing the congestion in that mode. The relationships are based on information from existing literature, basic concepts and assumptions. The different types of sub-models considered to be the building blocks for developing the framework of the requisite model are as follows:

- **Population Growth & Migration Sub-models**
  Typically, the population growth will directly lead to more travel demand. Demand on the individual modes will also change, thus affecting the total demand on the integrated transportation system. Total population on the other hand is affected by the birth and death rates.

- **GDP Sub-model**
  As discussed before, increase in GDP of a country affects the travel demand by attracting more people to settle in that area. A decrease in GDP on the other hand might lead to emigration and thus decrease the overall travel demand and change demand on the individual travel modes.

- **Car Ownership Sub-model**
  Car Ownership, also considered as a level variable, plays an integral role in determining the demand on the private transportation network. Higher number of car ownership might lead to higher road congestion level and render the other modes of travel such as metro, rail and water ferry to be more convenient. However, the emergent behavior of the system cannot be predicted and it is unique for each individual scenarios.

- **Demand Sub-models**
  The demand sub-models include multiple auxiliary variables such as private and public transport attractiveness, people availing private transport, bus demand, HSR demand, metro demand, tram demand, and water ferry demand (shown in Figure 3). The attractiveness of each mode is assumed to be affected by road traffic congestion, fare, and level of service.
5 RESULT DISCUSSION

The framework developed in this paper would provide an essential tool for analyzing how a demand change for a particular mode would affect the total demand on the integrated transportation system. This would serve as an important decision making tool for the policy makers and investors to plan for the integrated transportation system. A major limitation of system dynamics model is that it requires mathematical relationships to run the simulation and study several scenarios and policies. Lack of data is a major problem in developing such types of system of system models. However, as a proof of concept we developed a hypothetical situation and run the model with synthesized data. The outputs of the simulation with respect to different time periods is given in Table 3.

6 CONCLUSIONS AND LIMITATIONS

This paper presented a system dynamics model framework for an integrated public transport network based on a system-of-systems approach. The model can be used to forecast passengers demand on a public transport network as well as on individual modes such as bus, metro, tram, HSR, and water ferries. The model can be further used to evaluate multiple scenarios by changing the values of variables and
rates incorporated in the model to show how the demand will change if GDP, migration rate, fare, crowdness, and level of service are changed for example. Several constraints and assumptions were made in developing and implementing the model. These include limiting the model to cover only passengers with no allowance for freight transportation, which resulted in omitting trucks and rail freight transport from the network. In addition, the model assumes that all stakeholders have the same objective of providing quality transportation services to the residents of Abu Dhabi. Profit making by the operators of each transport mode is not recognized as an objective of the stakeholders. In other words, the different transportation modes do not compete with each other but rather collaborate. Since the actual project is still in an early design phase, the capacity of each transportation mode as well as the fare are not yet determined.

MANAGEMENT OF CONSTRUCTION RISK THROUGH CONTRACTOR’S ALL RISK INSURANCE POLICY – A SOUTH AFRICA CASE STUDY

Suwisai Musundire¹,² and Clinton Aigbavboa¹
¹ Department of Construction Management & Quantity Surveying, University of Johannesburg, Johannesburg, South Africa
² caigbavboa@uj.ac.za

Abstract: Contractors’ All Risks (CAR) is a special insurance cover, which insurances those losses not covered by an ‘excluded peril’ in a construction contract. The benefit to the insured under this type of policy is that the burden is shifted to the insurer who, to resist the claim, is required to show that the cause of the loss falls within an exclusion. The objective of the current research is to study the efficiency of CAR in mitigating construction risk and to determine the factors which affect the use of CAR insurance policy in South Africa. The data for the study were derived from both primary and secondary sources. The primary data was obtained through the survey method, while the secondary data was derived from the review of literature. The primary data for the study was collected through a structured questionnaire survey distributed to a sample of 67 contracting firms who had taken CAR insurance and are currently using CAR in mitigating construction risk and 6 insurance companies who insure contractors under this policy. Findings from the study revealed that CAR Effectively covers work in progress, CAR protects the contractor’s interest effectively, CAR policy also protect the client’s interests effectively and that CAR assist the contractor in risk management by recognising potential risks and reducing the probability of such risks. Whilst the factors which affect the use of CAR insurance policy in the South Africa construction industry include: stipulation of the adopted conditions of standard construction contract, client’s requirement, cost and contractor’s own interest. The study adds to the body of knowledge on the use of CAR in the management of construction risk in the South Africa construction industry.

1 INTRODUCTION

Risk is inherent in any business venture, much more to the construction industry. Vital organizational resources are invested in business opportunities in the hope of obtaining a favourable financial return (Liu, Li & Lin, 2007). Risk lies in the possibility that such a return might not be realized; hence, risk management is crucial in a project. The rapid growth of the construction sector in South Africa since the end of the apartheid era and with the hosting of the 2010 FIFA world cup, brought new challenges due to the risks involved in design and production. South Africa construction enterprises are experiencing significant developments and structural reforms. South Africa construction companies are mostly privately and publicly owned whose risks, losses and profits are undertaken by the individuals and the enterprise managing directors. The changing business environment in the South Africa construction industry requires all contractors to manage risks adequately thus protecting the client’s from any form of loss.
According to Hertz and Thomas (1983), construction risk refers to a variety of situations involving many unknown, unexpected, frequently undesirable and often unpredictable factors. While, Perry and Hayes (1985) also referred to risk as an uncertain event or condition that, if it occurs, has a positive or negative effect on a project objective. Likewise, Jaffari (2001), asserted that risk is the exposure to loss, gain, or the probability of occurrence of loss/gain multiplied by its respective magnitude, whilst Abbasi et al. (2005) considered risk by the possibility of loss, injury, disadvantage or destruction from a given task. On the other hand, Berk and Kartal (2012) described risk as the potential for unexpected consequences of an activity. Construction risk management is widely recognized as one of the most important procedures and capability areas in the field of project management according to Tadayon et al (2012). Because construction projects are unique and dynamic, the construction operation involves numerous uncertainties, multiple intricacies, varies techniques, and divergent environments with uncertainties. Hence, recognising and managing the potential risk factors, which can considerably differ from project to project depending on several conditions, plays a crucial role in enhancing the performance and accomplishing the successful delivery of the enterprise.

Construction risk management has been the subject of numerous research studies. One of the earliest attempts to study construction risks and systematically identify their sources can be credited to the work of Chapman and Cooper (1983), whose study presented the “risk engineering” approach, which incorporated different techniques and tools, such as PERT, decision trees, and probability distributions. Liu et al. (2003) inform that managing risk involves creating awareness of uncertainty, qualifying the risks, managing the controllable risks, and minimizing the impact of uncontrollable risks by risk allocation. The ineffective implementations of risk management are often caused by (Liu et al., 2007):

- a lack of formalized risk management procedures, including risk identification,
- analysis and control (Tah and Carr, 2001);
- a lack of continuity of risk management in the different stages in the project life cycle, including conceive, design, plan, allocate, execute, deliver, review and support;
- poor integration between risk management and other key processes, including design, estimating, planning, production, logistics, cost analysis, manufacturing, quality assurance, reliability, schedule analysis, support (e.g. maintainability), and test and evaluation; and
- a lack of interaction among different parties, including clients, contractors, Insurers, and suppliers.

Construction risk management mechanism and procedures are not new to the South Africa construction industry. One of the major methods of mitigating against construction risk in South Africa, include risk transfer. Transferring risk is normally through subcontracting, insurance and modifying contract conditions. Out of these, insurance is one of the commonly used risk transferring methods in the construction industry. Hence, the contractor’s all risk insurance policy is a major risk mitigating tool in the South Africa construction industry. Hence, Odenyika (1999) observed that the insurance is one of the main methods of construction risk transfer in the construction industry. Also, Perera et al. (2008) scholar work also revealed that in the Sri Lankan construction industry risk is managed through insurance. Risk if, not managed properly, impacts negatively on the construction industry, hence the need to assess the efficiency of the generic solutions for risk management such as insurance. Therefore, the objective of this study is to assess the efficiency of CAR in mitigating construction risk and to determine the factors which affect the use of CAR insurance policy in the South Africa construction industry. The next section of the study discusses the subject matter of the research and thereafter, the methodology used for the study is presented before the presentation of the research findings, and thereafter, some conclusion and recommendation are made.
2   CONTRACTOR’S ALL RISK INSURANCE

Contractors’ All Risks (CAR) insurance is an all-inclusive insurance cover used in construction contracts. CAR is a short term insurance policy, which insures “the works” in a construction contract. The first CAR policy is said to have been issued in 1929 to cover the construction of the Lambeth Bridge across the Thames in London. Further to that, a special policy was created in Germany in 1934, but the real development of the policy took place with economic recovery and the construction boom after the Second World War (Wassmer, 1998). In South Africa, the Contractors’ All Risk policy is also often referred to as the ‘Builder’s risk’ or the ‘Course of construction policy’.

