This paper investigated KAs taught in 20 Master’s PM degree programs around the world (U.S.A. [7], U.K. [6], Australia [1], China [1], Hong Kong [1], Spain [1], Switzerland [1], Trinidad [1], and Vietnam [1]) with emphasis in construction. Nineteen specific KAs, including 10 PM and nine related KAs, were explored in these programs. Six KAs that had high percentage (50% or more) of the programs offering more than ten teaching hours were time management, risk management, procurement management, sustainability, legal and ethical aspects, and cost management. The four PM KAs including project integration, human resource, communications, and procurement management followed these six KAs in teaching hours. In terms of relative teaching priority within a program, time management, risk management, sustainability, and cost management were frequently the top focus in these programs. Project scope, quality, and stakeholder management had the least teaching priorities among the PM KAs. While relative teaching priorities of many KAs were anticipated, the lowest teaching hours and priorities of project scope and quality management, and occupational safety and health were a surprise because they were identified as major competencies for construction graduates. Construction educators may use these findings when reviewing, refining, and updating their PM degree programs.

Acknowledgements

The authors sincerely thank the construction and project management educators who participated in this study.

Abstract: Decision making for construction of modern civil infrastructure not only involves internal stakeholders, but also aims to include interests of as many external stakeholders as possible. In mega-projects, complexity and diversity of stakeholders call for more advanced communication tools and channels. Extensive prevalence of social web as a two-way communication channel during the last decade has caused a paradigm shift in communication among the e-society, and this has attracted the attention of decision makers in the domain of urban infrastructure among other domains. Although having a wide public outreach, the open and unstructured nature of inputs from the e-society results in chaos and makes it difficult to distil knowledge from the contents communicated by the public. This paper presents tools from topic modeling to process such an unstructured data collected from online social media into information which can be plugged into the process of decision making. We use k-means clustering to cluster followers of an infrastructure project on micro-blogging website Twitter based on semantic similarity among their user profile descriptions. This helps profiling the main groups of followers of the infrastructure project and can provide decision makers with valuable hints regarding typology of external stakeholders. We also extend our analysis to project-related tweets through Latent Semantic Indexing, and find the main topics discussed. The latter guide help decision makers understand the public’s major vested interests in the project. We have applied the proposed method to a Light Rail Transit (LRT) mega-project in Toronto, Ontario and have discussed the results.

1 INTRODUCTION – INFRASTRUCTURE DISCUSSION NETWORKS (IDN)

Decision making for construction and development of civil infrastructure in the modern society is involved in a networked procedure. This is not only related to the network of interdependent sub-decisions, random variables involved, and the governing criteria; but also requires interactions among a multitude of decision makers (internal stakeholders), each having their own beliefs, goals, and interests in the project. On the other hand, the external stakeholders (those affected by the decisions) and their vested interests must be considered in decision making, and it adds even more to the complexity of the decision network. The final decision in such a networked scenario will be in form of a 'package-deal' (Bruijn and Heuvelhof 2000); a sub-optimal solution which accommodates major interests of different internal and external stakeholders of the project.

One major goal of community engagement practices in the domain of urban infrastructure is to detect the main groups of external stakeholders along with their interests and to involve them in the network of decision making. Public engagement in infrastructure projects has traditionally been carried out through off-line tools such as community meetings, public hearings, questionnaires, etc. or online tools such as
Web 1.0 portals and project websites which are considered as one-way communication channels to educate the society about the project and its related decisions. On the other hand, as a social-network-related issue, this procedure is influenced, if not re-shaped, by the wind of Web 2.0 (social web). Many public engagement agencies have recently started trying tools such as weblogs and micro-blogging websites (such as Blogger and Twitter), multimedia sharing websites (including YouTube and Instagram), and other tools for a bi-directional communication with the public about infrastructure projects (Bregman and Watkins 2013), (Azhar and Ablen 2014). Social web is not only a portal used to comment on design and planning; rather it is a platform for bringing community members along with their ideas together. Web 2.0–based engagement will hence create a ‘network of people’ together with a ‘network of ideas’. Such networks formed around infrastructure projects are called Infrastructure Discussion Networks – IDNs (Nik Bakht and El-diraby, 2013a & b & 2014).

The formation and evolution of these two interdependent networks (network of people and network of ideas), around the physical network of the infrastructure should be closely and precisely monitored and different trends in them must be followed in order to make the best out of users’ ideas and innovations in design and construction of a sustainable infrastructure. This requires employing tools and methods from network science, information retrieval, and computational linguistics to link people to their ideas and understand their patterns of connectivity over IDNs. One important outcome of monitoring such patterns is to detect cores of interest in a project, in conjunction with the people who support them. Some potential applications of making such a connection between users and ideas over the IDN can be listed as:

- Classifying typology of stakeholders, particularly the end users of the infrastructure system;
- Profiling core interests to be involved in package deal solutions offered for infrastructure project;
- Detecting relations and interactions among different community groups;
- Finding possible communication bottlenecks in the process of public consultation;
- Demand detection in a more direct, and pro-active manner;
- Activating ‘user innovation’ by understanding and ranking community generated inputs.

Achieving such goals requires detection and analysis of interests for nodes and communities of the IDN. Steinhaeuser & Chawla (2008) suggested assigning interest as node attribute to the social network and then clustering the network based on the similarity of attribute. In a similar study, Kalafatis (2009) harvested Twitter users based on their similar interests through occurrence of some pre-defined keywords in their Twitter biography. To include the degree of importance for nodes, Nik Bakht & El-Diraby (2013a) proposed community detection through analysis of the network topology, and then extracting shared interests within each community through computational linguistics. While segmenting users through the similarity among their attributes is a ‘top-down’ approach, finding communities and then interpreting similarities among them can be considered as a ‘bottom-up’ method. Applications such as topic detection in collaborative tagging systems, reviewed by Papadopoulos et al. (2012), and social trust evaluation for recommender systems, addressed by Pitsilis et al. (2011) are among other examples which combine the two approaches to create tools for profiling and labeling groups of followers.

Although the bottom-up approach is helpful for understanding the social construct of e-society around the infrastructure project; it does not necessarily result in cores of interest in the project. In order to detect the major lines of interest to be included in the package-deal solution, the main clusters of ideas discussed by project followers must be detected and highlighted. This paper presents a top-down approach to reach this goal. We start by clustering users and ideas based on their semantic similarity (rather than social connectivity). We use data collected from Micro-blogging website Twitter as the most popular social media used in the domain (Bregman, 2012), (Azhar & Ablen, 2014). By focusing an LRT mega-project in Toronto, Ontario, Canada we use semantic analysis combined with clustering algorithms to detect the main lines of interest in following this project on Twitter. We apply our method to the IDN of the project and cluster its nodes based on the semantic similarity among their profiles. Then we focus on tweets about the project over a certain period of time and use our proposed method to detect the core themes discussed. We will finally show how the results can be a representative of the public community’s vested interests in practice.
2 METHODOLOGY– CLUSTERING BASED ON SEMANTIC SIMILARITY OF USER PROFILES

Users in online social network websites normally address their interests through their online activities including contents they share, and comments they leave. However, in many cases they also state their interests directly in user profile descriptions (also known as biography or ‘bio’ for short). Twitter users can indicate their location, professional affiliations, and interests in a short bio in fewer than 160 characters. Such descriptions are accessible through Twitter API (Application Programming Interface). Also, one can use Twitter API to retrieve most recent tweets of a user\(^1\). Such tweets can also indirectly reflect users’ interests. The aim of this paper is to partition the IDN into groups of nodes with similar interests.

We collect descriptions/tweets of all nodes of an IDN as a set of ‘pseudo-documents’, and form an analysis corpus. Data clustering techniques combined with semantic approaches are then employed to cluster the corpus based upon the similarity between those pseudo-documents. The method can therefore be simplified as: clustering nodes of an IDN based on semantic similarity among their descriptions collected from their user profiles. This requires cleaning and pre-processing the collected data; modeling it and evaluating the semantic similarity among each pair of data points, and finally clustering nodes to the most similar groups.

2.1 Pre-processing and modeling users as vectors

In order to analyze documents they must be first modeled as data-points (vectors) with specific attributes (dimensions) and attribute values (entries). In text mining and natural language processing (NLP), dimensions of analysis vector space (called features in NLP and attributes in data mining) are associated with terms of the corpus. Texts collected via Twitter API, are normally not in a uniform encoding format and also include some ‘noise’. Therefore, the first step in modeling documents is to tokenize, unify, and clean up the collected data. These tasks are called pre-processing and include the following steps:

Cleaning:
- Removing html tags and attributes which are not visible in a browser;
- Replacing all html character codes (such as &amp, &quot, etc.) with their ASCII equivalents;
- Removing all URLs (as most of them are associated with advertisements and commercials);
- Removing Twitter specific characters such as hash-tags (#) and mentioning handles (@);
- Replacing monetary values and percentages with a trackable variable (for this purpose we transformed all numbers followed or preceded by dollar sign to XXX and all numbers followed or preceded by percentage sign to XX);
- Removing all other numbers (as they are less probable to contribute to semantics).

Tokenizing:
- Splitting texts at white spaces;
- Decomposing clitics and punctuations from their hosts;
- Saving ellipsis and other forms of multiple punctuations as separate tokens.

All these activities were performed using RegEx (regular expression). Stemming may also be a part of pre-processing; i.e. all words with the same root could be transformed into their roots. However, this was not done in the present paper due to aggressive nature of most stemmers available and confusions caused by stemming. Apart from the noise, common words with no specific semantics (such as conjunctions, articles, the gibberish, punctuations, etc.) should be filtered out from the corpus. This is normally done by introducing a ‘stop list’ (a complete list of such words). We started by a compilation of some standard stop lists and added new terms to it as the analyses progressed. As the text processing is involved in occurrence and co-occurrence of terms in multiple documents, terms which appear in one document only, were also removed to reduce dimensions of the analysis space.

A dictionary was formed by collecting all tokens of the cleaned corpus. Each term in this dictionary would be one dimension of the analysis space. Project followers were then modeled as vectors in such a vector

\(^1\) Currently, up to 3200 most recent tweets by a user are accessible
space. Assuming the dictionary contains $M$ terms in total ($t_1$ to $t_M$), each user $X$ with description $d(X)$ that is called a pseudo-document here and is specified by a set of attributes (terms) $t_i$, was modeled as an $M$-dimensional vector with non-zero values in its $i$th entries only. In the simplest case, $d(X)_i$ is 1, if term $t_i$ occurs in description of node $X_i$, and is 0, otherwise. A collection of pseudo documents (modeled as column vectors $d(X)$) for all members of an IDN of size $N$ would then form an $M \times N$ matrix which is equivalent to ‘term-document’ matrices in topic modeling, and attribute-relation tables in data analysis. Such a matrix takes the following form:

$$\begin{bmatrix}
\text{Dictionary terms} \\
\text{(size: $M$)}
\end{bmatrix}
\begin{bmatrix}
d(X_1) \\ \vdots \\ d(X_N)
\end{bmatrix}_{M \times N}$$

More advanced versions of such a matrix can also be considered; they include bag of words in which entries are positive integers reflecting occurrence frequency of words in pseudo-documents, or using TF-IDF (Term frequency – Inverse Document Frequency) as attribute values, which is a measure describing the level of representativeness of a term for a specific user.

### 2.2 $k$-means clustering

By considering each node of the IDN as a data-point and each word of the dictionary as an attribute, the abovementioned term-document matrix collects attribute values for all data-points. It can accordingly be used to formulate the top-down clustering as an unsupervised clustering problem. The goal of such a problem is to partition database $D$ into $k$ classes $C$ such that members in each class are the most similar to each other and less similar to members from other classes. Global optimality (exhaustively enumerating all possible partitions), and heuristic methods are the two main options for performing such a task. Heuristic search can be either agglomerative or divisive; while the former starts with individual nodes and looks for the most similar ones to be collected in the same group, the latter starts at the network level and tries to find the best cut-offs. $k$-means clustering and $k$-medoids clustering or PAM (Partition around medoids) are two of the best known heuristic methods for clustering. Many studies in the literature have successfully applied $k$-means to cluster documents or to detect dominant themes in them. Table 1 lists some recent works in clustering short-length texts (such as tweets, URLs, and comments).

Clustering needs a measure of similarity before anything else. Different metrics are used in the literature to measure distance (dissimilarity) among data-points. Minkowski distance (with its two well-known variants: Manhattan distance, and Euclidean distance), cosine distance (calculated based on the angle between two datasets as two vectors), and Jaccard distance can be mentioned among other basic distance metrics. Distance function must be carefully designed associated with the context of use, and by using the domain knowledge. For semantic clustering purposes, two main groups of distances are used: first, calculating distance through corpus statistics; and second, calculating semantic distance of terms though an external ontology or knowledge-base. The latter is calculated based on the distance of two terms in a taxonomy and the former is the vector distance between pseudo-documents calculated either as cosine or as Jaccard distance. In the present problem, these can be calculated as follows:

$$d_{\text{cos}}(X_i, X_j) = 1 - \frac{\sum_{m=1}^{M} d(X_i)_m \cdot d(X_j)_m}{\|d(X_i)\| \cdot \|d(X_j)\|}$$

$$d_{\text{jac}}(X_i, X_j) = 1 - \frac{|d(X_i) \cap d(X_j)|}{|d(X_i) \cup d(X_j)|}$$

In which:
- $d(X_i)_m$ is the value of $m^{th}$ attribute ($m^{th}$ term) for user $i$ in the term-document matrix;
- $\|d(X_i)\|$ is the norm of vector $d(X_i)$;
- $|d(X_i) \cap d(X_j)|$ is the number of terms in common between profiles of users $i$ and $j$; and
- $|d(X_i) \cup d(X_j)|$ is the number of distinct terms in profiles of users $i$ and $j$.

After selecting a distance measure, $k$-means algorithm takes the following steps:

- Randomly selects $k$ nodes and takes them as centroids of the $k$ communities;
• Assigns each node of the IDN to the community of its closest centroid;
• Centroids are re-calculated for each community and the second step is repeated;
• The algorithm stops when, for a specific number of iterations the position of centroids do not change beyond a certain threshold (stopping criteria).

As it is seen in Table 1, in unsupervised clustering of tweets most studies use ‘terms’ (unigrams) rather than features such as grammar or syntax. More sophisticated NLP-type features such as length, n-grams (sequence of n terms), punctuations, and part of speech are mostly common in supervised learning for training classifiers. Also, the table suggests that semantic distance in one of its two forms is commonly used as the measure of similarity.

Having an unsupervised learning problem in hand, an important question to be answered is how to set a value for k. Different measures are offered in the literature to evaluate clustering performance when different values are selected for k. Similarity among objects within each cluster (intra-cluster similarity) and dissimilarity across different clusters (inter-cluster similarity) are the main criteria controlling the performance. Average distances between the centroid of a cluster and nodes in that cluster (centroid distance) can show the level of similarity among cluster members. This is called intra-cluster similarity (or intra-cluster centroid distance). Clusters with lower intra-cluster distance are more uniform and include more similar members. An Average of centroid distances over all nodes of dataset gives a measure of general intra-cluster similarity. However, at the same time with high intra-cluster similarity, a good clustering system must have low inter-cluster similarity. This criterion is measured through Davies-Bouldin (DB) index (Davis & Bouldin, 1979). Without going to calculation details of this index, it returns lower values for algorithms resulting in clusters with high intra-cluster similarity and low inter-cluster similarity. Therefore, the best k will be associated with the lowest DB index.

To summarize, k-means algorithm can cluster nodes of the IDN through their descriptions (pseudo-documents d(X)) into k classes based on the similarity between terms used in pseudo-documents. This is a term-level comparison which can be known as a first order analysis and matching. However, a more
profound matching among nodes should consider the similarity between 'concepts' addressed by users. Many studies have reported higher level of intra-cluster similarity when semantic distance (rather than a plain cosine distance) is used (see Antai et al. 2011 as an example). This requires highlighting hidden patterns of semantic similarity among pseudo-documents which can be handled through semantic transformation.

2.3 Semantic transformation

Transformation from $M$-dimensional lexical space which explained above, into a lower size (let's say $q$-dimensional) semantic space, under some conditions can expose the underlying semantic correlations among terms and pseudo-documents. Dimensions of the new space are *topics* or *common semantic themes* in documents, and such a transformation is referred to as 'topic modeling'. One important advantage of this approach is the fact the corpus statistics are the base of deriving semantic relations. Hidden patterns of semantic similarity are detected from co-occurrence of terms in multiple documents and therefore, the detected similarity will have a *context-sensitive* nature (Landauer et al. 1998). There are different forms of semantic transformation among which Latent Semantic Analysis (LSA), Probabilistic Latent Semantic Analysis (PLSA), and Latent Dirichlet Allocation (LDA) are the most popular ones. In the domain of construction, such techniques have recently found some applications in classification tasks. Classifying general conditions for contractual documents (Zhang & El-gohary, 2013) and classifying environmental regulatory documents (Zhou & El-gohary, 2014) can be mentioned among other limited examples of such applications.

Latent Semantic Analysis–LSA (or latent semantic indexing–LSI) is a powerful technique in vectorial semantics, working based on estimation of a matrix through Singular Value Decomposition (SVD) and inferring semantic relations among terms and documents. In terms of data analysis, SVD is a transformation of a dataset from one space in which the data has high variations, into a new space with lower variations. This transformation decomposes correlated variables and exposes the level of variation along each dimension in the new space. Therefore, by ignoring variations below a certain threshold, one can reach the best estimation of the original data in a lower-dimensional space. Mathematically, this transformation is decomposition of a rectangular matrix $A$ into the product of three matrices:

$$ A = U \times S \times V^T = \hat{A} $$

Where:
- $U$ and $V$ are formed as collections of eigenvectors of matrix $A^T \cdot A$ (called singular vectors);
- $S$ is a diagonal matrix with *singular values* of matrix $A$ (square root of eigenvalues of $A \cdot A^T$) as its diagonal entries; and
- $\hat{A}$ is the least square fit of matrix $A$.

If the full matrix $S$ is used, then, $\hat{A}$ and will be exactly the same. However, selecting a limited number of (say $q$) dimensions in $S$ will make $\hat{A}$ an estimation of $A$ in a lower dimensional space. As singular values of matrix $A$ are sorted in a descending order in the diagonal of matrix $S$, selecting dimensions which are associated with the $q$ largest singular values will be easily possible. The noise will be filtered out in the resulted estimation ($\hat{A}$), hence it will reflect the underlying structure beneath the first order data. Selection of $q$ will influence the results; if it is set too large, then the noise of first order data will not be fully filtered, and if it is set too small, then some latent correlations will be lost. Reaching an optimal dimensionality for SVD is involved in some levels of trial and error (Antai et al. 2011).

LSA is in fact the result of applying SVD to the term-document matrix. As the result, semantic dependencies and similarities will be highlighted at a deeper level and in a low-dimension semantic space. The results will allow investigation in semantic correlation at three levels: term–term, term–document, and document–document. The latter correlation between pseudo-documents of our problem can be taken as a measure of semantic distance to evaluate semantic similarity between profile descriptions for nodes of the IDN.
3 CASE STUDY PROJECT

We aim to apply the methods explained above in an actual infrastructure project to see how the main groups of social interests in the urban infrastructure system can be crystallized through analysis of online public participation contents. The ‘Eglinton Crosstown LRT’ line is an under-construction project to span 19km of Light Rail Transit, out of which 10km is tunnelled, cutting across Toronto in the east-west direction along Eglinton Avenue and connecting to Scarborough Rapid Transit system. The project at a glance can be summarized as:

- Type: Light Rail Transit – New Construction
- Construction start year: 2011 – Estimated completion year: 2020
- Estimated cost: CAD8.4 Billion – Funding: Provincial funds
- Owner: Metrolinx – Ultimate operator: Toronto Transit commission (TTC)

The Crosstown project is one of the largest transit projects currently underway in North America and it has raised several issues that have gained public and media attention. The owner launched a Twitter account for the project on December 2011. At the time data we first collected data (September 2012), it had 521 followers, and now in more than two years, this number has increased into more than 2800 followers\(^2\). We applied \(k\)-means clustering through topic modeling to investigate which commonalities form the main groups of these followers and what topics they mainly discuss.

3.1 Followers Typology

Using semantic distances (calculated through LSI) as a measure of similarity, IDN of the Eglinton Crosstown project on Twitter (September 2012) was clustered by applying LSI to node descriptions and using the outputs as a distance measure for \(k\)-means clustering. \(k\) (the number of clusters) was selected through distance-based performance measures as illustrated by Table 2. As seen, the lowest DB index (the highest inter-clustering similarity) and the lowest inter-cluster distance are resulted for \(k=4\).