There are broadly two types of construction risks insurance. The first covers damage to property, such as damage to buildings and other structures being constructed or to the existing building in which the construction is being carried out (Dunning, 2009). The second type of CAR covers liability for third party claims for injury and death or damage to third party property. Modern forms of contractors’ all risks policies in the South Africa construction industry covers both. CAR’s basic principle is that the insurance covers those losses not covered by an “excluded peril”. The Contractor’s All Risks Insurance is specially designed to cover engineering projects involving both constructions of the building and other civil engineering works that are being carried out. CAR insurance provides coverage against any unforeseen and sudden physical loss or damage from any cause, other than those specifically excluded. Newman (2010) explains that the main characteristic of the CAR policy is that unlike other insurance policies, the CAR clause is not limited by reference to specified perils; in other words, everything is covered unless it is excluded, expressly or by implication. CAR policy is usually combined with (but must be distinguished from) Public liabilities or Third party liabilities policies in the South African setting. CAR is designed to provide cover for all the parties involved in a construction project, hence, the policy is usually acquired in the joint names of the Client or the Principal agent and the Contractor. Other interested parties, such as funders, often ask to be added as a joint name. According to Dunning (2009), the theory is that if damage occurs to the insured property then, regardless of fault, insurance funds will be available to allow for reinstatement. The effect of joint names insurance is that each party has its own rights under the policy and can therefore claim against the insurer. Each insured should comply with the duties of disclosure and notification. However, insurer has no right of subrogation against the other insured party, which means that the insurer is not able to recover sums paid to one co-insured under the policy by pursuing a subrogated action in the name of the other insured (Bunni, 1986; Flanagan & Norman, 1993; Dunning, 2009). The CAR insurance has a standard format regarding cover although different insurance companies may have different special wordings to suit their clients. Some significant features and benefits of the Policy include:

- Covers permanent and temporary works being carried out.
- Covers contractors’ tools, plant, equipment (including spare parts), site huts and scaffolding.
- Covers cost of recovery of property that is immobilised or embedded in soft ground providing it is not due to mechanical or electrical failure of the property.
- Covers materials in transit to or from or, held in storage at contract site.
- Policy provides cover as standard in Great Britain. Republic of Ireland, Northern Ireland, Isle of Man, and the Channel Islands.
- Covers the cost of professional fees incurred during the reinstatement of property.
- Unlimited cover for the cost of debris removal.
- Cover applies during any maintenance periods specified in contract.
- Cover for the cost of rewriting plans and specifications (this is project specific).
- Provides cover (to a specified limit per employee) for the loss of employees’ tools and effects.
- Contents cover (to a specified limit) for loss and damage to contents of show houses.
- Optional extension to cover continual hiring in fees.

The CAR insurance not only transfer risks, it is also assist the contractor in risk management by recognizing potential risks and assist in the reduction of the probability of such risks. Hence, Flanagan and Norman (1993) state that the readiness of the insurer to write an insurance coverage reflects favorably on the insured’s efforts at risk prevention. According to McNameee, (1999) risk management
practice of the past largely focused on hazard insurance and probable loss. But today it focuses on the broad issues of general management. Among the insurance covers used in construction, Contractors’ All Risk (CAR) policy has been accepted worldwide as a comprehensive cover by which all the material damages and third party damages are covered (Perera et al., 2008). The CAR policy used in South Africa is almost the same as that of other countries. The next section of the research discusses the methodology used in conducting the research.

3 METHODOLOGY

The data used in this study were derived from both primary and secondary sources. The primary data was obtained through the questionnaire survey method, while the secondary data was derived from the review of literature and archival records. The primary data was obtained through the use of a structured questionnaire aimed at 67 contractors, construction professional and insurance companies in Johannesburg to meet the research objectives. The construction professionals and contractors were randomly selected amongst their peers. Whilst the insurance companies that are known for undertaking CAR were surveyed. Survey participants included contractors, architects, quantity surveyors, civil engineers, construction and project managers who have experience in the use of CAR policy. A list of construction professional who works within the greater Johannesburg Metropolitan Municipality was obtained from the respective professional council and the Council for the Built Environment- the watchdog of professionals in the country via the various professional councils; whilst the list of contractors was obtained from the Construction Industry Development Board, the entity responsible for the registering of contractors in the country. This approach concurs with the work of Swan & Khalfan (2007) who advise that the inclusion of all construction professionals and contractors, is essential for successful project delivery- which applies to the current study. Random sampling was used to select the professionals and the contractors from the obtained list. According to Kombo and Tromp (2006) random sampling is the probability whereby people, place or things are randomly selected. From the list of construction professionals and contractors, 60 were randomly selected. This yardstick was considered vital for the survey in order to have a true assessment of the efficiency of CAR in mitigating construction risk and likewise to determine the factors which affect the use of CAR insurance policy in the South Africa construction industry.

Because all professionals as contained on the list had an equal chance to be drawn and participate in the survey. Out of the 60 questionnaires sent out, 51 were received back representing 85.0% response rate. This was considered satisfactory for the analysis based on the assertion by Moser and Kalton (1971), that the result of a survey could be considered as biased and of little value if the return rate was lower than 30% to 40%. Because the sample size for this study was relatively small, all groups of respondents were combined together in the analysis in order to obtain significant results. The data were analysed by calculating frequencies and the mean item score (MIS) of the rated factors. Although the empirical study is based on a relatively small sample of 51 construction professionals and contractors, the findings provide an insight into the general perception of the efficiency of CAR in mitigating construction risk and likewise the factors which affect the use of CAR insurance policy in the South Africa construction industry. The calculation of the MIS is explained in the next section. The research was conducted between the months of July to October, 2014. The questionnaire was designed based on the information gathered during the literature review and does not form part of an existing survey instrument.

3.1 Mean Item Score (MIS)

A five point Likert scale was used to determine the efficiency of CAR in mitigating construction risk and likewise the factors which affect the use of CAR insurance policy in the South Africa construction industry with regards to the identified factors from the extant review of literature. The adopted scale was as follows: (1) = Strongly disagree; (2) = Disagree; (3) = Neutral; (4) = Agree; and (5) = Strongly agree. The five-point Likert scale scores were transformed to an MIS for each of the identified factors as scored by the respondents. The indices were then used to determine the rank of each item. These rankings made it possible to cross compare the relative importance of the items as perceived by the respondents. The computation of the MIS was calculated from the total of all weighted responses and then relating it to the
total responses on a particular aspect. This was based on the principle that respondents’ scores on all the selected criteria, considered together, are the empirically determined indices of relative importance. The index of MIS of a particular factor is the sum of the respondents’ actual scores (on the 5-point scale) given by all the respondents’ as a proportion of the sum of all maximum possible scores on the 5-point scale that all the respondents could give to that criterion. Weighting were assigned to each responses ranging from one to five for the responses of ‘strongly disagree’ to ‘strongly agree’. This is expressed mathematically in Equation 1.0. The relative index for each item was calculated for each item as follows, after Lim and Alum (1995):

\[
MIS = \frac{1n_1 + 2n_2 + 3n_3 + 4n_4 + 5n_5}{\sum N}
\]

Where; \( n_1 \) = Number of respondents for strongly disagree; \( n_2 \) = Number of respondents for disagree; \( n_3 \) = Number of respondents for neutral; \( n_4 \) = Number of respondents for agree; \( n_5 \) = Number of respondents for strongly agree; \( N \) = Total number of respondents. Following the mathematical computations, the criteria were then ranked in descending order of their relative importance index (from the highest to the lowest). The next section of the article presents the findings of the survey and some discussion.

4 FINDINGS AND DISCUSSION

4.1 Efficiency of the CAR policy- The Insured’s perspective

Based on the ranking (R) of the weighted averages, the mean item scores (MIS) for the listed perception of the efficiency of CAR in mitigating construction risk in the South Africa construction industry were identified (Table 1). The survey findings revealed the six list factors were all significant. The most important efficiency of the use of CAR in the industry were that: CAR policy protect the client’s interests effectively (MIS=3.80; SD=0.71; R=1); CAR policy protect the contractor’s interest effectively (MIS=3.71; SD=0.90; R=2); and that CAR assist the contractor in risk management by recognising potential risks and reducing the probability of such risks (MIS=3.68; SD=0.91; R=3) as shown in Table 1.

<table>
<thead>
<tr>
<th>USE OF CAR</th>
<th>RANK</th>
<th>MIS</th>
<th>SD</th>
</tr>
</thead>
<tbody>
<tr>
<td>Contractor’s all risk policy protect the client’s interests effectively</td>
<td>1</td>

</tbody>
</table>

Whilst the two least rated usage of CAR as shown in Table 1 are that CAR effectively covers work in progress (MIS=3.46; SD=1.04; R=5) and that CAR serves the procurement needs by covering material related risks (MIS=3.20; SD=1.13; R=6).

4.2 Factor affecting the use of the CAR policy

Furthermore, when the perspective of the Insurer’s was solicited on the factors which affect the efficiency of CAR, result emanating from the questionnaire analysis revealed that the most significant factors were

<td>1.26</td>
</tr>
</tbody>
</table>

Also, when the factors which affect the use of the CAR policy was assessed from the contractors’ and design professional perspectives, it was found that the following statements as shown in Table 3 were scored higher: client’s requirement (MIS=4.07; SD=0.96; R=1); construction industry environment (MIS=4.00; SD=0.88; R=2); conditions of standard construction contract in use for the project (MIS=3.87; SD=0.92; R=3) and knowledge and experience of the contractors / professionals (MIS=3.77; SD=0.80; R=4). However, the findings further revealed that the contractor’s own interest and cost were not factors that affect the usage of CAR in the construction industry.

Findings from the study concurs with the work of Perera et al. (2008) which was based on the Sri Lanka construction industry; which revealed that the client’s requirement is the most significant motivation for the
use of the CAR policy as opposed to the contractor's own interest. Also, the contractor's own interest was rated low which may have a bearing to the fact that contractors are not paying attention to the two concepts as theorised Flanagan and Norman (1993) which informed that contractors should not have a mentality of “All Goes According to plan” but must consider “What happens IF” in order to trigger their personal interest in obtaining the CAR insurance. The findings for the study was further supported by Liu et al. (2007) who inform that Chinese contractors do not use insurance because of the high influence of the environment which the Chinese government has caused contractors not to have a realistic attitude towards risk.

5 CONCLUSION

The study investigated the efficiency of CAR in mitigating construction risk and likewise the factors which affect the use of CAR insurance policy in the South Africa construction. This study identified the efficiency of the use of CAR and likewise the factors which affects it usage in the industry. The most critical efficiency of CAR's were identified to be that CAR policy protect the client’s interests effectively; CAR policy protect the contractor’s interest effectively; and that CAR assist the contractor in risk management by recognising potential risks and reducing the probability of such risks. Furthermore, the study found that the insurer’s factors which affect CAR's usage in the industry as: lack of background of construction; lack of risk management knowledge and expertise in managing or administering CAR; lack of understanding of contractor’s/ construction risk and lack of risk assessment (extend to known). The study also identified the contractor’s and design professionals’ factors which affect the use of CAR as: adherence to client’s requirement; construction industry environment; conditions of standard construction contract in use for the project and knowledge and experience of the contractors / professionals. The study concludes that there are a number of usefulness in the use of the CAR insurance in mitigating against construction risk in the South Africa construction industry. These usage have the potentials to greatly reduce risk to all parties to the construction projects in South Africa; and when properly implemented, it will give the industry an advantage to meaningful enhance profitability, productivity, compatibility and delivery of construction jobs which will boost the South Africa national economic growth and strength and performance of the construction industry. Hence, it is therefore recommended in order to increase the efficiency of use of CAR insurance, insurance companies should investigate the site in order to assess the risk and before computing the premium. Also, the contractors need to maintain a good records of accidents throughout the project to enable me see the need to protect their own interest. Also, insurance companies and contractors should maintain a cordial relationship by means of active communication especially with underwriters, loss adjusters, which will assist in knowledge sharing that will be mutually exclusive in the formation of the policy and that contractors should implement maximum safety measures as a priority especially if it can be foreseen as a potential risk of damage.

AN IMAGE-BASED FRAMEWORK FOR AUTOMATED DISCREPANCY QUANTIFICATION AND REALIGNMENT OF INDUSTRIAL ASSEMBLIES

Mohammad Nahangi¹, Thomas Czerniawski¹, Jamie Yeung¹, Carl T. Haas¹, Scott Walbridge¹, Jeffrey West¹
¹ Civil Infrastructure Sensing Laboratory, Civil and Environmental Engineering Department, University of Waterloo, Waterloo, ON, Canada

Abstract: Image-based frameworks for automated as-built modeling and infrastructure 3D reconstruction are increasingly being used in the construction industry. The increasing use of image-based technologies in the construction processes is due to the ease of application, cheap cost of enhancement, time effectiveness and high level of accuracy and automation. Automating the tasks involved in the inspection, quality control and quality assurance (QA/QC) processes are the potential avenues for utilizing such frameworks. This paper presents an image-based approach for acquiring the built status of fabricated assemblies and describes a framework for realigning the defective segments by borrowing concepts from robotics and forward kinematics. A laboratory set of experiments is then conducted to measure the accuracy and performance of the proposed framework for realignment of industrial facilities, in general, and pipe spools, in particular. Results demonstrate that it can be utilized in real cases providing the required level of accuracy as well.

1 INTRODUCTION

Inspecting and monitoring of civil infrastructure is a critical challenge that has to be performed in various construction and maintenance phases. Inspection processes guarantee that construction segments and components are reliably fabricated, transported, and erected. They also provide the determination of as-built status and dimensions required for potential considerations needed to be given to defective segments. These tasks are difficult to perform on construction sites. Inspection processes to perform quality control and quality assurance (QA/QC) processes become more critical in staged fabrication that requires sequential fabrication and installation. In the construction industry, in particular, staged fabrication includes but is not limited to prefabricated steel columns, concrete segments and huge pipe spools/modules. Although construction segments are typically correctly fabricated considering recent advances in the fabrication industry, they still require continuous inspection as dimensional errors are introduced during transportation and shipment. As-built status acquisition is therefore necessary to assess the current state of construction elements and determine the potential considerations for repair and realignment.

Manual and conventional approaches to acquire the as-built status are inherently prone to error and therefore often ineffective and inaccurate. Craft workers use tape measuring and paper-based methods to inspect and control the fabrication quality. The as-built status acquired is therefore often unreliable and may cause profound unfavorable effects on construction sites such as schedule delays and rework. For example, in the case a defective segment is erected on site and discrepancies are not detected in a
timely and accurate manner, the segment is going to be either repaired or replaced whereby both cases are associated with rework. Therefore, as-built status of construction elements must be acquired in a timely manner and electronically transferred to various interfaces involved in order to provide managers and decision makers with an effective framework. In the last couple of decades, adequate accuracy and speed for as-built status acquisition and assessment has become possible utilizing various sensing technologies including Ultra Wide Band (UWB) tags, Global Positioning System (GPS), Radio Frequency Identification (RFID), and 3D imaging techniques. Among these sensing technologies, 3D imaging that provides spatial and detailed geometric information of objects is a reliable method for detailed and geometric as-built status acquisition. 3D imaging is the general name for the process used to generate three dimensional images, also called point clouds, that includes LADAR (Laser and Distance Ranging), range imaging, videogrammetry, traditional photogrammetry, and modern photogrammetry which is also known as image-based sensing technology. Among these technologies, laser scanning is the most common technique in the related industry because of the ease of use and the level of accuracy provided. However, there are major limitations involved with laser-based methods that make it less applicable under some conditions. These conditions may include the time required for setting up, data preprocessing, and occlusion occurrences in busy construction environments. Cost of purchasing is an additional barrier for laser scanners that makes them less accessible by all contractors and project managers. Developing a cheaper framework, commonly affordable, with a high rate of accuracy that can address the mentioned deficiencies of laser scanners is therefore necessary.

In recent years, some research efforts have attempted to address these limitations of laser scanners. Image and video based techniques that have been developed during the past several years are the emerging solutions that are significantly less expensive than laser scanning. It has been stated that image-based methods can provide the desirable level of accuracy and automation if well applied. According to (Dai et al. 2013; Golparvar-Fard et al. 2011; Zhu and Brilakis 2009) image-based 3D reconstruction has provided a comparable level of accuracy to laser-based methods without the previously discussed limitations of laser scanners.

One of the key advantages of utilizing the image-based techniques to assess the as-built status of construction elements is that it does not require any further consideration or procedure on construction sites as images are taken on a regular basis by inspectors (Golparvar-Fard et al. 2011). Such random and unordered images can be imported to a cloud server on a daily or weekly basis for further processing in order to generate 3D images for assessing the as-built status. This paper presents an image-based framework in order to accurately detect, characterize, and identify the discrepancies between the as-built status and as-designed data (Figure 1). Most research to date is relatively limited in its approach to the automated detection of visible damage and defects. There is still a significant lack of knowledge in civil infrastructure aimed at effectively and efficiently assessing the construction processes in different phases in order to realign defective assemblies in a timely manner.

![Figure 1: Proposed framework for image-based 3D model generation and realignment strategy](image)

This research is directed toward damage prevention by localizing and quantifying fabrication errors and generating a potential solution for repair and rehabilitation in a systematic way. In order to comprehensively determine the knowledge gap and the need in the construction industry, the related background is extensively investigated. The research methodology to develop the proposed framework is then presented, and required functions and metrics are formed. A set of experiments are then designed in
order to validate the proposed framework and evaluate its accuracy by comparing the results with previously acquired laser-based data.