Table 2 – Evaluation of clustering with different number of clusters (nodes with blank descriptions are excluded)

\(^2\) As of January 2015
The size of the semantic space \((q)\) was also set equal to 4; this was not only the same as number of clusters but also the same as number of communities detected in the same network via community detection (Nik Bakht and El-diraby, 2013b). It must be noted that some Twitter users leave their descriptions blank; these nodes were assigned to a separate cluster.

After clustering an IDN based on semantic similarity of its nodes’ descriptions, semantic analysis helped to detect dominant themes in each cluster. For this purpose, descriptions for all nodes in one cluster were compiled as one document and then through LSI the top terms in each of these documents were detected. Table 3 lists top terms for the four clusters found in Eglinton Crosstown network through \(k\)-means clustering. Results represent outputs of LSA with 95% of total singular values, in conjunction with a ranker system. In this analysis, bi-grams (combinations of two successive words) were also added to features for latent semantic indexing. Some terms which can help to speculate dominant topics within each cluster are highlighted in bold in this table. Although highlighted terms can give an overview of dominating themes in each cluster, high level of mixing among terms does not allow reaching a firm conclusion confidently.

It must be noticed that the authors had formerly shown through social network analysis that this network has four major communities, labeled as: politicians, technical decision makers, city policy makers, and the community of the public (Nik Bakht and El-diraby, 2013a&b). The results of semantic clustering support those findings; dominant terms in cluster2 refer to the owner and operator of the project who are among the main technical actors and decision makers. Also terms such as construction, transport, and project can support this speculation that this cluster is composed of a group of people with interests in technical and engineering aspects of the project. Cluster 3 has top terms which refer to the city councillors and city decision makers. Town hall, mayor, and progressive (referring to the progressive conservative party) are among those terms. As it is seen, here the line to separate ‘politicians’ from ‘city policy makers’ is blurred as many terms describing these groups belong to the same semantic classes. This was not the case when community detection was performed by looking at the social connectivity among followers. Terms in clusters 1 and 4 suggest that they are composed of nodes from the public with two main themes of interest: art/planning, and politics. It may be hard to make a firm claim about these communities due to the diversity of their top terms; but referring back to results of bisection through social connectivity and reviewing the major interests of nodes belonging to the community of the public can explains the source...
of such diversity. Most community leaders in the community of the public were either journalists or planners (Nik Bakht and El-diraby, 2013a).

3.2 Core Interests

Repeating similar analysis on tweets collected through project-related hashtags mentioning the project ID can result in detecting the core themes of interests in online discussions around the project. We repeated the same procedure including cleaning and tokenizing tweets, and then applying k-means clustering based on semantic similarity among the tweets. We applied the analysis to 170 tweets collected between July and September 2013 through mentioning of the project ID (@CrosstownTO) and related hashtags (such as #CrosstownLRT, #Eglinton-Scarborough, etc.). The analysis resulted in five clusters and then we detected top terms in each cluster through LSI. Reviewing the list of these top terms suggests some commonalities in each cluster:

- Economy is the dominant theme of one of the clusters. Terms such as XXX (representing monetary values), Dollars, Dollars_Risk, Investing, Millions, Oaarchitects, Construction_Safety, Mega_Contract are among top terms of this cluster;
- The second cluster is dominated by terms related to technical features of the project: Construction, Safety, Contract, Consultant, Contractor, Procurement, Procurement_Process, LRT_Project, and Tunnel_Boring are among those terms;
- Community related issues, and local/regional aspects are the third group of topics tweeted regarding the project. Terms such as Neighbourhood, Community, Neighbourhood_Revitalization, Eglinton, Yonge_Bus, Finch, and Finch_LRT, Real_estate are some of the key terms representing these topics;
- A smaller group with fewer number of tweets compared to the above three classes use terms which imply Political issues; Councilor, City_Staff, Provincial_Government and Harper are the most outstanding terms of this type;
- Last but not the least, there was a small cluster that we could not realize a specific team among its top terms. When tweets in this cluster were screened, we found that they mostly communicate news and updates about the project, its schedule and improvement, and public meetings.

4 DISCUSSION AND CONCLUDING REMARKS

Titles assigned to the clusters above may be arguable. For example, when focusing on sets of terms detected for different classes of interest, one may argue existence of some anomalies; although terms Construction and Safety are in the class we called ‘Technical issues’, the bigram Construction_Safety is in the cluster of ‘Economy’. The same is true for the term Contract versus the bigram Mega_Contract. Moreover, while Oaarchitects representing Ontario Association of Architects (OOA) is expected to be in the technical cluster, it is among the economy related issues. This made us take a closer look at the project and the associated discussions in this period.

In late July 2013, CDAO (Construction & Design Alliance of Ontario), representing about 200 firms, published an online report, criticizing Infrastructure Ontario and the project owner (Metrolinx) for the procurement contracting process. The report claims that bundling station and maintenance facility construction into one contract does not allow many competitors (particularly the local small or medium sized firms and consortia) to bid and kills the competition. They claimed that as a result, the selected proposal is imposing up to $500million extra cost in design and construction on tax-payers (CDAO, 2013). In a similar report, OAA questioned feasibility of awarding $1.75 billion architectural components in the project worth $4 billion in total in form of a single mega-contract (OAA, 2013). These reports also mention other consequences to the bundled contract including ‘stifling innovation’, accepting bids from a foreign multi-national firm (rather than domestic industries), and concerns regarding the public safety due to contracting the project to the foreigner companies who – according to the reports – lack professional trainings in this regard. Metrolinx responded to such criticism in August of that year, listing Canadian companies having roles in design and construction of the project and providing the hardware. These reports attracted attention in the social media, forming disputes in August 2013. In the data analyzed here a total of 30 tweets were discussing this issue, mainly by emphasizing the economic impacts of such a
decision and that is why the abovementioned terms can be found in the same cluster as terms Dollars, Investing, and Monetary values.

In conclusion, although semantic clustering can successfully detect groups of terms used to discuss the same aspect of a project, making a conclusion on the topic addressed by those terms is a subjective and judgment-based task. Using a taxonomy (when a specific context is scoped) and positioning distribution of detected terms in different branches of the taxonomy may help to automate this phase to some extent. This must be investigated in the future research. Consequently, outputs of the presented method are certainly a good starting point for decision makers to understand the composition of the e-society and the content of discussions around the infrastructure project at stake. This can add meaning to the unstructured and chaotic process of online public engagement by bundling participants and their vested interests. Findings of this paper suggest that it is worthwhile to invest more time and effort in this regard. Expanding domain of the analysis and experimenting with larger datasets can result in more insights.

Abstract: Much research has been conducted on capital project sustainability in the last two decades, but most of the findings only provide guidelines for its implementation during facility planning or design. This nearly exclusive focus on early project phases has left the industry with the need for more detailed guidance on implementing construction sustainability practices during jobsite execution. With this need in mind, the Construction Industry Institute (CII) chartered Research Team (RT) 304, "Sustainability Practices and Metrics for the Construction Phase of Capital Projects", to develop this missing practical guidance. This paper overviews the findings and products of the research team. The team developed a catalog of 54 Construction Phase Sustainability Actions (CPSAs) for onsite implementation during the construction phase to increase overall project sustainability. Each CPSA is characterized in terms of corresponding construction functions, potential sustainability impact, influence on project performance (i.e., cost, schedule, quality, and safety), ease of implementation, barriers to implementation, conditions that leverage benefits, and output metrics. The research team also developed two spreadsheet-based tools—the CPSA Screening Tool and the CPSA Implementation Index—to facilitate CPSA implementation during construction. The screening tool enables users to prioritize the 54 CPSAs according to project characteristics, while the index tool assesses CPSA implementation levels. Through its validation efforts, the team determined that the current level of CPSA implementation across the industry is at approximately 60 percent, and that this rate should increase with the regular use of the CPSA catalog, screening tool, and implementation index.

INTRODUCTION

As project teams seek to lessen the environmental impacts of their construction activities—water and electricity consumption, earth work, and wastes generated during demolition and construction, among others—they increasingly recognize the importance of construction sustainability techniques. More and more, owners, contractors, and other capital project stakeholders are looking for guidance and resources for conducting sustainable construction activities to improve their sustainability performance (CII 2014a and CII 2014b).

In recent decades, researchers have developed much practical sustainability-related guidance for construction activities. One of the globally recognized sources of guidance is the Leadership in Energy and Environmental Design (LEED) certification program developed by the United States Green Building Council (USGBC). While this program has been widely implemented, it only offers sustainability objectives and recommendations in the planning and design phases of projects (USGBC 2009). Similar programs were developed by the City of New York Department of Design and Construction and the
Chicago Department of Aviation (City of NY DDC 1999 and CDA 2013). These examples also focused on early project phases.

To provide the industry with practical sustainability guidance for the construction phase, the Construction Industry Institute (CII) organized Research Team (RT) 304, "Sustainability Practices and Metrics for the Construction Phase of Capital Projects." This paper introduces the research products developed by CII RT 304, the Construction Phase Sustainability Action (CPSA) Catalog, the CPSA Screening Tool, and the CPSA Implementation Index. Examples of the construction phase sustainability activities presented in these products are temporary facility design and construction, and construction means and methods.

1 RESEARCH OBJECTIVES

The objectives of the research were (1) to provide practical sustainability guidance for construction field operations, (2) to develop a spreadsheet-based tool to support sustainability implementation during the construction, and (3) to provide sustainability metrics for benchmarking. Since these objectives addressed sustainability implementation during the construction-phase, the scope of the research extended from the contractor's initial set-up to the final commissioning report of a capital project, and sustainability activities during the planning or design phase were excluded.

2 RESEARCH METHODOLOGY

Before proceeding to develop the objectives, the research team defined three key terms, i.e., construction sustainability, construction phase, and conventional project performance criteria. Construction sustainability was defined as "the processes, decisions, and actions during the construction phase of capital projects that enhance current and future environmental, social, and economic needs while considering project safety, quality, cost, and schedule." Construction phase was defined as "all fabrication/jobsite/field activities and decisions starting with construction/fabrication contracting and planning for site mobilization through to initial operations, final performance testing, and handover of the completed facility." Lastly, conventional project performance criteria were defined as "typical criteria for assessing a project's success: safety, quality, cost, and schedule" (CII 2014a and CII 2014b).

As illustrated in Figure 1, the research team reached alignment on the objectives and terms before conducting its literature review. After that the team developed the Construction Phase Sustainability Actions (CPSAs) Catalog and two spreadsheet-based tools—the CPSA Screening Tool and the CPSA Implementation Index. Finally, the team engaged a panel of external sustainability experts to validate these research products (CII 2014a). The following section provides detailed descriptions of each phase of the research.

2.1 Literature Review

The research team examined the relevant literature in the following areas: sustainable development and sustainable construction; common sustainability models; sustainability drivers and barriers; corporate-level and project-level sustainability; advances in project-level sustainability practices; construction and demolition waste management; materials management and selection; construction site energy management and emission reduction; indoor air quality during construction; water consumption/quality during construction; and community and social aspects of sustainability. Due to the page limitations of this article, all detailed findings of the literature review can be found in Implementation Resource 304-2, "A Framework for Sustainability during Construction" (CII 2014a).

While conducting the literature review, the research team was able to study a variety of construction sustainability opportunities and their impacts on construction sustainability performance, i.e., their improvement of economic, social, and environmental aspects of a project. However, most previous research was conducted in early phases of construction projects, such as planning or design. This finding showed the need for more detailed guidance and applicable strategies for construction-phase sustainability practices for owners, contractors, and other stakeholders.
2.2 Development of Construction Phase Sustainability Actions (CPSAs) Catalog

In order to fill the research gap as lacking of guidance on construction-phase sustainability practices, the research team developed the CPSA Catalog with optional 54 actions which enhance project sustainability during the construction phase. The preliminary CPSAs with construction sustainability practices were originated from literature review. Then the research team brainstormed to assemble industry sustainability practices and collected experts opinion on construction sustainability. The team also estimated sustainability impact magnitude of each CPSA implementation with five different levels as significantly positive impact, positive impact, negative impact, significantly negative impact, and minimal/negligible impact. Before finalizing the 54 CPSAs, the draft of CPSAs had been refined with multiple reviews by the research team (CII 2014a).

Each catalog entry follows a template with the following information: CPSA title; primary construction function; secondary construction function; CPSA description; characterization of sustainability impacts; influence on conventional project performance criteria; ease of CPSA accomplishment/implementation; project conditions that leverage benefits from the CPSA; potential sustainability performance output metrics; barriers to successful implementation; and references (CII 2014a and CII 2014b). The team designed and modified the catalog throughout the course of numerous brainstorming sessions and workshops. The team was composed of 15 members, representing owners, contractors, design consultants, and equipment/material suppliers. The team’s cumulative years of relevant industry experience was 316 years, with 21 years as the average amount of experience (CII 2014a).

2.3 Tools Development and Validation

RT 304 developed the CPSA Screening Tool and the CPSA Implementation Index in four different phases: (1) conceptual, (2) detailed planning, (3) tool programming, and (4) testing/modifying. During the conceptual phase, the research team identified inputs, outputs, a logic, and an algorithm for the CPSA Screening Tool. During the detailed planning phase, the team developed the content of the introduction tabs, user guide tabs, input tabs, output tabs, and database tabs for computing, for both tools. Next, the team programmed the content into the tools, using Microsoft Excel software functions. Once the tools had been developed, they were distributed to the panel of external experts to test on specific projects, and the tools were modified according to the panel’s comments and suggestions (CII 2014a).
3 PRODUCT OF THE RESEARCH

This section describes the major characteristics of the research team's three research products: the CPSA Catalog, the CPSA Screening Tool, and the CPSA Implementation Index.

3.1 54 CPSAs Catalog

The research team developed 54 CPSAs for the CPSA Catalog to offer detailed guidance on construction sustainability implementation to owners, contractors, and other capital project stakeholders. Using the information provided in each CPSA, owners or project managers can decide whether to use sustainability activities to affect project performance. Figure 2 presents a sample image of CPSA No. 28. The entire CPSA Catalog can be found in CII Implementation Resource 304-2 (CII 2014a).

![Figure 2. Typical CPSA Catalog Entry (Adapted from CII 2014a and CII 2014b)
3.1.1 CPSA Title and Primary Construction Function

The team identified the following eight construction sustainability-related primary functions for the CPSA Catalog: (1) project management; (2) contracting; (3) field engineering; (4) site facilities and operations; (5) craft labor management; (6) materials management; (7) construction equipment management; and (8) quality management, commissioning, and handover (CII 2014a and CII 2014b).

Table 2 categorizes the 54 CPSAs, first by primary sustainability impact, and then by the most affected project areas and resources. Around 60 percent of CPSAs are relevant to the Site Facilities & Operations, Project management, and Field Engineering. (CII 2014a)

3.1.2 Characterization of Sustainability Impacts

The most affected areas and resources of each CPSA’s sustainability impact was gathered from literature and research team brainstorming. The collected areas and resources were assigned to one sustainability impact area as one aspect among economic, social, and environmental. Table 1 presents the entire list of most affected areas and resources of each sustainable area.

Table 1: Primary Sustainability Impacts of CPSA and the Most Affected Areas and Resources by CPSA (Adapted from CII 2014a)

<table>
<thead>
<tr>
<th>Primary Sustainability Impact</th>
<th>Most Affected Areas and Resources</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td>Economic</td>
<td>Project fiscal impacts, or Negligible effect</td>
</tr>
</tbody>
</table>

The tool prompts the user to indicate the most desirable sustainability impacts for a given project on a five-point scale. The research team also designed the tool to measure the positive impact of each CPSA on conventional project performance criteria, i.e., safety, quality, cost, and schedule objectives.

3.1.3 Ease of CPSA Implementation and Leveraging Benefits of CPSA Implementation

The research team assessed the level of difficulty of each CPSA implementation as easy, moderate, or challenging, considering the required resources, expense, skill-sets, and time to implement. In addition to rating the ease of CPSA implementation, the team identified project conditions that leverage benefits from CPSA implementation, grouping them into seventeen categories. These leveraging conditions can be found in CII Implementation Resource 304-2 (CII 2014a).

3.1.4 Sustainability Performance Output Metrics and Barriers to Successful Implementation

The research team identified output metrics for measuring the sustainability performance of each CPSA during its implementation, putting these metrics into nine categories. Moreover, the team examined barriers to each CPSA implementation to prepare project teams for potential challenges. The team grouped these barriers into the following five categories: lack of information; limited project resources; outside owner/contractor control; lack of infrastructure; and unfavorable site or project conditions. The full lists of output metrics and barriers can be found in CII Implementation Resource 304-2 (CII 2014a).

</table>
3.2 CPSA Screening Tool

The research team developed the Excel-based CPSA Screening Tool to help project managers or any capital project stakeholders select the most appropriate and relevant CPSAs. This tool utilizes user input about the project to screen for these relevant CPSAs from the total 54 CPSAs. It then ranks the selected CPSAs according to their likelihood of maximizing project sustainability performance.

The first user inputs for the CPSA Screening Tool are project-specific sustainability objectives; the user determines the relative importance of environmental stewardship, social progress, and direct project economics. Next, the tool prompts the user to provide information about project characteristics. The output is the prioritized list of CPSAs. Figures 3 and 4 show the screenshot of the tool’s Input tab. Figure 5 presents the screenshot of the Output tab. (CII 2014a)

![CPSA Screening Tool - Sustainability Priorities Tab](Adapted from CII 2014)

![CPSA Screening Tool - Sustainability Priorities Tab](Adapted from CII 2014)

Figure 3. CPSA Screening Tool - Sustainability Priorities Tab (Adapted from CII 2014)
Equation 1 presents the Relevance Index (RI), the tool’s prioritizing algorithm. The RI is the Impact Score (IS) times the Conditions Score (CS). The IS is the sum of the Project-specific Sustainability Priorities (PSP) times the Sustainability Impact Rating (SIR); these are shown in Section C of each CPSA sheet. (See the sample sheet in Figure 2.) The percentage of each sustainability priority entered in the Input tab of the tool is its PSP value, and the SIR value is defined as 0 when the SIR is “N,” 0.60 when the SIR is “+,” -0.60 when the SIR is “-,” 1.00 when the SIR is “++,” and, lastly, -1.00 when the SIR is “--.” (CII 2014a)

\[ \text{RI} = \text{IS} \times \text{CS} \]

where \( \text{IS} = \sum \left( \text{Project-specific Sustainability Priorities} \times \text{Sustainability Impact Rating} \right) \)
The CS is determined by the number of leveraging conditions applicable to the project; it is 0.10 when there are zero CPSA leveraging condition, 0.33 when there is one leveraging condition, 0.67 when there are two leveraging conditions, 1.00 when there are three leveraging conditions. (CII 2014a)

3.3 CPSA Implementation Index

To help project teams assess the sustainability performance of their projects, the research team developed CPSA Implementation Index. This tool’s numerical index score (out of 100 possible points) represents the project’s level of CPSA implementation. This score also allows project teams to compare projects for sustainability performance. As discussed above, the input for the CPSA Implementation Index is a rating of the extent of implementation of all 54 CPSAs. Figures 6 and 7 show screenshots of the tool’s Input and Output tabs, respectively. (CII 2014a)

To compute the CPSA Index score, the tool allocates a maximum of 1.85 points for each CPSA implementation, with a total of 100 possible points. That is, the points allocated for each CPSA will be 1.85 when the extent of CPSA implementation is selected as “Full or Almost Full.” Further, when the extent selected is “Substantial,” the points awarded will be 1.23. When the extent selected is “Minimal,” the points will be 0.62. When the extent selected is “None or Almost None,” the points will be 0.00. (CII 2014a)
4 VALIDATION OF THE PRODUCT

4.1 54 CPSAs Catalog

The research team distributed a survey to the review panel, to identify any missing content, to identify any items in need of correction, and to examine their current levels of CPSA application. The 33-member review panel was composed of research team members and external industry practitioners. They had an average of 26 years of industry experience (CII 2014a).

The first section of the survey assessed background, e.g., years of industry experience, project role, primary industry sector, and company size, among other characteristics. The second section asked frequency of CPSA application to the project and likelihood of application of each CPSA to future projects. The respondents indicated that they would either sometimes or frequently apply around 41 CPSAs (75 percent) to their projects; they also said that they were either somewhat or very likely to apply 53 CPSAs (98 percent) to their future projects (CII 2014a).

4.2 CPSA Screening Tool and CPSA Implementation Index

The research team demonstrated the CPSA Screening Tool on a large mining project in Mexico, and demonstrated the CPSA Implementation Index on a large U.S. urban rail transit project. In this validation process, project managers from each project gave constructive and valuable feedback that the team used to modify the tools. The CPSA Implementation Index demonstration showed that the current level of CPSA implementation is 60 percent (CII 2014a).