2 RESEARCH BACKGROUND

The key contribution of the framework presented in this work is an image-based reconstruction technique for the as-built status assessment of industrial facilities compared with laser-based status acquisition. Recent studies attempted for inspecting, monitoring, and assessing the built status of civil infrastructure, in general, are also briefly reviewed. The related background is extensively investigated in order to determine the current state of these methods, and the knowledge gap is therefore comprehensively identified.

2.1 Monitoring and Inspecting Civil Infrastructure for the Built Status Assessment

Using automated tools for monitoring and inspection purposes in construction provides a superior level of accuracy. The automated tools and techniques for reliable and accurate 3D measurement are also being increasingly used because of electronic communication and integration with other interfaces in the construction management system. 3D spatial locating devices such as ultra-wide band (UWB) and radio frequency identification (RFID) tags have been used for automated material location on heavy industrial construction facilities (Razavi and Haas 2010). They have been found to improve productivity and to reduce risk substantially.

Additionally, 3D sensing and imaging technologies such as laser scanning, image/video-based reconstruction methods, and range imaging are used for a wide range of applications in construction. Laser scanning was first introduced as a tool for structural health monitoring (Park et al. 2007). Automating the tasks involved in the processing step to use the point clouds generated by laser scanners improved the applicability of laser-based techniques in real-sized and complex construction sites. Bosche et al. (2009) developed a method for automated recognition of CAD objects in cluttered point clouds that was later employed for automated progress tracking of construction components (Turkan et al. 2012). Laser scanning can be employed for compliance control used for QA/QC purposes. An automated framework was used for compliance control of industrial assemblies using laser-scanned point clouds (Nahangi and Haas 2014). A video-based 3D point cloud generation technique (videogrammetry), was also employed to acquire the as-built status (Brilakis et al. 2011; Koch et al. 2013), to be used for various purposes such as progress tracking and status assessment discussed earlier. Recently, 3D sensing technologies have been actively employed for tracking the progress of the industrial construction or Mechanical Electrical and Piping (MEP) components (Ahmed et al. 2012; Dimitrov and Golparvar-Fard 2015; Lee et al. 2013; Son et al. 2014). The use of image-based techniques and their application in the construction industry are discussed in the following section.

2.2 Image-Based 3D Reconstruction State-Of-The-Art in the Construction Industry

Photogrammetry is well known as a 3D reconstruction technique. It was originally developed for generating the stereo elevation from aerial photos (Mikhail et al. 2001). In recent decades, advances in the camera production industry have provided the required accuracy for close-range applications such as industrial inspection and architectural documentation. The challenge associated with traditional photogrammetry techniques is the manual labour and computationally intensive processing involved. When high accuracy is desired for further investigations, computational cost and time also increased. This drawback of traditional photogrammetry has been a challenging factor over the years that makes it limited and currently not applicable for near-real-time modeling. Later advancements in the processing unit and related industry significantly improved the preprocessing time involved for common feature detection; however, it was still time consuming to achieve the required accuracy (Mikhail et al. 2001).

With the rise of digital images and digital photos, traditional techniques were replaced with modern and digital photogrammetry, which resulted in profound improvements in accuracy considering the required processing time (Brilakis et al. 2012; Jahanshahi et al. 2009; Liu et al. 2014). In the construction industry, the use of modern photogrammetry thus became more significant as it was much less expensive than
laser scanning, the most common technique in AEC industry for as-built status acquisition, mentioned earlier. A study by (El-Omari and Moselhi 2008) showed the enhancement of integrating photogrammetry and laser scanning for progress tracking, which was proven to be more time effective. Researchers enhanced the use of close range photogrammetry for pavement pothole localization and progress tracking in pipe-works construction (Ahmed et al. 2011; Ahmed et al. 2012). Most of this research showed the time effectiveness of the application of photogrammetry in the related industry, however, some major limitations such as the desired accuracy and required intensive preprocessing, such as camera calibration, severely diminished the method’s practical utility compared to its competitor, laser scanning.

New and innovative techniques have emerged, however for the detection of common features of the desired accuracy without requiring camera calibration. Such automated feature detection techniques include scale the invariant feature transform (SIFT) and speeded up robust features (SURF). (Golparvar-Fard et al. 2009) introduced as automated reconstruction techniques that use time-lapsed photographs to generate the as-built status of construction projects in order to measure the progress on construction sites. (Zhu and Brilakis 2009) investigated the accuracy of the optical-based methods compared to laser-based techniques for the reconstruction of the built status of civil infrastructure. They concluded that laser scanning has larger range for data collection with a higher level of accuracy that makes it more reliable though also more costly. They have suggested the efficient optical-based technique for different applications in the construction industry under various circumstances. These methods include videogrammetry and 3D range imaging that can be employed based on the level of accuracy required and the application used.

The construction industry, several research efforts have been attempted to evaluate the accuracy and investigate time and cost effectiveness of the image-based methods compared to laser scanning. Golparvar-Fard et al. (2011) evaluated the accuracy of an image-based 3D point cloud for determining the as-built status of construction elements compared to a laser-based 3D point cloud. They concluded that the accuracy provided by laser scanning is slightly higher than image-based techniques, however, image-based reconstruction is quicker and less costly.

Bhatla et al. (2012) evaluated the accuracy of an image-based reconstruction framework for assessing the built status of bridge girders. According to this study, image-based 3D reconstruction using free, promising commercial software packages provided the desired level of accuracy; however, their study also revealed that for highly accurate modeling purposes, laser scanning is more appropriate. (Dai et al. 2013) comprehensively compared the image-based techniques with time-of-flight in various civil infrastructure. Such a comparison includes the accuracy of reconstruction, density of the point cloud generated, cost of purchasing and utilizing, and the required time for setting up and processing. Their study revealed that both photogrammetry and videogrammetry can provide sufficiently dense and accurate point clouds to be employed for different applications such as visualization. It was stated that photogrammetry is sufficiently accurate to be used for as-built quality control on construction sites. In summary, image-based 3D reconstruction, which is originally known as photogrammetry, has provided the desired accuracy within a reasonable processing time due to the recent advances in the related industry that are previously discussed. Such improvements in image-based reconstruction provide the opportunity to employ related techniques in different inspection phases of civil infrastructure.

Despite the significant impact of automated tools, in general, and image-based techniques, in particular, in the construction industry, their uses are mostly directed toward object recognition for status assessment. A preventive approach to measure the discrepancies in a time effective way that can avoid rework is needed. Nahangi et al. (2015a) showed the effectiveness of laser-based point clouds for discrepancy detection and a realignment strategy. This paper is aimed to generalize the previous developments by employing an image-based framework for the as-built status acquisition and to measure the performances of the resulted realignment strategies. The detailed methodology along with the required functions and metrics are explained in the following section.
3 PROPOSED METHODOLOGY

For generating the 3D model required for performing the as-built status identification and discrepancy quantification, an image-based framework is used. As shown in Figure 2, the image-based algorithm for automated discrepancy detection and quantification has two primary steps: (1) Image-based 3D point cloud generation that provides the as-built status with a reasonable level of accuracy, and (2) processing that enables detection, localization, and quantification of incurred discrepancies based on the original drawings. The primary steps and the required components are extensively explained in the following section.

![Image-based framework](image.png)

**Figure 2: Algorithm for automated discrepancy quantification using an image-based framework**

3.1 Image-Based 3D Point Cloud Generation

Inspectors and QA/QC managers use off-the-shelf digital cameras. Cellphone and tablet cameras can also be used to acquire the required images. Once sufficient numbers of images with sufficient overlap are captured, they are imported to a cloud server/database for point cloud generation. The image processing toolboxes for image stitching and 3D point cloud generation can be employed. These toolboxes include MATLAB Image Processing Toolbox and open source databases such as Open CV (Open source computer vision library at the University of Washington) and PCL (Point Cloud Library). In this study, Autodesk 123D Catch (www.123dapp.com/catch) is employed. The 3D reconstruction of construction assemblies using images is composed of a set of steps:

- Finding common features in the images taken,
- Matching the common features detected,
- Transforming the images into a global coordinate space based on the common features.

Based on the required processing steps mentioned above, more images taken improves the applicability and performance of the algorithm. Furthermore, a sufficient level of overlapping between images must exist in order to find a reliable set of matching features. Once a 3D model of the construction environment is roughly generated, unwanted objects and the existing noise are filtered. Noise removal is performed manually by removing the objects outside the region of interest. This can be automated in the future.
3.2 Processing

Once appropriate 3D model is generated using the proposed image-based framework, a set of processes is required to quantify the incurred discrepancies based on the framework developed by Nahangi et al. (2015b). Such processes include:

- **Registration**: the filtered 3D model can now be used for registration with CAD drawings converted to an appropriate format (i.e. point cloud format such as STL), in order to enhance a comparison. A modified iterative closes point (ICP) is used for registration in this study.
- **Kinematics chain development**: the geometric relationship is established using an analogy of robotics. The kinematics chain development results in a set of transformations required to identify the geometry of assemblies.
- **Local registration**: a sliding cube moves along the assembly and quantifies the discrepancies where it is occurred. A local registration is performed on the contained points in the cube at each location that the discrepancy is being investigated. The resulted discrepancy is then transformed to the local coordinate system defined by the previously developed kinematics chain.