5 CONCLUSIONS AND RECOMMENDATIONS

The industry’s need for practical guidance on construction-phase sustainability implementation motivated the research team to develop the Construction Phase Sustainability Actions (CPSAs) Catalog, the CPSA Screening Tool to prioritize relevant CPSAs for each project, and the CPSA Implementation Index to measure the level of CPSA implementation efforts. All three outputs were validated by selected experts in construction sustainability. The tool demonstrations showed that the current level of CPSA implementation is 60 percent. (CII 2014a)

Acknowledgements

The authors would like to thank the Construction Industry Institute (CII) for chartering this research project, the members of CII Research Team 304 for their commitment and participation, and the survey participants for their valuable feedback.

A RAPID LIFT STUDY GENERATION SYSTEM FOR HEAVY INDUSTRIAL PROJECTS

Brian D. Ofrim\textsuperscript{1,4}, Zhen Lei\textsuperscript{2}, Tarequl Hasan\textsuperscript{2}, Mohamed Al-Hussein\textsuperscript{2}, and Ahmed Bouferguene\textsuperscript{3}

Abstract: The process of creating mobile crane lift studies for heavy industrial projects can be time-consuming and tedious. A large portion of the lift studies required for such projects involve modules that are prefabricated and transported to the site. Composing these lift studies currently requires a considerable amount of time and manual work. Due to the complex nature of these projects the lift studies also often require significant revisions to accommodate changes to the initial plans. This paper introduces a rapid lift study generation program to assist in the planning stage by expediting the drafting process. The program utilizes Autodesk’s AutoCAD, which is one of the most widely used drafting software applications in North America. A custom plug-in to AutoCAD written in the Visual Basic programming language is used to create the graphic portion of the lift study. A separate Windows Form application is used to produce a table of the crane and lift information, such as lifting capacity, ground bearing pressure calculations, and mat design. This application is supported by a database of specifications for various crawler cranes and configurations as well as capacity information. The application allows the user to input information such as the module’s weight, rigging weight, and lift radius in order to obtain a table of relevant information for each lift. This rapid lift study generation program has been tested for validation on a heavy industrial project for which the lift studies had already been prepared by NCSG Crane & Heavy Haul Services using the traditional method.

1 INTRODUCTION

In Alberta, Canada, mobile cranes are frequently used in heavy industrial projects to erect modules that are prefabricated in a controlled environment and then shipped to site. (This offsite construction process is efficient and consumes less waste in general.) In order to achieve a successful lifting process, extensive planning is needed and lift studies are required for each individual lift. Lift studies contain detailed drawings of the crane picking the modules off of the delivery trucks, as well as drawings of the crane placing each module at its final destination. These drawings need to be dimensioned to ensure that the crane and module are placed in their intended locations. Supportive engineering information and calculations are also necessary, such as: (i) the crane configuration; (ii) the length of the boom; (iii) the percent of the crane’s capacity used for the lift; and (iv) the ground bearing pressure (GBP) and mat pressure. However, due to the complicated planning process, lift study requires much preparation time and is error-prone. In addition, any change to the site or project will lead to re-planning and re-design. The objective of the system described in this paper is to accelerate the process of creating these lift
studies by programming the designing algorithms into computer applications. The system involves two main components, one that handles the graphics and one that handles the calculations and table of information. The graphical component is achieved using a plug-in to AutoCAD, which aids with the insertion of transport trucks, modules, rigging, mats, and cranes as well as with dimensioning. The calculations and tables are made by means of a Windows Form application called Smart Lift Planner. This two-program system improves upon the traditional methods of drafting by making it faster and more user-friendly. In previous crane-related research, automation has been the focus in engineering planning and design; this scholarship has included (i) automatic crane selection and positioning (Hanna and Lotfallah 1999; Huang et al. 2011; Safouhi et al. 2011; Wu et al. 2011; Lien et al. 2014); utilizing 3D visualization to simulate crane operations (Al-Hussein et al. 2006; Tantisevi et al. 2009; Lin et al. 2012; Hasan et al. 2013); and lift path planning with the assistance of computer technology (Chang et al. 2012; Zhang and Hammad 2012; Juang et al. 2013; Lei et al. 2013a and 2013b; Olearczyk et al. 2014). However, there are few software applications/systems in the market that can be directly used for heavy lift planning. In Alberta, most large-scale construction companies currently employ drafting personnel that create the graphical portion of lift studies using drafting software such as AutoCAD. Once the site layout has been prepared and the locations of modules, cranes, and transport trucks have been determined, the graphic portion of the lift study must be prepared. To do so the draftsperson must manually insert the transport truck into the drawing, orient it correctly, place the module in the correct position on top of the truck, manually insert the rigging on top of the module, place the crane in its predetermined location, orient the tracks in the right direction, rotate the crane body such that it is facing the module, raise or lower the boom so that the hook block is on top of the pick point, draw a lift line, insert a layout tab, generate the correct view ports, and dimension both the plan and elevation views. Then when it comes time for the set-point drawing to be created, the draftsperson is required to move the module to its set position, rotate it to the correct angle, reposition the rigging in a similar fashion, rotate the crane body, raise or lower the boom, delete the old lift line and draw a new one, delete the old dimensions, and create new dimensions. It is easy to see that this process is tedious and time-consuming. Therefore a level of automation to make the process faster and more efficient would prove to be extremely valuable.

2 AUTOMATED LIFT STUDY GENERATION

The graphical component of the system is handled by an AutoCAD (AutoDesk 2015) plug-in developed in the Visual Basic programming language (Microsoft 2015) at the University of Alberta. The primary use of this plug-in is to aid in the insertion of blocks—objects created from AutoCAD drawings that can be inserted into other drawings. The blocks used by the program have been previously created specifically for the project used to test the program. (These blocks must be saved as individual .dwg files in a specific location so that the program can properly insert them.) Various measurements of the block must be carried out and entered into the spreadsheets from which the program retrieves data. The plug-in is designed to be used after the user has created and inserted the site layout into AutoCAD’s model space.

2.1 Step 1: Crane Matting insertion

The user selects the insert button from a custom toolbar developed for the program. They then specify where they would like to place the mat—either on screen or by entering coordinates into the command line. Options are then given for the insertion angle. For the purpose of selecting the insertion point and angle by moving the cursor and clicking in the 3D environment, the program supports what is known as jigging. In this process, the object being inserted will follow the user’s cursor around the 3D environment and its position will become fixed when the user clicks the mouse. Jigging provides the user with a visualization of the block before its insertion point has been fixed in order to more closely represent how the block will appear in the drawing. This provides an efficient method for determining where to place blocks in relation to existing objects in the drawing. Once a mat has been inserted, if the user requires additional matting they can simply specify a location in relation to the previously placed mat (front, back, left or right). A mat will be automatically inserted in the specified direction and at the same angle as the previous mat.
2.2 Step 2: Transport Truck/Module Insertion

In this step the user first selects the insertion button from the custom toolbar. A prompt will then appear which will allow the user to directly insert a module or to first insert a transport truck into the drawing. Next the option is presented for the user to specify an insertion point either by clicking a point in the model space (jigging supported) or by entering coordinates into the command line. For inserting a module, the insertion point is at ground level directly below the southwest rigging attachment point. For inserting a transport truck the insertion point is located at ground level directly below the trailer hitch. Similar options are then given for the insertion angle. The required module is then selected from a project specific list. This list contains relevant information such as module dimensions and weight, number of cranes necessary for lifting, number of rigging attachment points, rigging height, and locations of pick points in relation to the insertion point. Finally either the user selects where the module is to be placed or it is automatically placed on a previously inserted truck trailer.

2.3 Step 3: Rigging Insertion

After the module has been inserted the user selects the “insert rigging” option, and the rigging (previously designed and saved as a block) necessary to lift the module will be automatically placed on top of it. The automatic rigging placement is performed by inserting the rigging at the same (x,y) coordinates as the module insertion point but at the elevation of the rigging attachment point, which has been measured and entered into a spreadsheet. This displacement is shown in Equation [1] as position vector $\vec{R}_{\text{rig}}$ relative to the origin, where $M_X$, $M_Y$, and $M_Z$ are the insertion points of the module and $H_M$ is the height of the module. The block is then rotated about the z-axis to match the angle of the rigging.

\[ [1] \quad \vec{R}_{\text{rig}} = (M_X, M_Y, M_Z) + H_M \]

2.4 Step 4: Crane Insertion

Now that the module and rigging are in place the user selects a crane to insert. (Cranes available in the current program are the Demag CC2800 and the Manitowoc18000; however, the program could easily be expanded to accommodate other similar cranes.) The user is then prompted to select the desired boom length from a list of crane configurations. Next, the maximum radius must be specified. The program calculates the maximum radius for which the top of the boom will be above the top of the rigging. This value is used as the default maximum radius but can be easily overridden. It is recommended that the second component of the program (Smart Lift Planner) be used when determining this value, as it references the tables supplied by the crane manufacturer in order to determine the maximum radius for a given load. The next prompt provides the user with various options for inserting the crane. These options include:

- Side1/Side: Places the crane perpendicular to the module at a user-defined radius and elevation.
- Specify: Allows the user to either click a point on the screen on which to place the crane or specify the location by entering coordinates. Similar options are given for the crane’s track angle. This method supports jigging.
- Distance Direction: The user enters the location in polar coordinates (radius and angle) relative to the module’s center. Options for track angle are also given.
- Previous Location: This option is available if a crane has previously been inserted and will place the crane in the same location as the previous crane.

While these options are given temporary indicators appearing in the model space that show the locations of sides 1 and 2, as well as circles that show the minimum and maximum allowable radii, these indicators automatically disappear once the crane has been inserted. For all of the options the crane body and boom are automatically configured such that the crane hook will be on the rigging pick point (hook point). The hook point is described using 3D coordinates in Equation [2] by the module’s insertion point $(M_X,M_Y,M_Z)$, the distance in the $x$-$y$ plane from the module’s insertion point to the hook point $(M_{HD})$, the module’s insertion angle ($\theta_M$), the angle in the $x$-$y$ plane from the module’s side to the hook point with the
vertex being the module’s insertion point \( (\theta_{MH}) \), the height of the module \( (H_M) \), and the height of the rigging \( (H_{RIG}) \). Figure 1 provides a labelled plan and dimension views of the module and rigging. The equations the program uses to automate the crane orientation process are outlined below. In all cases the insertion point for a crane is located at ground level directly below the crane’s pivot point \( (\text{Piv}_X, \text{Piv}_Y, \text{Gnd}) \), shown in the position vector relative to the origin in Equation [8]. This is the position at which the crane track is to be inserted. The crane body is then inserted directly over the track at the position described by the position vector in Equation [9], where \( \text{Elev}_{BODY} \) is the elevation of the insertion point of the crane body relative to the ground. Next the crane body is rotated in the \( x-y \) plane by the angle \( \theta_{BODY} \) (Equation [5]) relative to the positive \( x \)-axis. The boom is then inserted at the position described by the position vector in Equation [10], rotated in the \( x-y \) plane by the same angle as the crane body \( (\theta_{BODY}) \), and finally rotated in the \( z \) dimension relative to the \( x-y \) plane by an angle of \( \theta_{BOOM} \) (Equation [7]). In Equation [7] the variable, \( r \), represents the distance from the pivot point to the hook point in the \( x-y \) plane (i.e., the lifting radius), \( L_{BOOM} \) is the length of the boom, and \( O_{BOOM} \) is the boom’s offset from the pivot point in the \( x-y \) plane. With everything in position the program also automatically draws a vertical line from the crane’s boom head to the hook block, representing the load line.

[2] \( \text{Hp} = (M_X + MH_d \cdot \cos(\theta_M + \theta_{MH}), M_Y + MH_d \cdot \sin(\theta_M + \theta_{MH}), M_Z + H_M + H_{RIG}) \)

[3] \( \Delta X = \text{Hp}_X - \text{Piv}_X \)

[4] \( \Delta Y = \text{Hp}_Y - \text{Piv}_Y \)

[5] \( \theta_{BODY} = \arctan(\Delta Y / \Delta X) \) \hspace{1cm} \text{(Angle in} \ x-y \text{ plane relative to positive} \ x \text{-axis)}

[6] \( r = \sqrt{\Delta X^2 + \Delta Y^2} \)

[7] \( \theta_{BOOM} = \arccos((r - O_{BOOM}) / L_{BOOM}) \) \hspace{1cm} \text{(Angle in} \ z \text{ dimension relative to} \ x-y \text{ plane)}

[8] \( \bar{R}_{\text{TRACK}} = \langle \text{Piv}_X, \text{Piv}_Y, \text{Gnd} \rangle \)

[9] \( \bar{R}_{\text{BODY}} = \langle \text{Piv}_X, \text{Piv}_Y, \text{Gnd} + \text{Elev}_{BODY} \rangle \)

[10] \( \bar{R}_{\text{BOOM}} = \langle \text{Piv}_X + O_{BOOM} \cdot \cos(\theta_{BOOM}), \text{Piv}_Y + O_{BOOM} \cdot \sin(\theta_{BOOM}), \text{Gnd} + \text{Elev}_{BOOM} \rangle \)

Figure 1: Labelled plan and elevation views of the module and rigging.
2.5 Dimensioning and Lift Study Layout

An available feature of the program can automatically create a plan view dimension for the lift study. The program generates radial dimensions for the lift radius, tail-swing radius, and super-lift radius. It also creates both horizontal and vertical dimensions from the crane to the pick point. The user can use the dimension grips to arrange the dimensions as they see fit. The dimensions are placed on a layer, called PlanDimension, that the program creates. Once the user is satisfied with the drawing, another function from the custom toolbar can automatically insert a lift study layout into paper space. When this option is selected a command line prompt appears asking the user if the layout is for the final or initial position (pick point or set point). These layouts contain viewports for a plan view, an elevation view, and an additional custom view. The user then creates the elevation dimensions on the layout with a pre-made dimension style on a layer, called ElevationDimension, created by the program. Finally, the user turns off the PlanDimension layer in both the elevation and the custom viewports in order to find a custom view they are satisfied with. The graphical component of the pick point lift study is now complete. An example is shown in Figure 2.

![Figure 2: Completed lift study graphics](image)

2.6 Module Movement Options

Now that the pick point lift study is complete, the crane and module can be manipulated. These options, available on the custom toolbar, include lifting, straightening, swinging, and rotating the module, as well as raising or lowering the boom to move the module backwards or forwards (see Figure 3). The crane will automatically respond to these operations by orienting itself in the correct fashion. Another available option is to simply choose the set point, which will remove the module from its pick position and allow the user to manually select the module's set point and set angle. Again the crane will automatically change orientations to accommodate this (see Figure 4). The user can then create a set point lift study layout in much the same way as with the pick point.

![Figure 3: Module and boom manipulations](image)
3 SMART LIFT PLANNER

The Smart Lift Planner (SLP) is a Windows Form application designed to aid in planning and calculations necessary for lift studies. It accomplishes this through use the combined use of databases and user inputs such as module weight, lifting radius, and matting type. Several databases of technical data are constructed in order to minimize the need to sift through data tables to obtain information. These include a crawler crane database, a capacity database, and a rigging database. The crawler crane database contains hundreds of unique crane configurations, each with 45 parameters including weights, dimensions, and lift form. The capacity database contains the capacities at different radii for many of the configurations. The rigging database contains the specifications for hundreds of shackles, slings, spreader bars, and turnbuckles. The SLP can be used to determine maximum lift radius, percent capacity, total weight, ground bearing pressure, mat pressure, and matting necessary, among other things. Further details pertaining to the SLP are provided below.

3.1 Crane Info Page and Lift Design Page

Dropdown menus allow the user to select the crane manufacturer and the crane model they require. Once these selections have been made a data grid view appears, where the user can scroll through and select the configuration that will meet the specific needs of the project. Crane Info Page 1 then automatically displays information such as weights, lift form, and boom length. It also brings up the capacity table for the chosen crane, which shows how the lifting capacity varies with radius. A hook block table is also available for the user to select a hook block. The dimensions of the chosen crane are automatically displayed on Crane Info Page 2 (see Figure 5). Now moving to the lift design page the user inputs the weights of the module, rigging, and other relevant components. The program then calculates the total weight and checks the capacity chart to provide the user with a range of radii acceptable for lifting modules with the selected crane. The user then inputs the radius for the current lift, and the program outputs the maximum capacity at that radius and the percentage of the maximum capacity that the lift requires.
3.2 Ground Bearing Pressure Page

After the capacity has been determined the ground bearing pressure must be calculated. All of the information needed for this calculation is already available, so the user simply needs to click “calculate GBP”. The required information is retrieved from the database entries for the selected crane, as well as from the lift design page where information has been inputted by the user. By default these values are used in GBP calculations; however, they can be manually overridden if need be. The program also generates a chart that displays the GBP on each side of the crawler as a function of the boom angle. The values given are the maximum pressures on the front boom side, rear boom side, front counter weight side, rear counterweight side, and the crane body angle that gives these maximum pressures. If the GBP at a specific crane body angle is required, then that angle can be specified and the program will give the corresponding pressure values. A screen capture of the ground bearing pressure page can be seen in Figure 6.

3.3 Mat Design Page

GBP information is automatically passed to the Mat Design page. The user is prompted to input the allowable soil bearing capacity for the project site, the number of timbers forming the mat, number of
layers of mats, and sectional dimensions of the mat, and to choose the type of wood for the mats. The program then verifies if the stresses induced by the lift are within the allowable limit. If the allowable limit is exceeded then an error message is displayed along with a message containing suggestions such as “Bending Fail! Please increase the depth of mat or number of layers”. If the pressures are within the allowable limit then the necessary mat length, p value, load on mat, and minimum mat cantilever distance are generated. A screen capture of the mat design page can be seen in Figure 7.

![Figure 7: Labelled screen capture of mat design page](image)

3.4 Generating and Exporting Lift Study Table

With all information required for a lift study table now available, the user returns to the Lift Design Page and clicks “Generate Table”. The generated table has a feature that exports the table into an MS Excel spreadsheet. The spreadsheet can then easily be imported into the AutoCAD layout created by the lift study AutoCAD plug-in.

4 VALIDATION

The Rapid Lift Study Generation system was used to recreate the graphical portion for a total of 34 pre-existing lift studies from a project by NCSG Crane & Heavy Haul Services. The project was located in Fort McMurray, Alberta and involved the assembly of prefabricated pipe racks that had been transported to the site by trucks. The crane featured in the lift studies was the Manitowoc 18000. The 55A configuration was used with a boom length of 280 ft. The studies featured 18 pipe racks weighing up to 211,974 lb with lengths up to 120 ft. All lifts featured were single-crane lifts. The transport truck, pipe racks, custom rigging, and crane blocks had been created by the drafting-people at NCSG for use in traditional lift studies. The blocks were then modified for use with the Rapid Lift Study Generation Program. Information relevant to the insertion of the blocks was measured using existing AutoCAD tools and entered into spreadsheets. Use of the program substantially reduced the time needed to insert the blocks into the drawing. Because of the level of automation offered by the plug-in it was possible to create lift studies with less effort and drafting knowledge. Tedious tasks such as manually inserting, rotating, and aligning the blocks were mitigated. During the process of creating lift studies, it should be noted, it is often necessary to explore multiple crane position options. Through use of the program it is possible to create many versions of the same lift study in a short period of time, making the planning phase more efficient. For a few of the 34 lift studies created the table of crane information was constructed through use of the SLP. The SLP was tested against existing software, “Crane Support Design”, developed by Hasan et al. (2010). A sample comparison between the two programs is provided in Table 1. For actual industrial implementation of the developed system, further and more rigorous validation is necessary.
Table 1: Comparison between SLP and crane support design

<table>
<thead>
<tr>
<th>Calculation</th>
<th>SLP</th>
<th>Crane Support Design</th>
</tr>
</thead>
<tbody>
<tr>
<td>Boom Side Front Pressure</td>
<td>8,284 psf</td>
<td>8,010 psf</td>
</tr>
<tr>
<td>Boom Side Rear Pressure</td>
<td>2,570 psf</td>
<td>2,732 psf</td>
</tr>
<tr>
<td>Counter Side Front Pressure</td>
<td>6,697 psf</td>
<td>6,429 psf</td>
</tr>
<tr>
<td>Counter Side Rear Pressure</td>
<td>1,982 psf</td>
<td>2,169 psf</td>
</tr>
<tr>
<td>Horizontal Angle For Max Pressure</td>
<td>30°</td>
<td>30°</td>
</tr>
<tr>
<td>Min. Mat Length</td>
<td>47.7 ft</td>
<td>42.7 ft</td>
</tr>
<tr>
<td>Mat Depth</td>
<td>12 in</td>
<td>12 in</td>
</tr>
<tr>
<td>Mat Width</td>
<td>3.8 ft</td>
<td>3.8 ft</td>
</tr>
</tbody>
</table>

Differences between values are assumed to be due to minor differences in the implementation of formulas in creating the respective programs and the way the programs handle values. The difference in mat length is due to the fact that SLP takes into account the bending and shear strength of the wood, whereas the Crane Support System does not.

5 CONCLUSION

In this paper, an automatic system has been introduced for rapid lift study creation for heavy industrial projects. The system has been proven efficient in engineering planning and the design stage for heavy lifts. Many design factors have been considered in the calculations, such as the lifting capacity and ground bearing pressure. The crane is inserted to its predefined pick and set locations in an AutoCAD system using a plug-in developed by researchers at the University of Alberta; lift drawings (2D and 3D views) are automatically generated, which shortens the drafting time and reduces the human component involved. The designed graphical system has been tested by recreating documents for an actual industrial project in Fort McMurray, Alberta, and the SLP results have been compared with the system previously developed by Hasan et al. (2010).

CHARACTERIZING COORDINATION IN BOTH LOOSE AND VERY TIGHTLY COUPLED UTILITY RECONSTRUCTION PROCESSES.

Abstract: Privatization of the utilities sector created a fragmented multi-client, multi-contractor system in which reconstruction works are, in fact, a constellation of multiple smaller projects. During planning stages, these projects are loosely coupled, since stakeholders limitedly align construction plans. Consequently, coordination of unresolved issues moves toward construction stages, creating very tight on-site couplings. This paper focuses on the coordination activities that balance these loose and very tight couplings in the planning and execution stages of utility reconstruction. To this end, we identified seven well-performing 'utility coordinators' and conducted ethnographic interviews to explore their work practices. To better characterize these different practices, we introduce level of involvement and moment of involvement as two dimensions for coordination within loose and tightly coupled systems. Based on this, we distinguish two dominant approaches for coordination in utility coordination practice: pro-active involvement in early planning stages, and reactive approaches during execution stages. Findings complement to literature by providing dimensions for coordination of loosely coupled systems. Consecutive research efforts should aim at validating these findings and at identifying contextual factors that drive various distinctive coordination approaches.

1 INTRODUCTION

Privatization policies have changed utilities sectors around most of the Western hemisphere. Nowadays, many utility companies own operate and maintain their own subsurface network. Especially in urban space, these networks are often located in the shallow, densely occupied ground. Utility reconstruction processes – defined as the planned activities related to renewal or relocation of utility service networks such as sewage, energy and water pipes, and telecom lines - therefore involve myriads of utility providers. When these companies concurrently re-align or refurbish their infrastructure, each organization is individually responsible for design and construction of its own network. At the same time, they should manage the interfaces with reconstruction work on surrounding utilities and therefore need participation of other utility companies.

In reality, alignment of the various utility companies is difficult for various reasons: First, concurrent utilities reconstructions involve no formal principle client. Instead, all municipalities and utility contractors are clients on their own. They need to collaborate within a shared workspace to reconstruct their own assets. In contrast with ‘common’ construction projects such collaboration cannot be forced through hierarchical coordination mechanisms. Instead, all clients negotiate to decide about design interfaces and
construction methods. A second difficulty for alignment is that clients often hire distinctive contractors to execute reconstruction work. These contractors formally have limited influence on one another's construction plans. Therefore, they mutually adjust plans based on informal improvisation on-site, relying on one another's participation and goodwill.

In short, utility reconstruction comprises of multiple smaller projects – with distinctive clients and contractors. In absence of any mediating or central coordination function, however, organizations often align their construction plans too loosely. Resulting insufficient planning causes interface conflicts. This necessitates troubleshooting and improvisation onsite. Concepts from literature can be used to describe these processes as loosely coupled upfront and very tightly coupled onsite. To address this issue, coordination activities are needed to tighten coordination in planning stages. It is, however, unclear how the activities that balance these couplings can be characterized.

This paper is outlined as follows: To better understand how to loose and tightly couplings in utility projects are managed, the next paragraph explores the activities and behavior of 'utility coordinators'. These 'utility coordinators' are mobilized by utility owners to facilitate collaborative design, planning and execution processes in collaborative reconstruction works. In the research method, we then discuss how we conducted ethnographic interviews with seven coordinators, focusing on their behavior and goals. Outcomes from our qualitative analysis then show that coordination activities differ along dimensions level of involvement and moment of involvement. The paper ends with a discussion and conclusion.

2 THEORETICAL POINTS OF DEPARTURE

The construction industry can be conceptualized as a system of events that are loosely coupled (Dubois and Gadde 2002). Within this system, couplings describe the responsiveness between events. In a loose coupling, mutual relations between events are weak, slow, or infrequent. Loose couplings occur between, for example, individuals, organizations, organizational environments, actions and activities (Weick 1979). These weak couplings allow events to preserve their unique character and create flexibility.

Furthermore, construction industry provides products and systems that are tightly related, i.e. have tight physical couplings. Since these systems have unique and location-centric characteristics and uncertainties, they also need to be coordinated in a tight way. In addition, construction projects often involve a variety of specific trades, contractors and subcontractors (Eccles 1981). These organizations have sequential and reciprocal dependencies (Thompson 1991) that also require tight couplings on the construction project level (Dubois and Gadde 2002). To enhance innovation in construction firms, couplings are also needed between successive construction projects (Dorée and Holmen 2004).

When tight couplings are dealt with in a loose way, however, coordination can become inefficient and erroneous. Similar is shown by Sherman and Keller (2011). They argue that selection of an inappropriate integration mode (i.e. selection of organization structures and means of information processing) decreases coordination performance. One problem in utilities reconstruction is, however that tightly coupled coordination during planning stages is hard to establish. We provide two reasons for this: First, stakeholders may not perceive project-level couplings to be tight. This might be because utility reconstruction works form a constellation of projects comprising of multiple clients and contractors. In this constellation, clients and contractors are not equally committed to streamline project delivery plans. They may even intentionally loosen processes by avoiding making early stage process commitments. This occurs, for example, when clients have different interests with regard to deadlines and use of construction methods. Second, tight integration of project schedules and designs cannot be forced through classical hierarchical coordination. As a result, all clients and contractors individually prepare construction plans. Since they can limitedly influence one another’s work planning processes this often results in a loose, slow planning process.

So, instead of having tight couplings, project planning stages seem to consist of loosely related construction plans and stakeholders. Since limited coordination takes place upfront, coordination issues are postponed and resolved in execution stages. This increases coordination pressure on the jobsite managers and work crew. We conceptualize this situation as loosely coupled upfront and very tightly
coupled onsite. We argue that the couplings could be better balanced to obtain a more desired situation. To this end, early planning stage couplings need to be tightened, for example, by increasing stakeholders’ early stage involvement and by mobilizing a central coordination mechanism (Table 1).

Table 1: overview of existing couplings; a more balanced situation of couplings, and their consequences for planning and execution of utility reconstruction works.

<td></td>
<td>Tight</td>
<td>More efficient coordination, increased flexibility onsite, less pressure on construction processes (\rightarrow) overruns less likely</td>
</tr>
</tbody>
</table>

To balance the couplings toward tighter planning stage integration and looser onsite couplings, liaison devices can be used (Mintzberg 1979). The liaison manager, for example, bridges the processes and needs of various clients and contractors. In the utility sector, this important bridging function is executed by a utility coordinator. In the paragraphs below, we explain how we empirically derived dimensions that enable a conceptual description utility coordination. This resulted in two dimensions: level of involvement and moment of involvement.

3 RESEARCH METHOD

To analyze the coordination activities that attempt to tighten loosely coupled planning practices, we conducted ethnographic interviews (Spradley 1979) with utility coordinators. This interview method allows respondents to obtain details and specific about the routines and work practices of respondents. To first identify respondents for our interviews, we searched for representative coordinators that, through years of experience, built up their own work practice to effectively address coordination issues. To this end, we asked service providers and authorities which utility coordinators in their network perform their tasks well. This resulted in a list of seven professionals whose job description relates to coordination of utilities. Their experience varied between two and more than ten years.

As a next step, we conducted the interviews. Two identified coordinators collaborated as a team and were therefore interviewed together; the other five were interviewed separately. The questions in the ethnographic interviews explored the actions, behavior and attitude of the coordinators. We asked the respondents, for example, to describe their common practice, and to elaborate how they deal with unforeseen process disruptions. We collected this data by tape-recording the interviews. We subsequently transcribed the interviews and qualitatively analyzed this data. First, instances of respondents’ actions, behavior and attitudes were identified and labeled. Then, we clustered similar codes and created an overview of stakeholders and their correlating actions, behavior and attitudes. The resulting overview allowed us to identify differences and similarities between work practices.
4 FINDINGS

This paragraph elaborates the identified coordination activities. Subsequently, we inductively derive a categorization scheme to conceptually distinguish these activities.

From the coordination activities we identified, Table 2 (page 5) summarizes fourteen activities that co-occur in work practices of multiple respondents. Surprisingly, though only three activities were executed by more than three utility coordinators, these are: pursuing utility owners to timely request/issue permits and provide work documentation; being aware of all current plans and decisions, and identifying interfaces between various disciplines. The table shows that most other activities were executed only by two respondents. We provide a few examples of identified coordination activities below (all translated from Dutch).

One respondent motivated his actions and behavior in the quote below. Here he argued that he wanted to play a key role in the reconstruction process. It fits the coordination activity 2 ('being aware of all current plans and decisions') from Table 2:

"I find it important to be mobilized by all involved stakeholders. I want to be recognizable. I want to be sure that people know that they can reach me in case they have questions. And I want to be able to answer these questions. In fact, I am a key figure in the whole process."

An example from another respondent relates to the third coordination activity, ‘identifying interfaces between various disciplines’:

"[we] start with the analysis, which should result in an object-code matrix, which is an overview of all utilities within the project boundaries…and, eventually, we identify conflicts between the design and these utilities. We visualize and code these conflicts on a large map. Then you can see, for example … [that there are] low voltage cables, and telecommunication cables. These are object code X at interface 2"

Furthermore, regarding the coordination activity 4 in Table 2, ‘visiting and monitoring on-site work’, another respondent argued:

"Well, I always inspect the construction site at the outset of the project. Just as soon as I get an assignment, I will go there to get a grip of how the street, neighborhood or intersection will look like. Because, when one is in a meeting, you need to know where the trees or culverts are."

Our last quote shows a more exceptional coordination action, number 11 in Table 2: ‘verifying accuracy and completeness of utility location information’

"First, make a good analysis of existing utilities. This creates the basis. Make sure the information and figures are correct. And, as soon as you have any doubt about the location of utilities, check whether the information is correct. This means that one might also need to do a field survey to clarify information".
Table 2: identified co-occurring coordination activities of respondents, the moment in which they are executed; the level of involvement characterizing the activity, and the amount of respondents employing the activity.

Further, we categorized the quotes to inductively derive two distinguishing dimensions for coordination in loosely coupled systems: First, one can characterize coordination work practice based on the coordinator's moment of involvement during a reconstruction project's life cycle stage. It seems, for example, that some coordinators are involved during early design and planning stages, while other coordinators participate more actively once construction activities started. Second, the level of involvement also varies between various work practices. Our analysis, for example, shows that some coordinators take a pro-active and leading role. They, for example, shape processes and procedures, initiate meetings and take initiatives to aligning parts of the reconstruction plan. Alternatively, other coordinators are more reactive and only interfere with reconstruction processes once holdups or stagnation occurs.

Figure 1 uses our proposed categorization to characterize the coordination activities of our respondents. This shows that there are essentially two approaches to coordinate loosely coupled utility projects: The first one is characterized by pro-active involvement in planning stages. Here, coordination actions focus on shaping design and scheduling processes and actively solving coordination issues. Second, coordination activities can also be more reactive during execution stage. Then, activities mostly involve information processing and follow only agreed formal procedures. It is unclear whether the coordinators deliberately choose to employ one of the two coordination approaches. We suspect that these decisions depend on the coordinator’s own coordination style and by procedures that the coordinator’s organizations prescribe.
5 DISCUSSION

Utility reconstruction processes are loosely coupled upfront, and very tight on-site. This study identified fourteen activities that are employed to balance the tightness of these two relations. With this, we provide first insight in activities used by coordinators in the domain of utilities reconstruction. We show how liaison roles (Mintzbeg 1979) are mobilized in practice. In the interviews, we found that only three activities were mentioned by multiple utility coordinators, these are: pursuing utility owners to timely request/issue permits and provide work documentation; being aware of all current plans and decisions, and identifying interfaces between various disciplines.

Second, closer investigation of the activities shows that the dimensions moment of involvement and level of involvement characterize the nature of the various coordination functions. The introduced dimensions show which concepts can be used to manage loosely coupled systems. More specifically, two concepts can be distinguished: pro-active involvement from planning stages onward and reactive involvement from execution stage onward. A logical explanation for these two coordination approaches might be that a pro-active involvement in early project stages tightens planning stage couplings. This enhances stakeholders’ commitment and supports their collaborative efforts to solve coordination issues. Instead, later involvement during execution stages does not allow coordinators to obtain these benefits any more. Therefore, onsite couplings are likely to be tightened to compensate for loose coordination upfront. Consequently, coordination actions are more reactive, focus on information exchange and contribute marginally to early-stage stakeholder alignment.

For future research, we suggest to expand the sample of our research to obtain more empirical data on the characteristics of coordination practice. Further, findings suggest that the coordination practices are used in different contextual situations. Hence, we propose future research to explore our differentiated
coordination practices more closely. To this end, one could identify environmental and contextual factors that shape coordination practices (e.g. as in Cynefin 2000, Burns & Stalker 1961).

6 CONCLUSION

This study shows that utility reconstruction processes can be characterized as loosely coupled upfront, and very tightly coupled on-site. We explain how the fragmentation of the utility sector created loose couplings in reconstruction planning, while planning ideally demands tighter couplings. This results in coordination issues on-site: re-planning, improvisation and overruns. To characterize how coordination in this loose-and-tightly coupled utility system takes place, we investigated the role of liaison managers that guide design and scheduling processes of utility projects. To this end, we identified seven professional utility coordinators. We conducted ethnographic interviews to explore the activities, behavior and goals constituting their work practice. Qualitative analysis shows that coordination activities can be characterized based on two dimensions: moment of involvement and level of involvement. This subsequently allows distinguishing two dominant coordination approaches: pro-active early stage involvement and reactive involvement during execution stages. We propose to conduct future research on how contextual factors drive the use of these two approaches. Finally, findings help practitioners to reconsider and categorize their own practices, and stimulates them to explore how new techniques, tools or methods help to achieve coordination practices.

Abstract: Assessment of true project progress and performance is of critical importance in the successful delivery of construction projects. Major challenges related to measuring project progress and performance are the lack of consistent, reliable, and objective metrics and indicators and the lack of appropriate interpretation of these data for establishing suitable corrective action plans. The objective of this paper is to provide a review of existing applied knowledge and practices pertaining to methods, metrics and indicators for progress measurement, performance assessment and forecasting, as well as performance influencing factors, evaluating the shortcomings of the current approaches, and providing recommendations for improvement. The findings of this paper are primarily based on a comprehensive literature review and limited discussions with industry experts in the following areas: (1) methods and metrics used for progress measurement, (2) metrics and indicators used for performance assessment and forecasting, and (3) other metrics that can influence project progress and performance (e.g., risk, safety, and quality). Several industry and academic publications are reviewed including the reports from the Construction Industry Institute (CII), guidelines developed by professional organizations (e.g. Project Management Institute, Association for the Advancement of Cost Engineering International), and scholarly publications. Industry experts serving on the CII research team (RT-322) also provide their insights. Based on the extensive review of the relevant literature, this paper identifies limitations of various measures, metrics and indicators across different project control levels. A framework depicting the current project control process is provided along with a gap analysis related to the problems associated with this approach.

1 INTRODUCTION

Performance inefficiency on construction projects has been adversely affecting the industry. Only 1 in every 20 projects is able to meet both its authorized cost and schedule within an acceptable margin (CII, 2012). Besides, Construction Industry Institute (CII) member industrial-sector EPC contractors are not able to generate any profit in 3 out of 5 projects (CII, 2014). One of the major reasons for the low efficiency in construction project performance is the incapability of the existing methods in providing a "true" measure of project progress and performance.

A review on the existing methods reveals that there is not a systematic, consistent and efficient approach to identifying and interpreting progress and performance assessment metrics in the construction industry.
This results in the true performance of construction projects being potentially misrepresented and causes misunderstandings since the true project progress and performance is not known with certainty. Lack of an integrated approach and standards for assessment of progress and performance prevents not only evaluating the quality of metrics and indicators, but also effective interpretation as a basis for improvement. Absence of objectivity in progress measurement and performance assessment misleads perception regarding the true status of the project.

In a field with a large number of studies and established methods and approaches, a systemic review and synthesis enables gap analysis that inform current and future research. Hence, the first step towards improving progress and performance assessment is to analyze the gaps and limitations in the existing methods and metrics. Despite a vast body of literature in the area of project progress and performance assessment, there are limited studies that provide systemic review and gap analysis related to the existing metrics and methods. To this end, this review paper addresses the following questions: (1) what are the components of progress and performance assessment, (2) what methods and metrics are used for each component, and finally (3) what are the strengths and limitations of the existing methods and metrics for a robust assessment. Section 2 explains the methodology of this literature review study. Section 3 introduces a framework to classify project control functions at a single project level. Section 4 provides an overview of existing literature pertaining to the methods, metrics and indicators used for progress measurement, performance assessment, performance influencing factors and performance forecasting. Section 5 discusses gaps in the existing body of knowledge and practice, as well as identifying areas for improvement. Finally Section 6 provides the recommendations and concludes the paper with highlighting the needed research tasks to address the identified gaps.

2 METHODOLOGY

The research methodology included three steps: (1) identifying relevant work; (2) collecting and summarizing information; and (3) conducting gap analysis. Two sources of information were used: academic and professional literature, and expert opinion from industry professionals with extensive experience in project management and project control.

(1) Identifying relevant work: Through a comprehensive review of literature, 116 relevant documents were identified and reviewed: 64 professional organization reports [e.g., Construction Industry Institute, Project Management Institute (PMI) and Association for the Advancement of Cost Engineering (AACE)], 41 scholarly articles, and 11 government agency reports (e.g., reports from the Department of Energy and Department of Transportation). The identification and selection of documents started with utilizing specific keywords (e.g., performance assessment, KPI, and project control) and continued through snowball method. The search for relevant work stopped when additional searches did not lead to identification of new information.

(2) Collecting and summarizing information: The articles and reports identified in the previous step were reviewed, analyzed and summarized to satisfy the research objectives. The collected information was used to identify the components of a framework for project controls and the methods and metrics associated with each component. The project control framework was then refined based on the feedback from industry professionals (i.e., individuals from eight owner and eight contractor companies, with over 100 years of combined experience) involved with this study through the channels of CII were essential in advancing the framework. Based on the knowledge and experience of industry representatives, the framework was iteratively improved to illustrate the project controls cycle as it occurs in projects.

(3) Conducting gap analysis: The framework created in the previous step was used to identify the existing gaps in the body of knowledge related to metrics and methods for improving project control and management to provide “true” insight about project progress and performance. The identified gaps were further analyzed and refined through multiple rounds of panel discussions with the industry professional participating in this study. The information collected from the panel discussions were analyzed through mind-mapping techniques to systemically evaluate the existing gaps.
3 A FRAMEWORK FOR PROJECT CONTROLS

Core components of a project control structure (i.e., progress measurement, performance assessment, performance influencing factor metrics and performance forecasting) take place in a cyclical nature, which is repeated for every new reporting period, until the project is completed. Figure 1 illustrates the control cycle of a project for a single reporting period. This framework depicts the project control cycle in current practice, obtained through extensive literature search and insights from industry experts serving on Research Team 322 of CII.

![Control Cycle Diagram](image)

Figure 1: Current practice framework for project controls

Although the terms “operational”, “tactical” and “strategic” are frequently used to define different control levels of construction projects, there is no consensus among construction industry stakeholders over what these terms represent in a traditional project controls setting. PMI recognizes operational, tactical and strategic project levels as organizational layers of a portfolio management structure and offers guidelines to identify the work performance structure through information and data flow between project control levels (PMI, 2013). AACE International approaches “strategic” and “tactical” levels as different layers of the investment decision making process, whereas the term “operational” defines ongoing endeavors or activities (AACE International, 2012). However, these approaches lack a single project emphasis. Concentration on project controls structure at a single project level would help identify areas of improvement.