The quantified discrepancy can be fed into a realignment planning framework for potential realignment strategies (Nahangi et al. 2015a).

4 EXPERIMENTAL VERIFICATION

A set of experiments is designed to verify and validate the performance of the explained image-based algorithm for discrepancy quantification.

4.1 Design of Experiments

The experiments are validated on a small-scale set of pipe spools existing in Civil Infrastructure Sensing Laboratory at University of Waterloo. The pipe spool is designed so that the connections and joints allow reconfigurability. In other words, the pipe spool can be reconfigured by introducing any alteration; so that the algorithm for discrepancy quantification can be tested. The reconfigurable pipe spool used for the experimental tests is shown in Figure 3.

![Adjustable connections](image)

Figure 3: The experimental specimen (reconfigurable set of pipe spool) and the investigated branch.

An off-the-shelf digital camera is used for this experimental study. An SX40-HS Canon camera was used at 12.2 megapixel resolution. Technical details of the camera can be found in Table 1.

In order to compare the accuracy of the proposed image-based framework with laser-based point clouds, a similar set of alterations to the previous experimental study by (Nahangi et al. 2015b) is applied. The alteration is applied in the form of rotational, translational, and combined discrepancies on the investigated branch shown in Figure 3.

4.2 Results

After uploading the taken images they are uploaded to the server for generating the 3D point cloud of the tested assemblies and spool branches. Typical photogrammetry data and results of the generated point cloud for the original state of the investigated branch are shown in Table 2 and Figure 4.

</tbody>
</table>

Figure 4: Photogrammetry results. 123D Catch software output (a); the mesh is converted to point cloud (b); the noise is manually removed and the branch is properly retrieved (c)

Experimental results (Figure 5) show that the quantified discrepancies provided by photogrammetry are less accurate comparing to the similar tests performed on laser-based technologies. Maximum error for the image-based framework developed in this work is 0.369° and 0.184 cm for rotational and translational discrepancies, respectively; while, maximum error for the laser-based technique used in the previous study by Nahangi et al. (2015b) is reported as 0.237° and 0.02 cm. However, the image-based 3D point cloud is still reliable for discrepancy quantification based on the required level of accuracy in some
applications. Moreover, using a finer mesh for 3D reconstruction will provide a more accurate point cloud although it is computationally more intensive.

5 CONCLUSIONS AND RECOMMENDATIONS

An image-based framework was presented for automated discrepancy detection and realignment planning. The scope of this study was industrial assemblies, in general, and pipe spool assemblies, in particular. Typical users who are QA/QC managers or inspectors use cellphones, tablets or digital cameras to take unordered photos and upload to a cloud server for processing. The processing step results in a 3D point cloud representing the built status that will be compared with the original CAD drawings. For the comparison purpose, 3D image registration is employed. Once the two representing states are appropriately registered, an analogy of robotics results in the development of geometries of the assemblies. Such an approach provides localized discrepancy feedback to be used for realignment strategies. Some remarks on the experimental verification follow:

- The enhanced image-based framework is significantly cheaper than laser-based techniques. This makes it more applicable, particularly for the cases where a lower level of accuracy is required.
- The data acquisition step for the proposed image-based framework requires minimal prior knowledge and training.
- Image-based discrepancies are reasonably reliable and accurate; however, laser-based point clouds are more precise, which concurs with the previous evaluation studies (Bhatla et al. 2012; Dai et al. 2013; Golparvar-Fard et al. 2011)

A limitation of the proposed methodology is that it requires more processing time for the images to be retrieved and generate the 3D point cloud.

Acknowledgements

The authors would like to thank Ian Bowes for assisting in the development of the framework during his coop term at the University of Waterloo. This research is funded by National Science and Engineering Research Council (NSERC) of Canada (partially funded by NSERC CRD with Aecon and SNC-Lavalin and NSERC Discovery Grant).

A SMART MOBILE APP FOR SITE INSPECTION AND DOCUMENTATION

Long D. Nguyen¹, Anna Koufakou² and Colin Mitchell³

² Department of Software Engineering, Florida Gulf Coast University, USA
³ Department of Software Engineering, Florida Gulf Coast University, USA

Abstract: Extensive time and effort are spent on inspecting and documenting construction defects for facilities under construction or in use. The goal of this study is to provide construction engineers and experts with a smart mobile application to efficiently record and document construction defects. This study first investigated typical inspection processes, data, and reports which were used in site inspections in practice. An Android-based mobile application called InSite Inspector (Intelligent Site Inspector) was then developed to facilitate site inspection and documentation. This smart app is able to: (i) take images and catalog details of construction defects such as defect types, construction trades, building components, and date and time; (ii) automatically locate defects using the global positioning system (GPS); and (iii) produce various types of reports for different inspection purposes such as punch lists and defect reports. The inspectors are allowed to customize the app features such as text entries, type of data to be recorded and/or reported to meet their specific inspection requirements. Additionally, the InSite Inspector allows engineers and experts to manage different construction sites, inspections, and to keep track of past and ongoing inspections. Finally, the app can be used to save, email, or upload the resulting reports to cloud-based repositories. An inspection case study was used to demonstrate the application and utilities of this development. The InSite Inspector is expected to significantly streamline site inspection and documentation processes.

1 INTRODUCTION

In the construction industry, extensive time and effort are spent on inspecting and documenting construction defects for buildings under construction or in use. When a building project is almost completed, project parties conduct site inspections to prepare punch lists and repair defects before the building is handed over to its owner. For an occupied building, the owner, designer, contractor, and other parties may conduct site inspections when substantial defects are identified. Construction defects are therefore a major concern for all stakeholders, including owners, designers, builders, and insurance companies. Literature indicates the ratification cost of defects in between 2% and 12.4% of the construction cost (Lundkvist et al., 2014). With the construction value of $975 billion in 2014 (Census Bureau, 2015), the ratification of defects could cost the U.S. taxpayers in a range of $20 – $120 billion last year. In addition to the cost of repairs, defects are one of the major sources of costly and lengthy construction dispute and litigation in the U.S. In a construction defect dispute or litigation, both claimant and defendant inspect the property and report their findings and results of the inspection. Unfortunately, the current inspection, defect classification, and documentation process is time-consuming and expensive.
This paper presents a smart application called InSite Inspector (Intelligent Site Inspector) that efficiently records and documents construction defects. The InSite Inspector is able to (i) take images and catalog details of construction defects such as defect types, construction trades, building components, and date and time; (ii) automatically locate defects using the global positioning system (GPS); and (iii) produce various types of reports for different inspection purposes such as punch lists and defect reports.

2 BACKGROUND

Site inspections regularly take place during the course of construction to discover non-conformities for timely rectification. A study of 20,000-square meter conference center in Sweden showed that a combined total of 41 pre-inspections over the course of just over a year were conducted for the construction of roof, facades, balconies and glasswork alone prior to the final inspection (Lundkvist et al., 2014). In the inspection process, site engineers and managers typically record information about defects on documents, such as drawings and checklists, while walking around the site (Cox et al., 2002; Kwon et al., 2014). As such, Gordon et al. (2007) stated that the present defect management techniques require a lot of manual labor.

Site inspection may also be required in the operation phase of a facility if defects are recognized or potentially occur. Many defects were latent and only appeared a few years after commissioning (Park et al., 2013). In fact, construction defects are a major cause of dispute and litigation in all types of construction, from residential, institutional, and commercial to industrial and infrastructure. Figure 1 showed the typical current construction defect inspection and documentation. The parties in dispute are required to investigate and classify defects for allocating liabilities of the alleged defects (Figure 1, Step 1). When a construction defect dispute or litigation arises, both parties have to hire construction experts for numerous hours for site inspection, defect classification, and documentation (Figure 1, Step 2). In addition they must spend time to describe and classify defects, and document their findings (Figure 1, Steps 3, 4, and 5). Step 6 can be applicable to site inspection for disputes involving construction defects. Therefore, reducing the time and cost of the defect inspection, classification, and documentation is imperative. Fortunately, the current information and communication technologies (ICTs) can be employed to improve the defect management systems (Park et al., 2013).