Figure 1 matches project levels with project control functions from a single project perspective. Operational, tactical and strategic project levels are characterized mainly as they relate to metrics and indicators for progress measurement, performance assessment, performance influencing factors and performance forecasting, of a single project. The operational level basically serves the purpose of understanding the current state of the project. It mainly contains measurement of progress in terms of cost and schedule. Some observations and inspections for performance influencing factors also take place at operational level, such as measuring safety and quality aspects of the project. In the tactical level, data from progress measurement metrics and indicators obtained in the operational level are compared against the authorized baseline values in order to identify cost, schedule and efficiency variances and to understand the true current state. Also at the tactical level, performance influencing factor metrics are evaluated, as they relate to interpreting reasons behind why the project is at its current state. Finally, at the strategic level, the future state is predicted based on the current project trajectory.
4 METHODS, METRICS AND INDICATORS RELATED TO PROJECT PROGRESS AND PERFORMANCE

4.1 Progress Measurement

The successful execution of a project hinges on various factors, but one fundamental question that should be answered as the first step in the control process is: What has been accomplished so far? Progress measurement addresses this question at the operational level and serves as the basis for assessing, forecasting, and improving project performance. In this paper, progress measurement is defined as the measurement of outcomes and throughput of a project at a certain point in time. It provides the fundamental information related to “where are we at?”

There are several metrics used to measure construction project progress depending on the activities and work items. Although the names and definitions of these metrics could vary for different projects, they belong to one of the major progress measurement methods. The major methods for progress measurement include: units completed, incremental milestone, weighted or equivalent units completed, resource expenditure, and judgment (supervisor opinion) (CII, 1987; AACE International, 2012). Table 1 provides the definitions, applicable conditions, and implementation examples for each method.

<table>
<thead>
<tr>
<th>Method</th>
<th>Definition</th>
<th>Application Conditions</th>
<th>Implementation Example</th>
</tr>
</thead>
<tbody>
<tr>
<td>Units completed</td>
<td>quantity surveys or physical measurement of work items</td>
<td>homogenous units of work</td>
<td>linear-feet of wire pulling, cubic-yard of concrete placed</td>
</tr>
<tr>
<td>Incremental milestone</td>
<td>a percent completion be credited for completion of key incremental tasks</td>
<td>one deliverable with multiple activities performed in sequence; output for each subtask cannot be easily measured</td>
<td>Equipment installation, alignment and testing (e.g., 50, 70, and 100 percent of completion, respectively)</td>
</tr>
<tr>
<td>Weighted or equivalent units completed</td>
<td>a hybrid of units completed and incremental milestones</td>
<td>a major effort involving a long period of time; composed of two or more overlapping subtasks, each with a different unit of work measurement</td>
<td>Subtasks in structural steel erection with different units of measure are converted to equivalent tons and then the weighted percent complete is calculated</td>
</tr>
<tr>
<td>Resource expenditure</td>
<td>the percent of the total planned or forecast duration hours, or cost spent for the control account</td>
<td>no discrete deliverables or milestones in the work package; a relatively constant level of effort</td>
<td>Measurement for tasks such as project management, quality assurance, contract administration, and project controls</td>
</tr>
<tr>
<td>Judgment</td>
<td>the person responsible for the work package estimates the percent complete based on his or her informed judgment</td>
<td>only for relatively minor tasks where development of a more discrete method cannot be used</td>
<td>Measurement for tasks such as painting, dewatering, constructing support facilities, installing architectural trim, and landscaping</td>
</tr>
</tbody>
</table>

Some of these methods are identified with different names in practice. For example, resource expenditure is occasionally labelled as Level of Effort (LOE) or cost ratio. Judgment is also recognized as supervisor opinion. Variations of these five basic progress measurement methods also exist. For example, start/finish is a variation to the incremental milestone method in which the only milestones are starting and finishing. Activities in a construction project such as flushing and cleaning, testing and major rigging
operations do not have readily definable intermediate milestones. Workers know when the work starts and when it is finished, but not the percentage completion in between. For this type of activities, start/finish is the most appropriate progress measurement method.

Each progress measurement method has its own strengths and weaknesses. For example, the units completed method provides the most detailed and accurate progress information. However, it can only be applicable to homogenous units of work. Also, it might take a significant amount of time for data collection. On the other hand, the judgment method takes the least amount of time and effort. However, this subjective approach is highly dependent on the experience of the supervisor, and could be inaccurate and misleading. In general, there is a trade-off relationship between accuracy/consistency and efficiency in progress measurement (Chin et al., 2004). Table 2 summarizes strengths and weaknesses of these progress measurement methods.

<table>
<thead>
<tr>
<th>Method</th>
<th>Strengths</th>
<th>Weaknesses</th>
</tr>
</thead>
<tbody>
<tr>
<td>Units completed</td>
<td>• Most detailed and accurate</td>
<td>• Time for data collection might be lengthy, especially if not applied correctly</td>
</tr>
<tr>
<td></td>
<td>• Does not rely on subjective opinions or evaluations</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Claimed output can be readily verified</td>
<td></td>
</tr>
<tr>
<td>Incremental milestone</td>
<td>• Easy to use</td>
<td>• Long periods may elapse before an intermediate milestone is reached</td>
</tr>
<tr>
<td></td>
<td>• Simple to understand</td>
<td></td>
</tr>
<tr>
<td>Weighted or equivalent</td>
<td>• Detailed and objective</td>
<td>• May be inaccurate, especially if there are few items and the activity durations are lengthy</td>
</tr>
<tr>
<td>units completed</td>
<td>• Provides ability to compare and summarize several different subtasks and activity groups</td>
<td>• Weighing or equivalency conversions and calculations might be complex, as well as requiring attention</td>
</tr>
<tr>
<td>Resource expenditure</td>
<td>• Greater detail and objectivity than simply estimating how much work was done</td>
<td>• Requires much more effort than simply estimating the percent complete</td>
</tr>
<tr>
<td></td>
<td>• Less expensive than counting or measuring the units completed of subtasks</td>
<td></td>
</tr>
<tr>
<td>Judgment</td>
<td>• Simple</td>
<td>• Can be very inaccurate and misleading</td>
</tr>
<tr>
<td></td>
<td>• Inexpensive</td>
<td></td>
</tr>
<tr>
<td></td>
<td>• Quick</td>
<td></td>
</tr>
</tbody>
</table>

Since one complete project usually includes different types of tasks, multiple progress measurement methods are often used on a project. One limitation in the existing body of knowledge is the lack of an integrated framework which facilitates applying various progress measurement methods systematically in the project. The implementation of different progress measurement methods are usually based on the project manager's experience instead of objective criteria. The subjectivity may cause problems in providing true measurement of project progress in an efficient and effective way. For example, using the incremental milestone method for measuring the progress of landscaping as a minor component of the project instead of judgment method could improve the accuracy, however, it requires more time and effort to develop the criteria and collect the data.
4.2 Performance Assessment

Progress measurement is essential for successful project execution, although it is not adequate by itself for effective project management and control. It is of vital importance to compare measured progress against the baseline in order to evaluate the current performance of the project. This paper identifies performance assessment as an evaluation of the existing outcomes and results of the project cost, schedule and efficiency at a certain point in the project cycle. It answers the question of “Where should we be at?” There are several metrics and indicators used to assess performance of construction projects based on different approaches. The most commonly used performance assessment method in the construction industry is Earned Value Management (EVM). Due to certain shortcomings of EVM, other methods such as Earned Schedule Method (ESM) and Earned Duration Management (EDM), are offered as viable alternatives. Table 3 explains commonly used methods and their related metrics.

Table 3: Definitions, related metrics and calculations of main performance assessment methods

<table>
<thead>

</tr>
</tbody>
</table>

* “t” stands for the time status that ES is calculated for, whereas “t+1” is for the following time period.

** BPDi stands for Baseline Planned Duration of scheduled activity I, whereas APIi is the Activity Progress Index, measured schedule progress of an activity through whichever method is preferred in the project.

*** PDi is for Planned Duration of an activity i

EVM methodology uses metrics to answer questions such as: what are the actual and planned costs of a project at a given point in time in relation to its earned value (Vanhoucke 2009). At the operational level, EVM captures three major values namely Actual Cost (AC), Planned Value (PV) and Earned Value (EV) (Fleming and Koppelman, 2000). These values represent the measured progress in terms of cost. One significant drawback of EVM is its inability to capture the schedule performance, especially over the last third of the project (Lipke 2009). In order to improve the schedule assessment ability of EVM, ESM was proposed (Lipke, 2003). ESM relies on the same operational-level performance indicators as EVM (i.e. PV, AC and EV); however it uses a new set of time-based performance assessment metrics to identify Earned Schedule (ES) as the time at which the amount of earned value should have been accomplished. Although ESM solves some limitations of time management in EVM, it still uses cost as a proxy to measure schedule performance of a project. Therefore, when a disparity exists between time and cost
profiles of a project, ESM fails to capture the distinctive schedule behavior of the project. To address this limitation of EVM and ESM, Earned Duration Management (EDM) was developed, which decouples schedule and cost performance measures. EDM also identifies a number of indices to measure progress and performance of schedule and cost (Khamooshi and Golafshani 2013).

EVM, ESM and EDM treat delays on critical and non-critical paths equivalently. Also the correlations between time and cost of different activities are not taken into consideration in any of these methods. In terms of performance forecasting, the adaptive behaviors of the project managers is not considered. And finally the assessment of the project in all these methods is limited to time and cost and other performance measures such as quality of the final products are not part of the analysis (Hall 2012; Hazır 2014). Critical Chain Project Management (CCPM), an emerging approach for performance assessment, focuses on resource utilization and minimizing idle capacity (Goldratt, 1997; Leach, 2000). However, issues related to the stability of the critical chain and the network structure, as well as resource efficiencies and multitasking are considered problematic aspects of CCPM.

For different project types and phases, various performance assessment metrics and indicators should be utilized, sometimes in combination with one another. However, one general weakness of current performance assessment methodologies is lack of consistency and implementation guidelines for metrics throughout the construction industry, which eventually diminishes reliability of metrics and indicators.

### 4.3 Performance Influencing Factor Metrics

Performance influencing factor metrics are characteristics of the project or project organizations that influence the performance outcomes of the project (e.g., scope change, risk management, and resource management by answering the question “Why are we here?” Therefore, these metrics explain reasons behind the current state of the project by allowing managers to (1) know where to look if a problem related to cost, schedule or efficiency performance occurs, and (2) interpret performance assessment and forecasting more accurately and develop proactive response plans and corrective actions.

Lack of unified guidelines to tackle problems as they relate to project progress and performance through influencing factor metrics not only leads to inconsistent and unreliable project information, but also makes it difficult to objectively compare one project to another. One exception to this problem is related to safety metrics. Almost every project uses nearly the same metrics and indicators for safety: OSHA Recordable Incident Rate (ORIR), Days Away, Restrictions and Transfers (DART) rate, number of near-miss incidents, people based safety observation, new hire count-vs-recordable injury rate, Total recordable incident rate (TRIR), Lost time incident rate (LTIR) and Total severity rate (TSR) (NRC, 2005; COAA, 2007). In addition to being related to life and death situations, safety is also highly regulated through guidelines. This highlights the importance and necessity of having established guidelines for using other common performance influencing factor metrics in the construction industry.

### 4.4 Performance Forecasting

Performance forecasting uses current state performance information to predict the future outcomes and results. It basically answers the question of “Where will we be at?” Table 4 lists performance forecasting metrics for cost and schedule estimations.

Earned Value Management (EVM) offers several useful metrics to forecast what the expected cost values are for the remainder of the project (Vanhoucke, 2009). These metrics predict the final cost of the project based on the actual performance at the time of assessment and the planned cost of the remaining work. However, these projections are highly dependent on consistency of performance assessment metrics used and management’s opinion on some forecasted elements. (Fleming and Koppelman, 2000). The EVM methodology consists of metrics for schedule performance forecasting as well, similar to the cost metrics described above. However, similar problems can be observed with schedule performance forecasting metrics of EVM. At this point, ESM offers alternative schedule forecasting metrics (Lipke 2009). The same pattern with performance assessment metrics follows here; even though ESM metrics generate better results for schedule, they are yet to offer a robust forecasting alternative due to using cost as a proxy to estimate schedule of a project.

5 GAP ANALYSIS AND DISCUSSION

In this study, mind mapping was used to abstract the tacit knowledge of the industry panel regarding two central topics: (1) the problems related to the existing project progress and performance assessment metrics and methods, and (2) the required improvements. In the first step of mind mapping, each individual on the industry panel provided his/her perspective regarding the central topic. The information
was collected and visualized into a preliminary mind map with a tree structure using Free Mind software. In the second step, the preliminary mind map was presented to the industry panel. The panel was asked to cluster the branches in the mind map into categories of problems and required improvements related to the existing metrics and methods. This step was concluded when the panel reached a consensus. Mind map in Figure 2 clearly depicts problematic areas and needed improvement identified through this study.

Review of the current knowledge and practice revealed that there is no consistent set of progress measurement metrics and performance assessment indicators. Due to this lack of consistency, it is difficult to have a true comparison of one project performance to another. Also, there is potential for misrepresentation of progress and performance information, caused by unreliability of metrics and indicators. The existing use of metrics and indicators vary across the industry and depend on the level of the experience of project personnel. There is also limited understanding regarding the importance and effects of performance influencing factor metrics. Hence, there is a need for guidelines identifying what core metrics and key performance indicators (KPIs) should be used consistently on construction projects. Development of such guidelines can help reduce subjectivity in the metrics. Furthermore, in order to improve progress and performance assessment, identification of recommended practices for effective interpretation is necessary. Finally, understanding the significant impacts of performance influencing factor metrics and indicators to progress and performance can provide greater insight for performance improvement and foresight for forecasting project outcomes.

![Figure 2: Mind map for identified problems and improvement areas](image)

6 CONCLUSIONS AND RECOMMENDATIONS

The purpose of this paper was to review common project progress, performance assessment and forecasting methods used in the construction industry. A framework was presented describing the operational, tactical, and strategic levels of project controls. After reviewing the literature and current practices in project controls, it is apparent that construction industry needs certain actions to improve project progress and performance assessment. This paper recommends to: (1) identify core metrics and key indicators, (2) develop guidelines for improving the reliability of metrics and indicators, and (3) establish recommended practices for interpreting metrics and indicators, forecasting outcomes, and responding to variance to plan as they relate to progress and performance assessment.

In order to satisfy the industry needs and fulfill recommended courses of action, CII Research Team 322 (RT-322) is working on a rigorous three-step data collection and validation plan: (1) a web-based survey that uses the findings from the gap analysis presented in this paper to identify core methods, metrics and indicators, (2) case studies to understand the significance of core metrics and how reliability of these metrics can be improved and (3) Delphi method to validate findings using expert opinions.
Problems and suggested improvements identified through this study, can inform future research on applied project controls. Consequentially, real-life applications of these findings have the potential to advance many construction industry practices.

Abstract: Many Researchers have attempted to establish a methodology for the selection of bridge type in a systematic manner. Knowledge based systems (KBS) and other Expert Systems (ES) have been used for this purpose but they have some limitations and restrictions. This paper proposes a methodology to implement a Decision Support System (DSS) in an artificial intelligent environment that aims to suggest a bridge type with its main components at the conceptual design phase, based on the characteristics and performance of existing and similar bridges in order to predict the performance of proposed ones that have been analyzed by decision makers with limited subjectivity. The proposed methodology is divided into three main divisions: 1) this division includes a database that will be structured to store appropriated information besides including models like Point Scale and Quality Function Deployment (QFD) systems that will serve for linguistic conversion to numbers needed for the DSS engine. This division contains as well all the mandatory criteria that have influence on the performance of proposed bridges. 2) this division is the core of the “DSS Engine” where it receives the information from the database that will be implemented in an Artificial Neural Network (ANN) module for training, testing and then predicting the performance of a new case bridge. Afterwards a decision will be made to implement the ANN’s results into a Bridge Information Modeling (BrIM) environment to visualize the suggested design and to predict the potential problems. 3) In this division, a final decision will be made based on the results of the second division. In the proposed DSS, most of the factors are considered as criteria in the database; criteria that have influence on the decision are automatically considered during the analysis process and are introduced in the DSS Engine. The flexibility of the proposed methodology and particularly the database and the method of analysis will make the DSS very helpful in the area of bridge design and management. This will provide bridge engineers with an efficient tool that will minimize the subjectivity in their decisions. A case project will be considered to test the workability and capability of the proposed methodology.

1 INTRODUCTION

Lots of references mentioned that Bridge design is divided into two stages: conceptual & analytical design (Miles & Moore, 1991; Chen Wai-Fah & DuanLian, 2000; Troitsky M.S., 2000). The analytical design stage is very well defined where codes and formulas are widely applied, which is not the case for the conceptual design stage. Lots of studies conducted by engineering and consulting agencies have drawn different opinions that lead to diversity of final decisions (Smith & al, 1994). Based on many factors, designers (decision-makers) will choose the final perception to propose the type of bridge that should be adopted; the decision is based on their own experience and other factors that have remarkable influence on the decision taken. Generally, neither mathematical formulas nor deterministic or stochastic models
are used during the decision making process; just engineering judgments and subjectivities are the core of the final decision. The lack of clarity and the need to be away from the subjectivity issues are the cause of this proposal, which main objective is to propose a methodology that could be a starting point for advanced development toward minimizing shortcomings that influence the decision on bridges during the conceptual design stage.

2 LITERATURE REVIEW

A literature review is conducted in order to highlight the components, characteristics and factors that influence major decisions related to the bridge types and their relevant components.

2.1 Bridge Elements and Components

Tang (2007) has summarized the bridge types, behaviors and forms as follows:

- The anatomy of all structures in the world is a combination of three types of structure elements: Axial, Bending and Curvature; these can be defined as the “ABC” of structure, these elements take one of four basic forms: truss, box, stiffened plate or solid member, and

- Conceptually, he clusters all bridges in the world into four basic bridge types: girder bridges, cable-stayed bridges, arch bridges and suspension bridges.

However, in order to well define such bridge types, it is necessary to recognize the elements and components of every possible bridge. It is important to establish an inventory that will act as a “geometric” database to help decision makers in their selection process. Similar work has been conducted by Thompson and Shepard (2000) in which they proposed an inventory that will be the base for the inspection and maintenance tasks. In their report the bridge components were divided into four main groups: superstructure, substructure, decks and culverts. Those components are important to rate the bridge performance based on their performance and sustainability. Furthermore, the type of materials used in the bridge has its own and special influence. Smith and al., (1994) published the characteristics of some materials and their influence on bridges’ components.

2.2 Influencing Factors and Constraints

Smith et al. (1994) listed many factors that can affect the decision on selecting bridge’s materials. The analytical Hierarchy Process (AHP) has been used to rank the factors that have significant impact on the selection of bridge type. This ranking was based on data collected from over thirteen hundred (1,300) highways and bridges in USA. The collected data focused on non-structural factors that influence the bridge material decision. Out of twenty-three (23) factors, the following have been ranked as the most important ones: past performance, lifespan, maintenance requirement, resistance to natural deterioration, initial cost & life cycle cost. Choi (1993) has grouped the factors that affect the conceptual design of bridges into two sets of constraints: "Hard Constraints - HC" and "Soft Constraints - SC". This proposed methodology will consider only the Aesthetic and the Environmental factors, which influence the final decision of bridge selection.

2.3 Bridge Management System (BMS) and Bridge Information Modeling (BrIM)

The proposed methodology will be implemented within a Bridge Information Modeling environment and will be based on data retrieved from the Bridge Management System. Al-Hajj and Aouad (1999) considered that the design, construction and maintenance of bridges have to be addressed for any holistic productivity study, however the life-cycle cost of the elements should be considered early during the design phase. Abu Dabous (2008) referred to Pontis and Bridgit, which are two applications widely known and used in the USA, while there are other applications used by many agencies to manage the bridge behaviors and to predict its future performance in order to prevent any unexpected situations. Thompson and Shepard (2000) considered the CoRe (Commonly Recognized) elements for bridge inspection as the basic for data collection, performance measurement, resource allocation, and
management decision support. They mentioned that prior to the CoRe elements, bridge managers used data that was based on the National Bridge Inspection Standards (NBIS), which helped them decide on how to address problems related to the limited information available about the four groups of a bridge (Superstructure, Substructure, Deck and Culverts). Nedev and Khan (2011) mentioned that most of the engineers’ decisions are based on past experience and standard solution, which is probably the ideal method. Those engineers claimed that the selection of the different bridge elements and associated materials is not followed in a structural format, and despite of their research and proposed methodology, they revealed some limitations like the number of alternative to be compared, span length, type of bridge, and others. A study conducted by Dekker (2000) showed that engineers in Sweden stated that the biggest obstacle that causes problem is the lack of time. They provided different reasons for that but the final conclusion was that engineers need more time and money in order to create and to produce structures of high performance. As shown in Figure 1 it is obvious that if more time is spent during the conceptual design stage better and more appropriate solutions can be found. Niemeyer (2003) described his methodology in a graphical format where five main keys are identified: 1) need definition, 2) design requirements, 3) key parameter identification, 4) configuration and 5) evaluation. Engstrom (2002) stated that every structure has to meet a wide range of demands out of which six main areas were outlined for buildings in general, which might be also adopted for bridges. 3D modeling has been introduced by many application and tools where their use and benefits have been raised by introducing additional tools and levels of details. As 3D CAD software, Autodesk Revit has been the most known tool; Tekla structures offers a reasonable way of modeling the structural components of concrete bridges, while SolidWorks CAD has been used for terrain model around the bridge.

2.4 Existing Methods

Over the time, the construction industry used different methods based on artificial intelligence and human reasoning processes. In recent years, there has been an increased interest among researchers to explore the feasibility of applying artificial intelligence (AI) paradigms in order to improve the efficiency, safety, and environmental-compatibility of transportation systems (Sadek et al., 2003). AI has been used to solve difficult problems that couldn’t be solved by using classical mathematical methods. Quality Function Deployment (QFD), Knowledge-based Systems (KBS), Case-based reasoning (CBR), Expert System (ES), Fuzzy Systems (FS), Artificial Neural Network (ANN), Genetic Algorithm (GA), and other Learning Machine systems (LM) are among the models that have been used while making decisions related to design in the transportation field. The Gradient Descent methods as well as the Regression Analysis
methods are widely used to define some of the functions employed by these models. Otayek et al. (2012 and 2013) considered that researchers have mentioned and introduced these models by highlighting their ability, their functionality and effectiveness, which have been abridged.

3 PROPOSED METHODOLOGY

The proposed methodology is routed on incorporating the minimum necessary factors and restrictions that are needed into any model. Bridge parameters and characteristics are listed in a standard form in order to introduce the bridge identity by these values, which are stored into set of tables that contain the necessary information required to identify the bridge behavior and performance.

3.1 Models and Methods

Problems related to structural design are often unpleasant tasks that need a wide range of experience, good engineering judgment and high level of subjectivity. The Rule-Based Expert System (RBES) approach has the capability to incorporate some of the above-mentioned requirements while other similar approaches are needed to establish some platform for a right decision. Therefore, a Decision Support System (DSS) is proposed in this paper where all the required platform are considered while its development will be based on the following four steps: (a) establishing an accurate library of bridge types and their components, (b) structuring the necessary database that stores appropriate information collected from previous projects, (c) defining the model’s engine that will treat the information and that will provide a convenient solution in the form of output, and (d) using the BrIM concept and tools to provide a 3D visualization of the generated outputs. The most important and expected difficult part of the proposed system is to define and convert some aspects, information and situations into numerical values, such as the soil behavior that an engineer has to evaluate and to consider during his final decision. The performance of a proposed bridge is predicted and evaluated depending on the rate that the following factors will get: Aesthetic, LCC, Environment and public satisfaction/capacity and services. This will be based on existing bridges that have the same conditions as the proposed one. The proposed methodology will generate three different outputs that should be analyzed in order to decide if the values are relevant and acceptable or not. These values are: Total Cost $/m² (TC); Environmental Impact Rate (EIR), which varies from 1 (Friendly to the environment) to 9 (Very aggressive to the environment); and the Aesthetic Impact Rate (AIR), which varies from 1 (considered as very well fitted into its surround) to 9 (Considered as damaging the surround aspect).

3.2 Decision Support System (DSS) Framework

The main components of the DSS include a database module that contains the bridge types with their components (related to their geometric parameters) and the bridges’ parameters that influence their performances (such as the overpass area, soil behavior, bridge capacity, number of lanes, number of spans, total length, etc... ), a DSS engine that includes the input and output parameters, and a BrIM module to visualize and then verify the accuracy and suitability of the selection made by decision makers based on the output values provided by the DSS Engine. Thus, the framework of DSS is shown in Figure 2.

3.3 DATABASE: Components and Included Information

A database is a collection of information that is organized so that it can be easily accessed, managed, and updated. In computing, databases are classified according to their organizational approach. The most prevalent approach is the relational database, a tabular database in which data is defined so that it can be reorganized and accessed in a number of different ways. Thus, the type of information with their characteristics and relationships that will be stored in the database should be well defined. Therefore, Figure 3 describes the information that should be included in a well-structured database that will provide the proper values for the DSS engine. Furthermore, as shown in Figure 3, all criteria are grouped under 5 categories: (1) Administrative Info, (2) Geometric and Structure Info, (3) Restricted Variables, (4) Unrestricted Variables, and (5) Soft Factors.
The linguistic factors will be converted into numerical values by using two methods: the Point Scale method and the Quality Function Deployment (QFD) method. For instance, for the four linguistic bridge types, a 4-points scale is assigned as shown in Figure 4. According to this scale, a value of “1” is assigned to the Girder bridges, a value of “2” to the Arch bridges, a value of “3” to the Suspension bridges, and a value of “4” to the Cable-Stayed bridges. A library of photos is established in order to clarify the point scale assigned to a specific bridge.
3.4 DSS Engine

The main component of the DSS engine is the Artificial Neural Network (ANN) frame, as illustrated in Figure 5, which will retrieve the input data from the database structure and will provide a new data about the proposed Bridge type that will be constructed. The correlation between the number of existing cases to be used and the number of hidden layers, neurons and the activation function are studied, evaluated and defined in order to accurately structure the proposed ANN.

3.5 Bridge Information management (BrIM) Tools

Lots of tools are used to apply the BrIM concept. Some of them focus on the geometric part, which covers the architecture elements, while others focus on the structural parts, which look at the structural elements and their capacity to resist the acting loads, however they are all used by the construction industry in order to control and mitigate the engineer’s tasks. In this proposed methodology, these tools will receive the results from the DSS engine and will transform them into a real world environment. Decision makers (engineers) will verify all the bridge aspects that have already been extracted from the input and output data of the DSS engine, then they will verify and visualize the project’s design via a 3D model; afterwards a decision will be taken concerning the extracted results, which will either be acceptable, or be rejected or modified and in those two cases launching another iteration will be required. For this purpose, different types of software will be used (i.e. Tekla structure/ Bridge CSI for the structure analysis, and Autodesk Civil 3D-CAD and Design and Revit) for verifications and visualizations in a 3D environment.
3.6 Sensitivity Analysis (SA) and Level of Realistic (LR)

As described earlier, the DSS is based on many criteria (category 2, 3 and 4) that affect the results (criteria from category 5). In order to verify the influence of each input criteria on the results, a Sensitivity Analysis (SA) will be performed to understand the relationships between the input and output criteria. Also, the importance of the SA is that it will provide a general idea about the uncertainty in the DSS output that can be apportioned to different sources of uncertainty in its inputs, and accordingly it will identify the DSS inputs that cause significant uncertainty in the output in order to reduce its level.

On the other hand, the level of realistic (LR) will be evaluated for every output value provided by the DSS engine. This aims at quantifying how much the results are realistic. This procedure will be based on a comparative process between the ratio of the estimated over the actual values of a specified criteria (from category 5) of an existing case with the ratio of the estimated value over the value given by the DSS engine for that specific criteria. By this comparison, designers will have a tool to judge how much the output values have a sense.

4 CASE PROJECT

To validate the proposed methodology a real case project is used to test its workability and dependency. In the actual case project, data from 15 existing bridges located in different regions of Lebanon will be considered into the validation.

4.1 Database frame works and contents

The collected information related to the selected existing bridges is stored into tables 1 through 3 based on the appropriate factors for every criteria. Table 1 stores the parameters and factors to be considered based on the information related to the considered bridges. Table 2 contains the values to be considered for the factors that need Linguistic/Numerical conversion based on a Point-Scale of 1 to 9. Table 3 covers the values of the assigned parameters, which are arranged and evaluated especially those that need a linguistic/Numerical Conversion. The last column of Table 4 (Categories 1 through 4) covers the values related to the new bridge that will be entered into the DSS engine and then the output values of the criteria of category 5 is retrieved for analysis and accordingly a decision could be made to be implemented into the BrIM tools. The parameters Di, BTi and Li are defined and stored within separate tables by providing additional information concerning the project description, bridge name and its location respectively. These parameters (category 1) are considered to evaluate (if necessary) some values of the factors that are included into categories 2, 3, 4 and 5. For instance, the year of construction and location are considered to influence the Total Cost that needs to be adjusted.

4.2 Running the DSS Engine

Based on the data shown in tables 1, 2, and 3, the Neural network paradigm will run; based on the input data shown in Table 4 for categories 1, 2, 3 and 4, an output has been provided and shown in the last three rows of Table 4 (category 5). As mentioned in the methodology section, the factors are divided into 4 categories as input and one category as output as given by the ANN tool. Many possible values of the factors (categories 2, 3 and 4) are proposed in order to discover how these values affect the result. The values represented in Table 4 represent the selected case by the decision-maker.

Table 1 – Categories and Factors
4.3 Results and Analysis

The new case that has been studied is a bridge to overpass a highway with a length of 40 meters. The restricted factors are as follow: the Total Length is 40m and the Needed Traffic Capacity (semi-restricted) is 5,000 vehicles/day (possibility to be modified within a ±20 % interval). Other restrictions are defined by the different possible locations of the vertical elements due to the existing highway that needs to be overpassed and the soil type that will not be necessary to be considered as a deep foundation type. For the other factors, a sensitivity analysis has been conducted where the following ranges of results are received:

Bridge Type (1 or 2): Total Cost [1,229 – 2,259]; EIR [2.9 - 7.8]; AIR [4.6 - 8.6]

Vertical Element Type [1 - 9]: Total Cost [1,000 – 2,459]; EIR [3.1 - 10.9]; AIR [5.2 - 7.9]

After selecting the appropriate values for the factors and with the related output results, BrIM tools (e.i. Autodesk Civil 3D and CSI Bridge) have been used to create a 3D model of the new bridge where a visual inspection is made to preliminary verify the structure stability of the bridge. On the other side, a level of realistic has been verified by comparing the actual cost given by the DSS with the estimated cost provided by the BrIM tools used for this purpose. The ratio of the given actual total cost over the estimated cost is: 1.62, this value falls within the range of 0.9 and 2.1, which represents the same ratio of the existing project cases used in the model.
5 SUMMARY AND CONCLUSION

Based on a number of the existing projects, the implementation of the proposed DSS led to predict the performance (Total Cost, EIR, AIR) of the construction parameters and characteristics of a future bridge. The case project used in this paper is to show the functionality, flow of data and capacity of the proposed methodology. Additional parameters and factors must be added for the different categories and additional methods could be used to convert the linguistic information to numerical values accurately and efficiently, also the range of the sensitivity analysis could be widened by considering the correlation that could exist between the different factors, which makes the results more realistic and accurate. This is an ongoing research where its future works will be based on enhancing the methodology by introducing additional methods and models for risk analysis. Furthermore, additional investigation on the ANN application under its different paradigms and structures will be done in an attempt to get dependable and accurate results.

A METHODOLOGY TO EVALUATE THE EFFECTS OF SCHOOL BUILDINGS’ OCCUPANCY AND USAGE ON THEIR ENERGY CONSUMPTION

Mohamed M. Ouf1,3, Mohamed H. Issa1, Panos Polyzois1 and Phil Merkel2
1 Department of Civil Engineering, University of Manitoba, Canada
2 Customer Engineering Department, Manitoba Hydro, Canada
3 oufm@myumanitoba.ca

Abstract: Buildings contribute 20 to 40% of the world’s energy consumption, making the need to regulate and minimize their energy use a priority. Although several parameters can have an impact on buildings' energy use, the impact of buildings’ occupancy and usage seems to have been rarely investigated in the literature. This paper presents a methodology for the detailed assessment of building occupancy and usage, focusing on school buildings specifically. The methodology is part of an ongoing study aiming to evaluate the effects of school buildings’ occupancy and usage on their energy consumption, focusing on Manitoba school buildings. It is being conducted by the University of Manitoba Construction Engineering and Management Group in collaboration with the Government of Manitoba Public Schools Finance Board and Manitoba Hydro’s Customer Engineering Department. An extensive literature review was carried out to identify relevant methods used to evaluate occupants' behaviour and energy use. The review showed how the few studies that have developed such methods focused on commercial or residential buildings, with little emphasis on school buildings specifically. The methodology and study aim to investigate overall building occupancy, as well as real-time usage of specific indoor spaces using surveys, interviews, visual observations and document analysis. The methodology focuses on 1) comparing building occupancy and usage across old, middle-aged, and new green schools 2) evaluating the effects of overall building occupancy on overall energy consumption, and 3) evaluating the effects of occupants' behaviour and usage on space-level electricity consumption. It complements a previously developed methodology aiming to evaluate historical energy data and real-time electricity consumption in specific school spaces. The two methodologies will be validated by applying them at the building level to a sample of thirty-one schools in Manitoba and at the space-level to three representative schools. Once complete, the study is expected to provide a tool that researchers and industry practitioners can use to improve their schools' energy efficiency and thus improve their schools’ design, construction, operation and maintenance.

1 INTRODUCTION

The rapid increase in energy consumption around the world makes the need to regulate its use across various industries a priority, the building industry being the most important of all (Pérez-Lombard et al. 2008). This is because the building industry currently accounts for 20-40% of energy use worldwide (Issa et al. 2011), representing therefore an excellent opportunity to achieve large scale energy reductions, especially with the development of the green building industry (Azar et al. 2012). Green buildings can on average be 25 to 30% more energy efficient than conventional ones (Kats et al. 2003). This is despite a number of research studies showing different results (e.g. Thiers & Peuportier 2012; Kats et al. 2003;
Several factors can affect energy consumption in buildings. For example, buildings’ location and surrounding climate can significantly influence its use of energy for heating and cooling (Yu Zhun Jerry et al. 2011). Additionally, building-related characteristics such as its size and orientation, can directly affect its energy use. Other factors with an impact on energy use include building systems and their operation and indoor environmental quality (Yu et al. 2011). However, one of the key factors rarely studied is occupants’ behaviour and usage (Yu et al. 2011). Due to the subjective nature of this factor, it is often overlooked or estimated at best.

The goal of this paper is to present a comprehensive methodology for quantifying buildings’ occupancy and usage, focusing on school buildings in particular. It is part of a study conducted by the Construction Engineering and Management Group at the University of Manitoba in collaboration with the Manitoba Public School Finance Board and Manitoba Hydro’s Customer Engineering Department to evaluate energy consumption in relation to building usage and occupancy in Manitoba’s schools in Canada. As the study is still in progress and the methodology is currently being deployed, the paper will only focus on presenting it, not the results of its validation. This methodology will aim to evaluate 1) buildings’ overall occupancy in a sample of old, middle-aged and new green schools and 2) space-level occupants’ usage in three schools. This is to investigate the effects of occupancy and usage on building-level energy consumption and space-level electricity consumption.

2 BACKGROUND

Over the past decade, several studies found large differences in the energy consumed by similar buildings, speculating about the contribution of building occupants to these differences (e.g. Ridley et al. 2014; Guerra-Santin et al. 2013). In addition, several studies showed that green buildings do not perform as intended with respect to energy efficiency (e.g. Oates et al. 2012; Menassa et al. 2012; Berkeley & Grove 2011). In many instances, actual energy use exceeded these buildings’ energy models, raising concerns about the accuracy of these models. The models usually relied on predicted average occupant behaviour to predict the buildings’ energy consumption (Guerra-Santin et al. 2009), leading some studies to conclude that actual occupant behaviour may produce significantly different results.

A study by Klein et al. (2012) monitored the use of appliances in active and stand-by modes in an office building over a two week period. Active mode denoted times at which appliances (e.g. desktop computer) were used by building occupants, whereas stand-by mode denoted times at which appliances were not used but were turned on. The study found that 38% of total energy consumed by these appliances was consumed in stand-by mode and therefore, that simple actions such as turning off appliances when not in use, can result in 38% energy savings. (Klein et al. 2012).

Another study by Al-Mumin et al. (2003) surveyed the occupants of 30 residences about their occupancy patterns and their usage of electrical appliances and found an increase of 21% from what was originally estimated. The study found that annual electricity consumption could drop down by 39% with more energy-efficient behaviour (Al-Mumin et al. 2003). Gill et al. (2010) incorporated the Theory of Planned Behavior (TPB) in his survey to establish a relationship between wasteful energy-use and general lack of interest in energy efficiency. The study concluded that occupant behaviour can account for 51%, 37%, and 11% of the variation in heat, electricity, and water consumption, respectively, in residential dwellings.

A number of studies (Hart 1989; Jin et al. 2011) used different methods to evaluate the effect of occupant behaviour on building energy consumption. For example, Yu Zhun Jerry et al. (2011) collected end-use energy consumption, referred to as non-intrusive load monitoring and used it with three data mining techniques: cluster analysis, classification analysis, and association rules mining to analyze occupant behaviour. Another method by Zhou et al. (2008) involved using continuous video monitoring and intelligent video processing to analyze occupant behaviour. Zeiler et al. (2014) used the number of Wi-Fi
connections in building spaces as a proxy for occupancy patterns. Because of the non-applicability of the method to certain settings such as elementary and middle-school buildings where most occupants are not usually connected to Wi-Fi, other studies (Spataru & Gillott 2011) used Radio-frequency Identification technology (RFID) to map the occupancy patterns within buildings. Others (Yun & Lee 2014) used infrared motion detectors to analyze occupants movements. Despite their accuracy, these methods are expensive for large-scale deployments. Moreover they only provide data about occupants’ presence in certain spaces but not necessarily their behaviour or interaction with electrical appliances.

Many studies (e.g. Steemers & Manchanda 2010, Chiou 2009 and Chen et al. 2013) used surveys, such as time-of-use and residential energy consumption surveys for that purpose. Other studies (e.g. Ridley et al. 2014; Pinheiro & Heitor 2014; Durand-Daubin 2013) used walk-throughs and semi-structured interviews. Although these methods can provide more in-depth information about occupants’ behaviour and usage patterns, they can be qualitative in nature and rely on respondents’ ability to remember their actions which raises concerns about their accuracy. Therefore, they are better suited as complimentary methods to the more quantitative ones.

3 RESEARCH METHODOLOGY

Approximately, one hundred and fifty relevant studies were reviewed as part of this study. Of these, only fifty five specifically investigated the effect of occupants’ usage on building energy consumption. The others evaluated occupant behaviour in general. The methodology developed for this study to evaluate historical occupancy and real-time usage in schools at the building and space-level relied in part on methods found in the literature.

3.1 Methodology Development

Four school divisions in Manitoba are participating in this research study, providing a total population of 129 schools. The study involved using a stratified random sampling and Neyman proportional allocation process to select the sample of thirty-one schools to be analyzed based on their age and size. This is to create three categories of schools, with 14 schools representing old schools built on or before 1959, 13 middle-aged schools built between 1960 and 1989, and four new schools built on or after 1990. The cut-off dates used for these schools were similar to the ones used by the United States Commercial Buildings Energy Consumption Survey (CBECS 2003). The stratified random sampling process also aimed to include schools of different sizes, varying between 10,000 and 100,000 ft². Because of the limited resources, cost and manpower available, one school from each age category was selected for space-level occupancy analysis. The third school, representing new schools, is also the only school in Manitoba currently certified to the Canadian Leadership in Energy and Environmental Design (LEED) Rating System. This school will highlight the effect of LEED certification on schools’ real-time usage if any.

This methodology will involve evaluating 1) historical occupancy data at the building level (e.g. enrolment figures) in all schools within the sample and 2) real-time occupant usage data at the space-level in the three schools where advanced energy sub-metering systems were also installed. The data collected using this methodology will be correlated to energy consumption data collected at the building-level and electricity consumption collected at the space-level using a different methodology. Figure 1 shows a simple breakdown of data collection using both the energy and usage methodologies.
3.2 Methods Used

At the building-level, the study involved collecting data about the historical energy usage from the utility provider over the past 24 years. Additionally, the school divisions were asked to complete a data collection form for each of the 31 selected schools. These forms collected data about the schools' enrolment figures for each year over the past 24 years as well as the numbers of teachers and staff in each school. The forms also collected data about the numbers of classrooms, gymnasiums and other spaces in these schools, as well as their typical operating hours. This occupancy and occupancy pattern data will be correlated to the schools' occupancy data in order to determine whether there is a correlation between overall-building occupancy figures and their overall energy consumption.

At the space-level, the study involved installing sub-meters to monitor specific circuits within the schools for one classroom and the gymnasium in each of the three selected schools. Sub-meters were also used to monitor other non-classroom spaces such as one music room in one school and one multi-purpose room in another school. These sub-meters provide electricity consumption data for equipment plug loads and lighting over half-hour intervals. Three different providers were used to source the sub-meters depending on the requirements for each building space and its circuits' configuration.