Figure 1: Current construction defect inspection and documentation

Previous studies have proposed various ICT tools to improve defect management. The development of these tools helps not only improve the defect management but also reduce its costs (Lundkvist et al., 2014). Cox et al. (2002) investigated the use of Pocket Personal Computers (Pocket PCs) to automate the field data collection process. Dong et al. (2009) presented a synchronous collaboration between a
construction site and an off-site office using telematics digital workbench that incorporated mobile computing, wireless communications, and a horizontal tabletop interface. Kim et al. (2008) and Wang (2008) developed a computerized quality inspection and defect management system that can collect real-time data in construction sites using Personal Digital Assistant (PDA) and wireless Internet. A major drawback of the above approaches is that their technology platforms are obsolete or even no longer exist.

Recent studies attempted to improve defect management using Building Information Modeling (BIM), augmented reality, and ontology-based data collection template (Park et al., 2013; Kwon et al., 2014). These improvements may be useful for construction projects in which BIM are employed for collaboration. Thus, the improvements may not be widely used in a foreseeable future as BIM models are still not adopted in many construction projects in the present time. This is particularly the case for defect inspection and management for facilities under occupancy. This current research has attempted to develop a stand-alone application, InSite Inspector, which can be used specifically for site inspection and documentation for facilities either under construction or in use. Figure 2 demonstrates our proposed construction defect inspection and documentation.

![Diagram of construction defect inspection and documentation]

Figure 2: Proposed construction defect inspection and documentation

Step 2 (Figure 2) is focused at the current stage of our study and is the scope of this paper. Engineers and managers can use InSite Inspector for collecting defect information (images, location, defect type, partied involved, etc.) InSite Inspector allows users to customize and produce different types of inspection reports. Engineers and managers will then spend minimal time to finalize report of their site inspection (Figure 2, Step 3). The ultimate goal of the InSite Inspector is to support site inspection, automatically classify defects, extract defect records, and generate inspection reports. However, the automatic classification of defects using image processing and machine learning (Figure 2, Step 2') is currently under investigation and thus not presented in this paper.

3 METHODOLOGY

This study started with literature review regarding the state of practice in site inspection. Current relevant ICT tools published in previous studies and related applications available in iTunes, Google Play, etc. were also reviewed. Different types of inspection documents (e.g., issue reports, defect lists, punch lists) from the industry were collected for understanding the formats of the inspection reports. Because one of the authors worked in construction in various capacities and was involved in site inspections of constructed facilities under construction and under occupancy, real-world inspection documents were readily collected for this study.
The Android-based platform and JAVA/XML technology were adopted for developing the first and current version of InSite Inspector. As there are various platform versions of Android available (Figure 3), the evaluation and selection of the right platform was conducted in this study because choosing the right version target is critical. Choosing too high versions would result in more phones being incompatible, isolate more potential users, and hence decrease the user base, while choosing too low versions would result in the app missing important built-in features of the newer versions. In other words, choosing the right platform version is the trade-off of increasing the user base and utilizing newer and better features.

![Figure 3: Distribution of the Android platform versions in early January 2015](image)

Figure 3 displays the percentage of devices running different versions of the Android platform in early January 2015 (Android, 2015). The shares of these versions were 0.4% (2.2, API level 8), 7.8% (2.3.x, API level 10), 6.7% (4.0.x, API level 15), 19.2% (4.1.x, API level 16), 20.3% (4.2.x, API level 17), 6.5% (4.3, API level 18), and 39.1% (4.4, API level 19) (Figure 3). The current InSite Inspector employs Android 4.1.x version with application programming interface (API) level 16 that was released in July 2012. It should be noted that Android versions are backwards compatible. That is, Android version 4.1.x with API level 16 is compatible with its own version and newer versions (4.2.x, API level 17; 4.3, API level 18; and 4.4, API level 19). The Android version 4.1.x with API level 16 was selected for InSite Inspector because it is relatively new while it supports 85.1% of current devices (Figure 3).

Creating InSite Inspector involved designing and developing the user interface, with capability of taking and storing photos, as well as text entry in form-type fields. Multiple site inspection tests were conducted to evaluate and improve InSite Inspector. Finally, the current version was used and tested in inspecting the envelope of an academic building on the authors’ campus.

4 DEVELOPMENT OF THE INSITE INSPECTOR

4.1 Overview of the InSite Inspector

A few site inspection applications are available in different platforms. Perhaps the most related app was Defects app. The Defects app required iOS 6.0 or later (Contractors Apps, 2015). While this app can generate reports in PDF format, it seemed not able to generate a more flexible and customizable format, such as csv (comma-separated values) files. The Defects app also seemed not to allow to associate the responsible parties with defects. InSite Inspector includes those features not available in the current apps.
and other features that assist efficient site inspection. Figure 4 displays a simplified Unified Modeling Language (UML) class diagram of InSite Inspector.

![Figure 4: Simplified UML class diagram of InSite Inspector](image)

Within Android activities, there are six classes, including Main Menu, Inspection, Location, Concerned Party, Defect, and Report (Figure 4). These Android activities interact with the built-in global positioning system (GPS) package to locate site location and defects. They interact with the Image Handling package when a defect image is taken by the camera. The Image Handling is used for subsampling. That is, InSite Inspector will automatically estimate the memory usage of loading a defect and resize the image file and/or change resolution if necessary. Finally, the Android Activities interact with Data, Database and File Management packages for restoring and reporting inspection data and information. A SQLite database was developed to store the inspection data. It stores these data as "db" files hidden on the system. The File Management package is used to write the inspection data (e.g., defect images, locations) to or read them from internal/external device storage. The next two sections describe the two major modules, namely Site Inspection and Documentation and Reporting in detail through a case study. The case study was an inspection of the envelope of an academic building on the authors’ campus in January, 2015.

### 4.2 Site Inspection Module

The site inspection module includes processes used by the site engineer or manager in InSite Inspector in order to collect and store inspection data. Figure 5 demonstrates four screenshots of the major processes for site inspection with InSite Inspector. An inspector may create a new inspection, continue previous inspection, or generate reports from previous inspections. These are features in the Main Menu class (not shown in Figure 5). If an inspector starts a new inspection, he/she may first assign his/her inspection name, location, inspector profile.

![Figure 5: Site inspection module](image)
The inspection can proceed by adding a new defect (Figure 5a). The defect recording process allows an inspector to take multiple images of a defect and to choose up to two images representing the defect (Figure 5b). An inspector may provide entries such as type and location of defect (Figure 5b) and additional defect information (not shown). These entries can be recorded either by text or voice to text with the Google Voice typing feature. InSite Inspector will automatically capture the inspection time and date of the defect and locate the defect location using GPS. It utilizes the built-in GPS for Android in two different ways for two scenarios. If the device and hence InSite Inspector search and find at least four GPS satellites of the available 24, a defect can be located by all three: latitude, longitude, and altitude. The “Window sill crack” defect in Figure 5b was located by these three coordinates. If not, InSite Inspector can determine a defect location through a network provider based on availability of cell towers or WiFi access points. In this case, only latitude and longitude of the defect will be determined. As the current defect management systems tended to error (Park et al., 2013, Lundkvist et al., 2014), the proposed automatic positioning of defects will eliminate this drawback.

InSite Inspector allows site engineers and managers to associate a defect with concerned and/or responsible parties. Defects occurred due to many reasons such as design, specification, materials, workmanship, and managerial errors and malpractice. The reasons are all related to human errors and more specially, parties involved throughout the project life cycle, including owners, designers, general contractors, subcontractors, suppliers, and users. During or after an inspection, site inspectors can add parties involved (Figure 5c) and relate them with any defect already investigated (Figure 5d). For example, D&W Sub C installed windows for the building investigated and thus might be associated with the “window sill crack” defect (Figure 5d). The association of defects and concerned parties facilitates engineers and managers in customizing inspection reports as discussed in the next section.

4.3 Documentation and Reporting Module

Figure 6 presents the selected snapshots of the inspection documentation and reporting module. An inspector can customize inspection reports in different ways. All or a subset of defects can be easily chosen before generating reports (Figure 6a). For example, an inspector may only select defects related to stucco work (Figure 6a) for a report and send it to Stucco Sub B (Figure 5c). For a certain defect, an inspector may also choose information to include or not in an inspection report, such as defect type, location, associated parties (Figure 6b).

![Figure 6: Documentation and reporting module](image)

After customizing information for the report, a few export options are available for the report (Figures 6c and 6d). The output types include the portable document format (pdf) files or csv files where inspectors
can further edit and format the report (Figure 6c). Finally, inspectors have different options to export their report. They can save it in their current device, email to related parties, or upload to clouded-based repositories such as Dropbox (Figure 6d).

Figure 7 presents portions of two reports, one created with a specialized software on a PC by a professional inspector for an actual project in California (Figure 7a) and one created by InSite Inspector in the inspection case study in Florida (Figure 7b). A professional inspection report such as one shown in Figure 7a may take hours or days to be prepared. InSite Inspector efficiently creates professional-like reports (Figure 7b) with more details, especially those automatically captured on site in a few seconds or a few minutes depending on the magnitude of the inspection and the capacity of the mobile device. Substantial time savings and more accurate defect information can be achieved with InSite Inspector.

![Figure 7: Real-world vs. InSite Inspector generated reports](image)

5 LIMITATIONS AND FUTURE WORK

There are a few limitations of the present version of InSite Inspector. First, it is currently available only on Android although the share of Android was 84% as of the third quarter of 2014 (Barrie, 2014). Second, to position accurately the location and including all latitude, longitude, and altitude of a defect, an inspection device has to detect at least four GPS satellites. From our case study, this could only work for locating defects outside of the building (e.g., exterior walls, roofs, windows). For defects inside the building, the approximation of the defect location was retrieved from the cellphone or WiFi network provider and only included latitude and longitude.

Future work will include employing techniques to overcome the above limitations and, especially in the longer term, utilize image processing and machine learning techniques for automatic defect classification (Step 2, Figure 2). The ultimate goal of this ongoing research is to develop InSite Inspector that allows engineers and managers to take pictures of defects and automatically classify the types of defects. Image processing and machine learning algorithms and techniques (e.g., Fast Fourier Transforms (FFT), Butterworth filters, Artificial Neural Networks (ANN)) may make the automatic classification of construction defects possible. Future research will also utilize the defect classifications available for different types of construction such as industrial construction (Fayek et al., 2003), timber construction (Johnson and Meiling, 2009) and bridge construction (Cheng and Leu, 2011).

6 CONCLUSIONS

An Android-based smart mobile app named InSite Inspector was developed for site inspection and documentation. It is designed to be effectively used for site inspection in both construction and operation phases. A case study involving the inspection of the envelope of a building was conducted with InSite Inspector. This inspection demonstrated that InSite Inspector facilitates engineers and managers to record defect information, parties involved, and automatically locates defects using GPS. Inspectors can
customize report information and formats and generate reports and documents for different purposes. The documentation and reporting process with InSite Inspector can significantly save site engineers’ and managers’ time and eliminate errors that potentially occur in current site inspection practices. Future work will include improving the accurate positioning of the defects and utilizing image processing and machine learning techniques to automatically classify defects captured on site.

EXPLORING KNOWLEDGE AREAS OFFERED IN PROJECT MANAGEMENT PROGRAMS IN CONSTRUCTION

Long D. Nguyen¹, Ying-Yi Chih² and Borja Garcia de Soto³
¹ Department of Environmental and Civil Engineering, Florida Gulf Coast University, USA
² Research School of Management, Australian National University, Australia
³ Institute of Construction and Infrastructure Management, ETH Zürich, Switzerland

Abstract: Construction project management requires various knowledge, skills, techniques, and applications. Therefore, project management (PM) degree programs have to equip future project engineers and managers accordingly. However, literature has provided limited understanding about how extensive these knowledge areas (KAs) have been offered in these degree programs. The goal of this paper is to explore to what extent different KAs are taught in PM Master’s degree programs with emphasis in the construction industry. A survey was conducted with respondents who were academic staff responsible for these programs. Most of these programs under the current study were at institutions located in the U.K. and the U.S.A. Six KAs that had high percentage (50% or more) of construction programs offering more than ten teaching hours were time management and risk management (65%), procurement management, sustainability, and legal and ethical aspects (55%), and cost management (50%). In terms of relative teaching priority within a program, time management, risk management, sustainability, and cost management were frequently the top focus in these programs. Project scope, quality, and stakeholder management had the least teaching priorities among the PM KAs. While relative teaching priorities of many KAs were anticipated, the lowest teaching hours and priorities of project scope and quality management, and occupational safety and health were not expected as they were identified as major competencies for construction graduates.

1 INTRODUCTION

Project management in construction requires a variety of knowledge, skills, techniques, and applications. Project management (PM) degree programs have therefore to account for those when preparing the next generation of project engineers and managers. Because construction project management has taken place in an ever-changing environment, the required knowledge has also evolved over time. Accordingly, PM educators have to constantly update curricula and knowledge areas (KAs) offered in their PM degree programs to respond to such change. The dynamic nature of the construction industry requires constant curriculum updates to meet the workforce demands (Ahmed et al., 2014; Azhar et al., 2014). Russell et al. (2007) urged that educators and those involved must integrate key concepts to improve students’ critical thinking, understanding globalization, social awareness, and the use of information technology for future construction professionals to meet the needs of society.

The need for investigating how various KAs have been delivered in PM degree programs in construction is essential. However, literature has provided limited understanding how extensive these KAs were offered in these degree programs. The goal of this study is to explore to what extent different KAs were
taught in PM Master’s degree programs with emphasis in construction. Consequently, this paper aims at (i) identifying the distribution of teaching hours for KAs in PM Master’s programs in construction and (ii) comparing the relative teaching priority of these KAs within a program. It should be noted that different degree names of these Master’s programs have been used by different institutions around the world. Examples include Master of Construction Management (CM), Master of Science in Construction PM, Master of Science in CM, and Master of Science in Civil Engineering with a major in PM. This study called these programs as PM Master’s degree programs with emphasis in construction or Construction PM Program.

2 BACKGROUND

As more than one-fifth of the global economic activities have taken place as projects (Bredillet et al., 2013), PM skills are generally needed in all industries, including construction. To respond to this demand, educators have launched new PM programs (Berggren and Soderlund, 2008) and increased enrollments. The number of accredited PM degree programs have also increased worldwide. For instance, as of 2014, more than 90 PM and related degree programs have been accredited by the Project Management Institute (PMI)’s Global Accreditation Center for Project Management Education Programs (GAC) (GAC, 2014).

The evolution of PM education is a point of concern as the PM body of knowledge (PMBoK) has been evolving from research and practice (Bredillet et al., 2013). In construction PM education Becker et al. (2011) urged that programs had a responsibility of anticipating the skills and competencies for effective future professionals and refining curriculums to best prepare students for the future work. Ahmed et al. (2014) identified desirable skills from today’s CM graduates. The top five skills were knowledge of health and safety regulations, interpreting contract documents, listening ability / giving attention to details, knowledge of building codes and regulations, and time management. Therefore, construction PM programs have to deliver KAs that provide the necessary skills to their graduates.

Previous studies investigated what construction graduate programs offered to their students. Arditi (1984) found that in 1982, the most three popular subjects in 24 graduate programs in construction in the U.S.A. were (1) laws, contracts, and specifications, (2) planning and scheduling, and (3) operations research methods. Later, Arditi and Polat (2010) observed that the trends in course offerings in 1982, 1996, and 2008 seemed to have minimal change except for the number of courses in PM going up significantly while the number of courses in cost estimating going down. A study in 23 PM Master’s degree programs with a construction emphasis worldwide showed that the average percentages of courses related PM, business management, leadership and human resources (HRS), and stakeholders’ relationships and a developed environmental framework were 45%, 32%, 13%, and 11%, respectively (Yepes et al., 2012). In addition, the top three common subjects in these 23 programs were PM (14.4%), followed by contract management (10.8%), and project scheduling (10.5%) (Pellicer et al., 2013).

Although these studies identified courses and/or subjects taught in PM degree programs there is still a need to investigate to what extent different KAs have been delivered in these programs. The reason is
that there are potential overlaps if course or subject level is investigated. Arditi and Polat (2010) reported PM and cost estimating as two courses. However, cost estimating is an aspect within project cost management of the PMBoK. Similarly, PM and project scheduling were considered two separate subjects in Pellicer et al. (2013) while project scheduling is a subset of PM. This current study explored the PM degree programs at the KA level. Nineteen specific KAs and one "others" were investigated in this study (Table 1). The 19 KAs consisted of 10 from the PMBoK (PMI, 2013) and nine related KAs.

3 METHODOLOGY

This study used a questionnaire survey as a primary tool of data collection. Potential population were academic institutions worldwide that offered PM degree programs. The population was first stratified into regions, e.g., Africa and Middle East, America, Asia, Europe, and Oceania. Internet search engines and available publications (e.g., World University Rankings, PMI GAC) helped identify institutions and their websites. The authors accessed the websites and identified if a PM degree program(s) was offered in these institutions. If there was a PM degree program, one academic staff (typically program leader unless not specified in the websites) and his/her contact were identified and added to the list of potential respondents. Finally, the authors compiled 256 respondents in 256 PM degree programs from 233 institutions. These 256 programs consisted of Africa and Middle East (8), America (91), Asia (20), Europe (109), and Oceania (28). A questionnaire were developed and pilot-tested with a group of five respondents. Their comments and feedback helped refine KAs, redesign the questions and improve the questionnaire. The final version was significantly shorter than the questionnaire used for pilot testing. An online survey was then created based on the final questionnaire (in an electronic form). The online survey was emailed to these 256 potential respondents. The data collection took place in October 2014.