In order to monitor real-time occupant usage of the selected school spaces, the study will involve using three different methods simultaneously to address the limitations of each method. Figure 2 depicts these methods graphically.
3.2.1 Room Schedules

This method involves collecting room schedules from school administration for six weeks for all classroom and non-classroom spaces used during regular school hours and irregular hours (e.g. evenings and weekends) by their communities. Correlating these schedules with real-time electricity consumption in these spaces will demonstrate the effect of space usage, including usage for non-school functions (e.g. community meetings) on its electricity consumption.

3.2.2 Surveys

The methodology will involve using surveys for real-time usage data collection. Teachers in classroom spaces where sub-metering equipment have been installed will be asked to fill out a daily-use survey over six weeks. This survey will ask about details such as the average duration of using equipment within these spaces. The questions will be tailored to each space listing all the equipment available there. By only indicating an estimated duration in minutes for using each piece of equipment, the respondent will only need 2-3 minutes to fill out each daily-use survey. Table 1 shows a sample of the questions included in the survey.

Table 1: Sample questions from daily-use equipment usage survey

<table>

</table>

In addition to the daily-use survey, all school teachers and staff will be asked to fill out a more comprehensive general usage and behaviour survey. This survey enquires about their attitudes with respect to energy efficiency and their energy-related behaviour over the period of the study (6 weeks). The general usage and behaviour survey will include questions about the frequency of using spaces and equipment based on the respondents’ location at the school (e.g. classroom, gymnasium) as shown in table 2. The survey results will be correlated to the real-time energy use of each school and evaluated.
across the new LEED-certified school, the middle-aged schools and the older ones. Table 2 provides a sample of the questions that will be administered in the general usage and behaviour survey.

**Usage Patterns**

*What is the frequency of these events over the past two months?*
- In my classroom, I use only natural light from the window without switching on the lights
- I switch off the lights at my workspace whenever I leave
- I use an electric heater when I feel my workspace is too cold

### 3.2.3 Observation Forms

In order to compliment data derived from the daily-use survey administered to teachers, point-in-time observations of the state of electrical equipment and space lighting (i.e. on, off, or idle/dimmed) used in specific locations will be conducted at regular intervals over a two week period. An observation form will be developed for that purpose tailored for each space listing all the equipment available there. In addition to giving the three options for observing each state, the sheets will enable the observers’ to write any notes regarding their observations. Two weeks was in general found to provide adequate data about occupants’ usage of indoor spaces in the literature (e.g. Klein et al. 2012). Exact definitions of each state will be identified as per table 3 to avoid human-error when recording these observations. The team will cross validate the observations during a pilot study involving all team members simultaneously to ensure the same understanding of each state definition.

These observations will aim to investigate behaviour as it occurs naturally with no intervention. Therefore, occupants will not have access to the observation form used by the research team to avoid influencing their behaviour. Additionally, the research team will only monitor behavioural activities related to energy consumption. During the visits to the selected locations, it was found that all equipment states can be observed from outside the spaces provided their doors are left open.
Table 3 shows a sample of the observation form used for a classroom space.

</table>

4 DATA ANALYSIS

The study will entail comparing historical occupancy data across old, middle-aged and new schools in order to highlight historical trends in occupancy in each of the three categories. The analysis will also involve correlating historical occupancy data to the schools’ historical energy consumption. This is to highlight the relationship between occupancy figures and energy consumption at the building level.

At the space level, the study will involve comparing space-level usage data for classrooms and gymnasiums across the three schools. The study will also compare the results derived using each of the three methods (e.g. daily-use surveys and observations sheets) to determine the accuracy and validity of each. The data collected using each method will be correlated to real-time electricity consumption to demonstrate the effect of specific occupant activities on energy consumption.
5 CONCLUSION

The collected occupancy and usage data for all schools will be correlated to their energy consumption data. This is to demonstrate the relationship between occupancy, usage and buildings’ energy consumption: a topic seldom investigated in the literature. One of the key contributions of this study is its novel methodology which relies on the use of a number of different methods. Correlating the results derived using each method should improve the research community and industry’s understanding of energy use in school buildings. The significance of the study also stems from its evaluation of school buildings in particular as opposed to the more common evaluation of office and residential buildings.

This methodology for evaluating occupancy and usage in schools should serve as a tool that future researchers and practitioners can apply in different contexts to evaluate school buildings in other locations. The methodology can also be used by school operators to identify occupant activities with the most impact on schools’ energy consumption and that can thus reduce it the most. It can also allow for more efficient space-utilization of the schools.

One of the most significant limitations of this methodology is its heavy reliance on human resources which can make it challenging to implement. This can be mitigated by implementing only parts of it through the use of only one of the methods making it up.

IMPROVED LOCALIZATION OF CONSTRUCTION WORKERS IN VIDEO FRAMES BY INTEGRATING DETECTION AND TRACKING

Abstract: Tracking of construction site resources from on-site cameras using vision trackers has been proposed as a means to efficiently track a large number of objects operating in a congested environment. The systems proposed so far use first either a less accurate/faster motion detection approach or a more sophisticated object detection approach to mark the moving entities of interest in the camera view. The marked entities are then passed on to a vision tracker, who follows the entities in all subsequent frames. The major drawback of this two-step process is that the resulting tracking systems are very sensitive to changes and, in most cases, deteriorate and stop tracking effectively after only a few seconds/minutes. The reason is that it is common for construction resources to frequently a) enter/leave the field of view, b) be temporarily occluded, or c) significantly change their pose. To resolve this issue, this paper presents a hybrid method for locating construction workers that interchangeably fuses the methods of tracking and object detection. Specifically, the proposed approach continuously detects construction workers, and tracks them. Continuous detection allows a) for the detection of workers that enter the view or reappear after being occluded at any given time, b) for the effective termination of tracking when workers leave the view or become occluded, and c) for relocating the marked area and detection confidence to fit all object poses. On the other hand, continuous tracking allows for seamless tracking across time and smoothing of the temporal detection variations. The proposed approach was implemented into a C# prototype and tested on videos taken from construction sites in Atlanta, GA. The method could detect and track all workers, preserving stability under occlusions. It enhanced accuracy by 9.6% when compared to the use of a detection method only. This indicates that the proposed approach is a significant improvement over prior work and has the potential to effectively monitor the location of construction workers.

1 INTRODUCTION

Construction sites involve various types of project-related assets that move, including construction materials, equipment and workers that interact with each other continuously. Given the dynamic and complex conditions during construction, it is useful for effective project control to monitor the movements of a large number of entities. As sites become larger and more complex having up to tens of thousands of active entities, it becomes extremely hard to monitor the entities and to provide accurate asset flow data.

In pursuit of effective monitoring of such complex sites, several state-of-the-art sensing technologies have been introduced to automatically track entities and generate real-time information on their spatial locations across time. GPS (Global Positioning System), RFID (Radio Frequency Identification), and UWB (Ultra Wideband) are the most well-known technologies that have been rigorously investigated and
deployed on sites. However, the size and complexity of the site, along with the overhead of installing, maintaining, and decommissioning tags or sensors on entities limit their application in large-scale, congested construction sites. In such cases, only entities with sensors installed can be tracked by such technologies. The limited amount of data leads to inaccurate analysis and improper decisions.

These limitations can be tackled with vision-based approaches that have been proposed to establish sensor-free positioning systems. Vision-based localization can be classified into two categories – detection and tracking. Detection methods can identify the location of construction workers and equipment that appear in cameras’ views. However, detection methods are not enough to provide data that can be transformed to meaningful information for productivity analysis and safety management. They do not link the results across frames, as the results of a frame are independent of those of the next and previous frames. Hence, trajectories of entities cannot be extracted. Also, no methods are so perfect as to provide seamless data across time. Entities are often missed by detection methods in a few frames. On the other hand, tracking methods locate an object in the current video frame based on its positions and image appearance features in previous frames. Accordingly, they can extract trajectories across frames. However, they require manual initialization to locate the object at its first appearance in a camera view. Also, occlusions significantly undermine the performance of the tracking methods.

To resolve these limitations, this paper presents a hybrid method for locating construction workers that interchangeably utilizes vision tracking and object detection algorithms. The proposed method continuously detects construction workers, and tracks them in parallel. Detection mainly acts as an indicator of new entities in the view and their disappearances, and reconfigures the tracking area when it is dislocated significantly. On the other hand, tracking allows for seamless positioning. Tracking links the detection results across frames and finally generates a trajectory of each entity. The proposed approach was implemented and tested on construction site videos. The method could detect and track all workers, properly handling occlusions. Compared to the use of a detection method only, a 9.6% improvement was achieved by the integration with a tracking algorithm. This indicates that the proposed approach is a significant improvement over prior work and has the potential to effectively monitor the location of construction workers.

2 BACKGROUND

Several radio-based technologies such as RFID and GPS have been used to generate real-time position information of construction personnel and equipment across time (Ergen et al. 2007, Goodrum et al. 2006). GPS is generally used for tracking a fleet of heavy equipment, and has evolved into a well-established monitoring system in construction sites. Numerous GPS-based methods have emerged for monitoring construction equipment. Equipment manufacturers have adopted these methods to provide for their customers (Construction Equipment 2010). At the same time, RFID is commonly used for monitoring construction materials and workers. When a piece of material passes through a supply-chain milestone or is installed on the structure, a tag attached to or embedded in it is read to record the event with its ID and timestamp of accomplishment (Engineering News-Record 2008). Another type of radio technology, UWB, has the advantages of wide ranges of frequencies and the low average power requirement (Fontana 2004). Its ability to provide accurate 3D locations in real-time is a definite benefit to tracking in construction sites. The data it provides is accurate. However, its applicability in large-scale, congested sites is weakened by the size and complexity of construction sites, occlusions in the site and the need for tagging entities, etc.

The methods discussed above only partially achieve the ultimate goal of extracting positioning data on demand with minimum human interaction. Vision-based approaches offer a way to further automate the positioning process by using on-site construction cameras. These approaches collect video streams from construction sites, and automatically locate project-related entities. Brilakis et al. (2011) proposed the concept of 3D vision tracking framework. It uses two fixed cameras to locate construction entities in 3D space. The framework is composed of three main steps: (i) object detection, (ii) 2D tracking, and (iii) triangulation. In the framework, construction entities are detected and tracked by step (i) and (ii), respectively. The last step (iii) correlates the results of the step (i) and (ii) to obtain 3D positions.
Several researchers have investigated object detection algorithms that classify and localize construction resources. Chi and Caldas (2011) proposed a method that enables real-time detection of construction entities using background subtraction and machine learning classifiers. Their method extracts motion pixels from video frames and groups them into distinct regions using a connected component algorithm. The features of foreground blobs such as aspect ratio, area size, occupancy percentage, and average gray-scaled colour, are trained for classifying the moving objects into worker, backhoe, and loader. Narrowing down the types of entities to equipment, Rezazadeh Azar and McCabe proposed an equipment detection method that employs HOG (Histogram of Oriented Gradients) features captured from various camera angles (2012a). Also, they introduced a part-based model to detect articulated shapes of equipment (2012b). On the other hand, Park and Brilakis (2012) focused on construction workers. They combined three types of features – motion, shape, and colour. Background subtraction, HOG + SVM (Support Vector Machine), and colour histogram + k-NN (k-nearest neighbour) were used to detect people wearing safety vests of fluorescent colours. The colour histogram is composed of hue and saturation components to eliminate illumination effects. Similar strategies were used in Memarzadeh et al.’s work (2013). HOG and hue-saturation-based color histogram features are integrated into a single feature vector and trained with SVM. The proposed method was applied to workers, excavators, and dump trucks.

Despite the high accuracy of the aforementioned detection methods, they are not capable of detecting 100% of the entities. There still exist missed entities and those few false detections prevent their practical applications. Also, detection itself is not capable of distinguishing the entities of the same type and does not tell the previous location of any entity detected in the current frame. These limitations can be overcome by tracking algorithms. Yang et al. (2010) proposed a machine learning algorithm to train a general spatial model for tracking workers. Park et al. (2011) conducted a comparative study of the tracking methods and suggested that kernel-based methods are the most appropriate for tracking construction entities. However, their method was lack of the function of detection, and thus it required manual interaction to initialize the tracker.

Rezazadeh Azar et al. (2013) presented a tracking method that integrated the step (i) and (ii). The method employed a HOG based detection method and a KLT tracker. It successfully detected and tracked excavators and dump trucks even when they were partially occluded. The proposed method was applied to the estimation of dirt loading cycles. Similarly, Park and Brilakis (2012b) fused the function of detection and tracking algorithms for locating construction equipment. In their method, background subtraction, Haar-like features, and eigen-images were employed for detection. The eigen-images were also used for tracking. Their method effectively handled total occlusions. It automatically identified the event of occlusion based on the absence of detection results and terminated the tracking process. The tracking process was triggered again by reappearance of the object. Notwithstanding the research efforts on the combination of detection and tracking, their object types were limited to construction equipment. The experiments involved a small number of entities with a few events of occlusion. However, the tracking of construction workers is far more challenging because of their nearly identical appearances and frequent occurrences of occlusion. To tackle the challenges, this paper proposes a vision-based hybrid method for locating construction workers.

3 METHODOLOGY

Figure 1 shows the overall framework of the proposed method. It basically employs two methods - detection and tracking. When a worker is detected by the detection method, the tracking method is initiated. After the initiation, both the detection and tracking methods are processed simultaneously. Every frame, the location is determined by matching the results of the two algorithms. The location is represented by a rectangle that fits the image region of the worker. For the rectangle region, the colour histogram is calculated. The details will be addressed in the following subsections.

3.1 Detection and Tracking

We employed Park and Brilakis’ method (2012a) for worker detection. The method is reported to detect workers wearing safety vests at over 99% precision rate. Also, the method is capable of capturing the
workers within a second after they first appear in the camera view. The worker detection plays a role in locating all workers in the camera view. For example, in Figure 2, the detection locates workers at three regions in both $n$-th and $(n+1)$-th frames. Each region is labelled as $R_{k,i}$, where $k$ is the order of the location from left to right, and $i$ is the frame number. The available information from the detection is that three workers are present in each frame $i$, at $R_{1,i}$, $R_{2,i}$, and $R_{3,i}$. However, it does not tell which of $R_{k,n+1}$ corresponds to $R_{1,n}$, $R_{2,n}$, and $R_{3,n}$. In other words, detection results are independent of the image sequence, and the detection does not associate the results across frames. Therefore, the movements of each worker, which can be referred as a trajectory, are unknown.

The links between detection results of consecutive frames are provided by the tracking method. The tracking makes inferences of the region of an object in the current frame based on the history of the object’s appearance and movements. Following the suggestion of Part et al.’s comparative study (2011), a kernel-based method (Ross et al. 2008) is employed for the tracking. This method models the objects’ appearances and movements with eigen-images and particle filtering, respectively. The method tracks an object based on the model template composed of eigen-images, and represents the object as a surrounding affine-transformed rectangle (i.e. a parallelogram). In the tracking process, only the upper half of the workers is taken into account since the lower part experiences continuous appearance changes as they move. In Figure 2, once three workers are detected in the $n$-th frame, three tracking processes are triggered to track them independently, and predict the workers’ new locations in the next frame.

The links between detection results of consecutive frames are provided by the tracking method. The tracking makes inferences of the region of an object in the current frame based on the history of the object’s appearance and movements. Following the suggestion of Part et al.’s comparative study (2011), a kernel-based method (Ross et al. 2008) is employed for the tracking. This method models the objects’ appearances and movements with eigen-images and particle filtering, respectively. The method tracks an object based on the model template composed of eigen-images, and represents the object as a surrounding affine-transformed rectangle (i.e. a parallelogram). In the tracking process, only the upper half of the workers is taken into account since the lower part experiences continuous appearance changes as they move. In Figure 2, once three workers are detected in the $n$-th frame, three tracking processes are triggered to track them independently, and predict the workers’ new locations in the next frame.
3.2 Mutual Compatibility of Tracking and Detection

If the detection and the tracking work perfectly, both provide the probable regions for every worker. In this case, priority is given to the detection region since it is more reliable. If the worker region experiences sharp changes in its appearance, the tracking process grows unstable and occasionally results in a dislocated region. On the other hand, the detection provides more stable results regardless of the appearance changes because, as mentioned in Section 3.1, it processes each frame independently and previous appearances do not affect the detection process at all. Figure 3(a-b) illustrates an example of this case. A worker is detected in a certain frame and represented as a solid rectangle in Figure 3(a). The solid rectangle region is tracked in the next frame, and shown as a dotted rectangle which is a little dislocated (Figure 3(b)). Meanwhile, the detection is also processed, providing a more accurate location (the solid rectangle in Figure 3(b)). The partial overlap of the dotted rectangle and the solid rectangle discerns that they are corresponding to each other. The location of the worker is determined to be the solid rectangle. The tracking process is reinitiated with this new region to eliminate the erroneous components associated with the dislocated rectangle.

Once a tracking process is initiated, it provides the best probable location of the object in every frame. On the other hand, the detection method often fails to locate workers, and does not generate any results. Therefore, as in Figure 3(d), it is occasional to have only the tracking result. In this case, the location is determined to be the tracked region.

3.3 Occlusion Handling

As described in Section 3.2, the tracking produces a result for every frame. However, the process should be terminated when the workers disappear from the camera view. There are three cases of disappearance. The first case is workers moving out of the camera view. This case is identified simply based on the worker location. When the worker’s location comes within a certain margin along the border of the video frame, the tracking process is automatically terminated. It can be expressed as follows.
The second case is workers being occluded by other types of objects such as construction equipment and materials. Figure 4 illustrates an example of the occlusion. A worker tracked in the $n$-th frame (Figure 4(a)), disappears behind a construction machine in the $(n+1)$-th frame (Figure 4(b)). Without any termination process, the dotted rectangle in Figure 4(b) would be stuck at the same position throughout the subsequent frames. This type of occlusion is identified based on two cues – the absence of the detection result and colour histogram transition. When the worker disappears, no detection result is given around the tracked region. In addition, the image feature of the rectangle region exhibits significant changes as the content inside the region is switched from the worker to the machine (Figure 4). Colour histogram is used to identify the appearance transition. The colour histogram of the tracked region is calculated ($C_{n+1}$), and is compared to the one calculated in the previous frame ($C_n$). In short, the tracking process is terminated if no detection result exist and the Euclidean distance between the colour histogram vectors exceeds a threshold determined as 0.25.

The third case is when workers are occluded by one another. This case can be characterized as two tracking results sharing the same detection result (Figure 5). In Figure 5(a), two workers are tracked and represented as dotted rectangles that partially overlapped with each other. Both rectangles intersect the solid rectangle which is a detection result. The proposed method divides the status of occlusion into two levels based on the degree of the overlap as follows.

- **Level 1**: $0 < p < 0.2$  
  ($p$: the proportion of the overlap area)
- **Level 2**: $p > 0.6$

For Level 1, the detection result is ignored since it is uncertain which tracked region is the correct match of the detection result. Also, it was reported that the tracking algorithm for itself generally is stable enough.
to handle the partial occlusion of Level 1 (Park et al. 2011). When the partial occlusion reaches Level 2 as in Figure 5(b), one of the workers becomes nearly invisible from the view and the tracking algorithm grows unstable. In Figure 5(b), Tracking 1 should be matched with Detection, and Tracking 2 needs to be terminated. The correct match is determined based on the Euclidean distances of the centroids and colour histograms. The distances of Tracking 1 and 2 are calculated as follows.

\[ d_{p,1} = |P_{D,n+1} - P_{T1,n+1}|, \quad d_{p,2} = |P_{D,n+1} - P_{T2,n+1}| \]

\[ d_{c1,1} = |C_{D,n+1} - C_{T1,n}|, \quad d_{c1,2} = |C_{D,n+1} - C_{T2,n}| \]

\[ d_{c2,1} = |C_{T1,n+1} - C_{T1,n}|, \quad d_{c2,2} = |C_{T2,n+1} - C_{T2,n}| \]

Here, \( P_{D,j} \), \( P_{Tj} \) represents the centroid coordinates of the detected region and the tracked region of worker \( j \) in the \( i \)-th frame. Similarly, \( C_{D,j} \), \( C_{Tj} \) represents the colour histograms of the regions. The worker that has smaller values of the distances is determined to be the correct match. Accordingly, the tracking of the other worker is automatically terminated.

4 EXPERIMENTS AND RESULTS

The proposed hybrid method was implemented using Microsoft Visual C# in .NET Framework 4.0 environment. To evaluate the performance, the method was tested on on-site videos taken with a HD camcorder. The collected HD videos were resized to 768×432 for the sake of fast processes with similar level of performance. 4-5 people are present in the videos, wearing different combinations of hard hats and safety vests. The “worker” is defined as a person wearing a safety vest as in the experiments of Park and Brilakis’ research (2012a).