The survey had a question: "In which industry (or sector) has the PM degree program you have selected mostly focused? (select all that apply)." The possible responses consisted of: (1) none in particular; (2) business; (3) production; (4) engineering; (5) IS/IT, software, and communications; (6) construction; (7) government; and (8) other, please specify. For the theme of this conference, this paper presents our analysis from programs which focused on construction. That is, this paper focuses on responses that selected either "construction" (6) or both "engineering" (4) and "construction" (6) for the above question. Due to the nature of the data and a limited number of responses, this study mainly used descriptive statistics for data analysis.

4 ANALYSIS AND FINDINGS

4.1 Characteristics of Respondents and Surveyed Programs

The online questionnaire was emailed to 256 potential respondents working at institutions offering degree programs in PM or with emphasis in PM all over the world. These respondents were holding academic and/or administration positions in PM degree programs. The survey was opened on October 1 and closed on October 17, 2014. Sixty respondents from 60 institutions attempted to complete the survey. Fifty four (out of 60) fully responded to all questions in the survey and were valid for analysis. The valid response rate was 21%. Among these 54 programs, twenty were Master’s programs that focused on construction. This paper presents our analysis and findings of these twenty Master’s degree programs. Table 2 summarizes the characteristics of these twenty programs. Seven and six programs were from the U.S.A. and U.K., respectively. The other seven programs were from seven different countries or territories (Australia, China, Hong Kong, Spain, Switzerland, Trinidad, and Vietnam). Eleven programs (55%) were accredited by at least one third-party entity. Four programs (20%) were accredited by two or more agencies (e.g., RICS, CIOB, PMI GAC). Nine programs (45%) were not accredited or accredited internally (Table 2).

Seventy five percent (15 out of 20) of the respondents had at least ten years of experience in PM education. Thirty five percent (7 out of 20) of the respondents had more than 20 years of experience. Only one respondent (5%) had less than five years of experience in PM education. The respondents
holding program director, chair, leader, or coordinator were 55% (11 out of 20). The other 45% were holding a professorship or lectureship position.

4.2 Teaching Hours for PM and Other Knowledge Areas

A PM degree program in construction provided not only PM KAs but other KAs. Among the ten PM KAs, cost, time, and risk management tended to be taught the most. All of the surveyed programs taught these three KAs (Figure 1). Figure 1 shows that 65% of programs offered more than 10 teaching hours (11-20 hours to over 50 hours) for time management and risk management. Fifty percent of the programs delivered more than 10 hours for cost management. Time, cost, and risk management were taught more than 30 hours (31-40 hours to over 50 hours) in 45%, 30%, and 30% of programs, respectively.

![Figure 1: PM knowledge areas with high teaching hours](image)

After risk, time, and cost management, four PM KAs, namely, integration, HR, communications, and procurement management, were taught in a considerable number of hours (Figure 2). Procurement management tended to be delivered between 6 hours and 30 hours (70% of programs). While 55% of
programs offered at least 11 hours for procurement management, only 10% offered 31 contact hours or more for this knowledge area. Communications management was prone to be offered in a range of one to 20 hours (70% of programs). Sixty percent taught HR and integration management in ten hours or less.

![Figure 2: PM knowledge areas with medium teaching hours](image)

PM degree programs in construction tended to offer least hours for scope, quality, and stakeholder management as the teaching-hour distributions skewed to the right (Figure 3). Project quality management and stakeholder management were taught less than 10 hours in 75% of the construction PM Master’s degree programs. Only 25% of programs taught quality and stakeholder management more than 10 hours. Scope management was taught less than 10 hours in 60% of these programs. No program taught scope and stakeholder management more than 40 hours.

![Figure 3: PM knowledge areas with low teaching hours](image)

In addition to PM KAs, these programs also delivered other KAs. Figure 4 presents other KAs that had significant teaching hours. Sustainability and legal/ethical aspects each had more than 10 teaching hours...
in 55% of programs. Computation tools/techniques had more than 10 teaching hours in 40% of programs. Sustainability were taught more than 30 hours in 30% of programs. The teaching hours of sustainability and legal/ethical aspects were comparable with such PM KAs with high teaching hours as project time, cost, and risk management.

### 4.3 Teaching Priority within a Construction PM Program

Teaching hours for each KA within a degree program depend on the length of this program. Therefore, the extent of the KAs taught should be analyzed not only between programs but also within programs. In other words, for a knowledge area, five teaching hours in this program and 10 teaching hours in another program should not only be compared each other but also be compared with the numbers of teaching hours for other KAs taught in that program. This study assigned a relative teaching priority for each knowledge area to compare its level of effort (in terms of teaching hours) to those of the other KAs within a degree program. Table 3 exemplifies the proposed teaching priority for analysis within a program. The highest priority (i.e., 1) was assigned to KAs that had the most teaching hours within that program. Because program A had 41-50 teaching hours for KA2 and KA6, both KA2 and KA6 had number one priority. Similarly, KA1 in program B also had number one relative priority. KA4 in program A had the next highest teaching hours and hence had priority 3 (after KA2 and KA6). If a program did not teach a certain KA, this KA had zero priority (e.g., KA3 in program A).

</table>

Within a program and among PM KAs, project time, risk, and cost management tended to be allocated more teaching hours while project quality, scope, and stakeholder management tended to be allocated less teaching hours (Figure 5). Fifty percent of programs had time management as the first teaching priority. Time and risk management was on the top five priority among nineteen KAs in 70% of programs while cost management and procurement management was on the top five priority in 55% and 50% of
programs, respectively. Project HR, integration, and communications management tended to have similar priority. They were in the top five priority between 35% (communications) and 40% (HR and integration) of programs. Surprisingly, quality management was never the first priority in these programs. Project scope, quality, and stakeholder management was in the top five priority in terms of teaching hours in only 25% of programs.

![Figure 5: PM knowledge areas with teaching priority within a construction PM program](image)

For other nine KAs, sustainability and legal/ethical aspects were on the top five priority among PM and non-PM KAs in 50% of programs (Figure 6). Similar to project risk management, sustainability had the first teaching priority in 30% of programs, only after project time management. Although computational tools/techniques was usually not the first priority (only 10% of programs), it was in the first five priorities in 45% of programs. Leadership and decision sciences was on the top five priorities in 35% and 30%, respectively, of programs. It was not surprising that entrepreneurship and intellectual property did not have high teaching priority in construction PM Master’s programs. Program/portfolio management was still not focused in these programs. Occupational safety and health had also low priority when it was on the top five priority in 15% of programs.

### 4.4 Discussion

The analyses showed that project time, risk, and cost management, sustainability, and legal and ethical aspects were the five KAs usually having highest teaching hours in PM Master’s degree program with construction emphasis. They also tended to have the highest teaching priority within a program. Time, cost, and risk management were undoubtedly the essential PM KAs. Legal / ethical aspects having high teaching hours and priority within a program was not a surprise. Many previous studies emphasized the need of legal aspects in construction programs (Householder, 1987; Shahbodaghliou and Rebholz, 1990; Mead and Gehrig, 1995). In fact, contract administration/legal issues was consistently ranked first in terms of percent of programs offered this course category over the past 30 years in the U.S.A. (Arditi, 1984; Arditi and Polat, 2010). In the U.K construction law was also considered as an important subject in construction programs. (Mihara et al., 2014).
The PM degree programs in construction increasingly focused on offering sustainability to their potential students. The sustainability knowledge area seemed not to appear in the 1982, 1996, and 2008 surveys of graduate programs in construction management (Arditi and Polat, 2010). A decade ago, only a few number of programs (members of the Associated School of Construction) offered sustainability-related courses (Tinker and Burt, 2004). However, the integration of the sustainability body of knowledge in construction curricula has been observed in recent years (Wang, 2009; Sullivan and Walters, 2013). Iyer-Raniga et al. (2010) stated that future construction graduates would be in a working environment where sustainability would be incorporated at the core level of their practice. Therefore, programs in CM progressively concentrated on environmental responsibility because of increased regulations and increasing opportunities for practicing sustainability knowledge upon graduation (Celik et al., 2014).

The fact that project scope and quality management, and occupational safety and health had the lowest teaching hours and lowest teaching priorities was a surprise. Scope management and quality management have been considered as critical KAs in construction project management. In fact, they are considered as primary project and project management objectives. Considering scope as important as budget and schedule, Oberlender (2000) observed that “the source of many problems associated with a project is failure to properly define the project scope.” Mincks (2008) argued that quality management was an essential knowledge for individuals involved in CM and had to be addressed in construction education. Finally, knowledge of health and safety regulations was the top skill desired by the industry from graduating CM students (Ahmed et al., 2014).

### 4.5 Limitations

This study has a few limitations. The findings were drawn from a small number of programs and responses. The small number of responses also limited the use of statistical analysis, i.e., inferential statistics. Although the authors endeavored to identify as many PM degree programs as possible, the research samples (256 PM degree programs) were programs that had information on the Internet (e.g., program websites), especially information provided in English.
5 CONCLUSIONS