Figure 6 shows example frames. It should be noted that, an integer ID was assigned to each worker and kept consistent over the frames. Counting the reappearance of a worker as a new identity, total 53 identities appeared in the videos. All 53 identities were detected in less than a second after their first appearance, and each of them was successfully tracked with a single ID until it disappeared. Regarding the stability against occlusion, total 39 occlusions are occurred, and all are identified correctly. In Figure 6, it is observed that the tracking process of Worker 2 is ceased when it is occluded by Worker 0 in the middle frame. In the third frame, the same entity is newly detected and tracked as a new worker with an ID number 3. A similar case is illustrated in a different way in Figure 7. In the video, the two workers on each side walk to the other sides crossing each other at the midpoint of the frame as in Figure 5(b). The obtained trajectories are shown in separate figures for clear exhibition. In both Figure 7(a) and (b) detection results are expressed as a spread of points without any identity information. When only the tracking algorithm was processed with manual initialization, after crossing each other, the tracking process tracked the other worker resulting in going back to original starting point. On the other hand, the proposed hybrid method successfully tracked the workers until they went out of the frame. It should be noted that the tracking of the worker on the right (the red solid line) was terminated when fully occluded in the midpoint, and newly initiated (the magenta solid line) after the occlusion.

![Figure 6: The result frames](image-url)
The performance of the method was also compared to the use of the detection algorithm (Park and Brilakis 2012a) only. Three metrics were used in the comparison – precision, recall, and accuracy:

\[ \text{Precision} = \frac{TP}{TP + FP} \]

\[ \text{Recall} = \frac{TP}{TP + FN} \]

\[ \text{Accuracy} = \frac{(TP + TN)}{(TP + TN + FP + FN)} \]

- TP: the number of correctly detected or tracked workers
- FP: the number of detected or tracked non-workers
- FN: the number of missed workers
- TN: the number of undetected people not wearing safety vests

Table 1 summarizes the comparison results. The combination of tracking and detection exhibits 1.1% decrease in precision, which is attributed to the tracking of false negatives for 3 seconds. However, the function of the tracking algorithm reduced FN's significantly which is reflected by the 17.1% increase in recall. The proposed method features the overall accuracy of 97.7% that enhances 9.6% from using only the detection algorithm.

5 CONCLUSIONS

Systematic control of the construction activities on dynamic, congested sites places a high demand on the ability to locate project related entities including construction equipment, workers, and materials. The location data can be used for site safety management, productivity measurement, and activity sequence analysis. For this purpose, tracking systems such as GPS, RFID, and vision-based system have been rigorously investigated. Whereas GPS and RFID have been applied to real construction projects to track construction equipment and materials, vision-based tracking systems still remain immature for practical uses. The vision-based system has a potential to track a large number of entities in congested construction sites without tagging each entity. Though several researchers presented methods for detecting construction entities in video frames, they are not adequate for tracking since their result data are lack of links among frames. Therefore, it is necessary to fill the gap between consecutive frames. To resolve the problem, this paper presented a hybrid method that automatically detect and track construction workers in video frames. The method is composed of the detection and tracking algorithms which mutually supplement each other such that each worker is smoothly tracked as an independent identity across frames. The method also works well under various occlusions by identifying the occlusions and terminating the tracking processes. In the preliminary experiments, 9.6% increase in accuracy was achieved by the proposed method, when compared to using only the detection method. The method successfully tracked all workers present in the videos, and retained stability in spite of recurrent occlusions. The experiment results signified the effectiveness of the hybrid method for vision-based tracking system.

Abstract: The paper considers technological features of erecting monolith objects with a variable cross-section, presents the formulated requirements to the robotic complex and the principles of its construction and gives the complex structure. It has been shown that for the control of slip form it is advisable to use a two-level structure; the upper level tasks of which are planning the complex hoisting and synchronization of control mechanisms operation, and the tasks of the lower level incorporate development of control signals having been formed in the previous level. Great attention is paid to the problems of the robotic complex movements planning taking into account restrictions on control and disturbing influences affecting the structure being erected. In order to remove the complex deviation from the designed location we suggest the method of the planning of movements with due account of limitations for control and effects of disturbing influences to the structure being erected. In conclusion the paper deals with the problems of forming adaptive laws of for controlling joint coordinates ensuring development of the planned trajectory.

1 INTRODUCTION

Construction of objects for different purposes requires great labour consumption and a number of regulating operations especially for the structures with varying cross-section and wall width. From the standpoint of control slip forms for erecting objects with variable radius represent a multivariable system with a number of control organs. The position and the shape of the forms as an object of control is determined by the aggregate of external and internal effects. The loading irregularity of the forms working floor, imperfect forms geometry and some other factors result in the forms deflection with respect to the projected axis, the working floor inclination and friction forces change of the forms shields against the concrete. The volume and the tasks of the sliding forms automation is determined by the construction objects appearance, their shape geometrical parameters. The main tasks for sliding forms automation so as to erect object of conic shape are:

- information-measuring provision to control the forms erection;
- the forms mechanical trajectory planning with consideration of external effects and current condition;
- control of slip forms shields erection and radial displacement;
- synchronized work of lifting jacks and mechanisms for the forms radial displacement;
- to keep all lifting jacks in the given plane and to fulfil overall control of jacks;
- compensations of disturbing effects on the control system actuating elements;
• adjustment of the forms position due to control of the working floor inclination within the range of shields taper.

The analysis of monolith construction technology has shown the expediency of designing mechatronic complexes on the basis of slip forms (MSC), they provide automation of the objects erection and continuous-cyclic placement and consolidation of concrete. Solution of the above mentioned tasks is possible on the basis of mechatronic complexes for monolithic construction.

2 THE CONSTRUCTION PRINCIPLE OF MSC

The principle of the mechatronic complexes by the kinematic, design and technological distinctions of the object controlled, the controls distinctions and also by the character and properties of the disturbing effects. Consideration of different variants of the MSC development on the basis of slip forms has led to the idea of using a movable platform 1, bearing against columns 2 with help of lifting posts 3 which are equipped with jacks 4 (Figure 1). The forms 5 are suspended from the platform with help of radial displacement mechanisms (RDM) 6 providing adjustment of panels location.

![Figure 1: MCS on the basis of a slip form](image)

For the purpose of lifting it is advisable to use frequency control electromechanical jacks, which allow to adjust hoisting speed and to synchronize movement. For the RDM it is preferable to use an induction motor drive with relay control. The main tasks of the mechatronic complex control are lifting the platform with forms during the process of concrete placement, change panels location when lifting, correction of the platform position when shifts and torsions occur, synchronization of the equipment operation.

The developed principles of the complexes construction make up the basis of the functional diagram for mechatronic complex control task to which is presented in Figure 2.

Information – measuring system provides control of the main parameters of the mechatronic complex condition. Laser system incorporating a laser set point device for the vertical (LDV) and a photodiode matrix panel (PMP) makes the forms measurements. The system of data processing first scans the photodiode panel PMP about the coordinate axis, records the results of scanning into the image storage area of the photopanel.

According to this information boundary values of the photopanel lit area are determined \((X_{\text{min}}, X_{\text{max}}, Y_{\text{min}}, Y_{\text{max}})\) and the coordinates of the forms position are calculated relative to the
When using two-beam laser control system the values of the coordinates of the beam center on each photopanel $X_{1\min}, X_{1\max}, Y_{1\min}, Y_{1\max}$ and $X_{2\min}, X_{2\max}, Y_{2\min}, Y_{2\max}$ become average.

Checking the vertical position of the erected object and the platform position is carried out with laser devices equipped with photomeasuring panels. The laser device consists of two laser set-point devices for the vertical axis and two photoreceiving panels with modules for reading-out and processing data. Location of the laser beam center on the photoreceiving matrix is determined by the way of photopanels scanning. And the coordinates of the beam center are calculated from the formulae:

$$X = 0.5(X_{\max} + X_{\min}), \quad Y = 0.5(Y_{\max} + Y_{\min}).$$
\[ x_{pr} = 0.5\left[8\left(d_{i}^{(x)} - 1\right) + b_{i}^{(x)}\right] + \left(8\left(d_{i}^{(x)} - 1\right) + b_{i}^{(x)}\right) - N_{pr} \];
\[ y_{pr} = 0.5\left[8\left(d_{i}^{(y)} - 1\right) + b_{i}^{(y)}\right] + \left(8\left(d_{i}^{(y)} - 1\right) + b_{i}^{(y)}\right) - N_{pr} \],

where \( d_{i}^{(x)}, d_{i}^{(y)}, d_{i}^{(x)}, d_{i}^{(y)} \) are initial and last active bytes when scanning along the axes \( X \) and \( Y \);
\( b_{i}^{(x)}, b_{i}^{(y)}, b_{i}^{(x)}, b_{i}^{(y)} \) are initial and last bytes corresponding; \( d_{i}, d_{i}; N_{pr} \) is the number of digits in bits) on the photopanel.

On the basis of the beam location coordinates on the photoreceiving panels we determine the position of the platform center:
\[ x_{pl} = x_{p}^{(o)} = 0.5\left(x_{pr}^{(1)} + x_{pr}^{(2)}\right) \cdot \cos \psi_{p}, \quad y_{pl} = y_{p}^{(o)} = 0.5\left(y_{pr}^{(1)} + y_{pr}^{(2)}\right) \cdot \sin \psi_{p}, \]

where \( \psi_{p} \) is the twist angle of the platform relative to \( Z_{o} \) axis.

On the basis of the obtained average values of the platform deviation from the designed axis we calculate modulus and the direction of displacement:
\[ \delta_{pl} = \left[(x_{pl})^{2} + (y_{pl})^{2}\right]^{1/2}; \beta_{d} = \arccos\left(\frac{x_{pl}}{\delta_{pl}}\right) = \arctan\frac{y_{pr}^{(1)} + y_{pr}^{(2)}}{x_{pr}^{(1)} + x_{pr}^{(2)}}. \]

The data received from the photopanels make it also possible to determine the twist angle of the platform with the forms
\[ \psi_{p} = \arctan\left[\left(y_{pr}^{(1)} - y_{pr}^{(2)}\right)/l_{pr}\right], \]

where \( l_{pr} \) is the distance between photoreceiving matrices.

Vertical position of each jack of the forms is controlled by the hydrostatic system of levelling, which is equipped with level gauges LG(1) - LG(n), mounted on each jack frame. The coordinates of the level gauges LG(1) - LG(n) disposition are:
\[ x_{i} = (R - h / \tan \varphi) \cdot \cos(2\pi i / n), \quad y_{i} = (R - h / \tan \varphi) \cdot \sin(2\pi i / n), \quad z_{i} = h \pm \delta_{j}, \]
where \( x_{i}, y_{i}, z_{i} \) are the coordinates of the level gauge, \( n \) is a number of jacks, \( R \) is the forms radius in the construction base, \( \varphi \) is a slope of the construction, \( h \) is an elevation mark of the forms working floor, \( \delta_{j} \) is a position of the \( i \)-th jack relative to the working floor. The vertical position of the forms centre is determined as an arithmetic mean of the elevation position of \( Z_{j} \) jacks:
\[ z_{0} = \sum_{i=1 \ldots n} z_{i} / n. \]

The platform deviation is closely connected with disturbance of its horizontal position therefore a hydrostatic leveling device has been introduced into the system. It permits checking the platform deformations and the swivel angle and also deviations of some jacks relative to others. Using level detector readings \( \Delta z_{ld}^{(i)} \) we determine upper and lower marks of the platform hoisting jacks position

\[ \Delta z_{ld}^{(max)} = \max\left(\Delta z_{ld}^{(i)}\right); \Delta z_{ld}^{(min)} = \min\left(\Delta z_{ld}^{(i)}\right) \rightarrow i = 1, 2, \ldots, n \]

and calculate the platform swivel angle and the direction of the swivel angle vector:
\[ \alpha_{p} = \arctan\left(\frac{\Delta z_{ld}^{(max)} - \Delta z_{ld}^{(min)}}{4R_{hj}}\right), \quad \beta_{p} = \frac{2\pi}{n} \left[\max\left(\Delta z_{ld}^{(i)}\right) - 1\right]. \]
The data about the jacks’ deviation \( \Delta z_{hj}^{(i)} \) from the horizontal plane are used to synchronize movements of the hoisting jacks. To provide the platform correcting inclination hoisting jacks’ speeds are set according to the required swivel angle \( \alpha_p^* \):

\[
\nu_{hj}^{(i)} = \nu_p \left[ 1 + R_{hj} \cdot \sin \alpha_p^* \cdot \cos \left( \frac{2\pi}{n} (i - 1) - \beta_p \right) \right],
\]

where \( \nu_p \) is the average speed of the platform hoisting.

Measurements of jack frames radial displacements is fulfilled by potentiometric or photoelectric encoding transducers PT(1)–PT(n). The measurement accuracy of these transducers must be \( \pm 1–2\) mm. When considering the system dynamic characteristics there transducers can be regarded as inertia free links. Measurement data processing allows to determine parameters of the mechatronic complex condition and the construction being erected: \( x_0, y_0 \) deviations from the construction line, the forms torsion angle \( \alpha \), the forms inclination angle \( \gamma \), the forms average radius \( R_{hj} \).

Taking into account complexity of MSC as an object of control, a great number of disturbing and adjusting influences, restrictions for control it is of interest to consider the problems of the complex control which include planning its motions, development of the laws of control, solution of the problem of mechanisms operation synchronization.

MSC is a multimeasuring controlled object the states of which at any period of time can be described by the system of equations

\[
\begin{align*}
U_{hj} &= \left[ U_{hj}^{(1)}, U_{hj}^{(2)}, \ldots, U_{hj}^{(m)} \right]; \\
U_{rm} &= \left[ U_{rm}^{(1)}, U_{rm}^{(2)}, \ldots, U_{rm}^{(n)} \right]; \\
Y_{ms} &= \left[ x_n, y_n, z_n, R_0, \alpha_n, \beta_n, \theta_n \right]; \\
F_1 &= [F_w, F_s], \\
F_2 &= [Q_n, F_{mp}, F_{cu}, F_{ms}, F_{m}],
\end{align*}
\]

where \( U_{hj}, U_{rm} \) are the vectors of control actions directed to the hoisting jacks and the mechanisms of radial displacement (MRP); \( Y_{ms} \) is the vector of the output parameters of the MSRS state; \( F_1 \) and \( F_2 \) are the vectors of disturbing influences acting on the erected construction and the mechatronic system.

The system state at any moment is determined by the coordinates \( x_p, y_p, z_p \) of the center position in the system of coordinates of the erected object \( X_0, Y_0, Z_0 \), by the forms radius \( R_0 \), by the angle of the platform inclination \( \alpha_p \), by the direction of the inclination vector \( \beta_p \), and by the platform turning (twisting) angle \( \psi_p \) round the vertical axis. For the structures of conical shape the relation between radius \( R_0 \) and the object height has the form of

\[
R_0 = R_0^* - (h \cdot \tan \varphi_0),
\]

where \( R_0^* \) is the radius of the structures at zero mark.

The process of the system operation is accompanied by influencing on it several kinds of disturbing influences. The first group comprises influences leading to deformation of the erected structure and displacement of the platform with the forms. They cover influence \( F_s \) connected with the structure sun-heating and influence \( F_w \) caused by the wind load. Due to the temperature difference \( \Delta \tau = \tau_s - \tau_c \) of the sunny and shady sides there occurs deformation of the structure and its deviation from the designed axis. The deviation quantity \( \delta_s \) is the function of the height \( h \), the object diameter \( D \), the walls width \( b \), and
the period of heating $t_s$: $\delta_s = f_s(\Delta \tau, h, D, b, t_s)$. In order to evaluate the influence of the object temperature gradient on the MSRS operation we have introduced the coefficient of deformation, which is calculated by the formula: $k^d_s = h \cdot e_s / (16\pi \cdot R_o)$. The platform deviations connected with temperature heating will be

$$\Delta x_s = 0.5k^h_s \cdot h \cdot \Delta \tau \cdot \cos \theta_s; \quad \Delta y_s = 0.5k^h_s \cdot h \cdot \Delta \tau \cdot \sin \theta_m;$$

$$\Delta z_s = k^h_s \cdot R_o \cdot \Delta \tau; \quad \Delta \alpha_s = k^\varphi_s \cdot \Delta \tau.$$

As a result of the wind load there occurs inclination of the structure by the angle of $\alpha_w$ and deviation of the MSC platform center from the vertical. The deviation parameters can be evaluated by the formulae:

$$\Delta x_w = k^{(h)}_w \cdot F_w \cdot \cos \theta_w; \quad \Delta y_w = k^{(h)}_w \cdot F_w \cdot \sin \theta_w,$$

where $k^{(h)}_w$ and $k^{(\varphi)}_w$ are the coefficients determined by the structure shape and its rigidity; $F_w$ and $\alpha_w$ are the quantity and direction of the wind load.

Net deviations should be considered as a sum of deviations due to heating ($x_t, y_t$) and wind deformation of the structure ($x_w, y_w$):

$$x_{sb} = x_t + x_w = \delta_t \cos \alpha_t + \delta_w \cos \alpha_w;$$

$$y_{sb} = y_t + y_w = \delta_t \sin \alpha_t + \delta_w \sin \alpha_w;$$

where $\alpha_t = \psi(time)$ is the direction of sunlight heating; $\alpha_w$ is the direction of wind; $\delta_t = f_1(\Delta \tau, h, \alpha_t, \nu_w)$ is heat deformation; $\delta_w = f_2(h, \sigma_w, \nu_w)$ is wind deformation; $\nu_w$ is wind velocity; $\Delta \tau = \tau_h - \tau_c$ is difference in temperature between sunny and shady sides of the object; $h$ is the complex elevation.

The platform turn caused by actions of external factors is convenient to connect with coordinates of hoisting mechanisms by equations:

$$\alpha_g = \arctg \left[ \max(\Delta z^{(i)}_j) / R_j \right];$$

$$\beta_g = \frac{2\pi}{n} \int \left( \max(\Delta z^{(i)}_j) \right);$$

$$\psi_g = \frac{1}{n} \sum_{i=1}^{n} \left[ \arctg(C) - \frac{2\pi}{n} (i - 1) \right];$$

$$C = \left( \frac{\sum_{i=1}^{n} \sum_{j=1}^{n} \frac{y^{(i)}_j - \sum_{j=1}^{n} y^{(i)}_j / n}{x^{(i)}_j - \sum_{j=1}^{n} x^{(i)}_j / n} \right),$$

where $\alpha_g$, $\beta_g$ are the angle and the direction of inclination; $\psi_g$ is a platform torsion.

The second groups of the disturbing influences constitute those applied to hoisting jacks and mechanisms of radial displacement. During the system operation hoisting jacks are under action of static and dynamic loads created by the weight of the platform, forms, equipment and materials: $Q_{\Sigma} = \sum Q_i$ and also under the influence of friction forces $F_f$ and cohesive forces $F_c$ of panels with concrete.

An important factor in lifting jacks work is the interaction of concrete formwork. In the early lifting platform effort sharply increases and reaches a maximum at the time of separation from the concrete formwork (Figure 3). With a further rise formwork occurs overcoming the forces of adhesion between the concrete and sliding formwork. Further, in the contact area and the friction force is observed decreases proportionally to the reduction of contact area.

When the platform lifts, the load changes due to concrete – panels interaction. During the operation irregularity of hoisting jacks’ loads can achieve 75-86% that results in violation of the platform horizontal displacement, its deviation from the designed axis and twisting of the platform with forms. Such condition
of hoisting jacks work make stringent requirements to drives and causes the necessity to synchronize lift speeds.

RDM operation is under the influence of friction and elastic forces appearing when the forms’ elements deformation takes place. When synchronization of operation of hoisting and adjusting units is broken, then reaction forces of concrete additionally act on the RDM and they have a non-linear character (Figure 4). This causes increase of load and decrease of the mechanism speed. Therefore, the operation of the RDM drives should be strictly synchronized with the platform hoisting and coordinated with curvature of the walls being erected.

The characteristic feature of the MSC control is the availability of restrictions for control connected with structural features and technological control cycles. Maximal inclination of the platform with forms in hoisting step cannot exceed conicity of the forms’ panels. Maximal deviation of jacks’ travel from the average meaning in hoisting step is limited by the magnitude:

$$\Delta h_{\text{max}} = \left( h_j^{(i)} \right)_{\text{max}} - \left( \sum h_j^{(i)} \right) n \leq \frac{\Delta D_j l_b}{2},$$

where $\Delta$ is a clearance at the bottom of the forms’ panels, $l_b$ is panels height, $R_j$ is the radius of jacks arrangement.

Therefore, to control the MSC it is necessary to provide measurement and compensation of wind and temperature influences upon the object being erected. The complex lift control should be carried out with due account of limitations for controllability and provision for the trajectory minimal curvature. We suggest to correct the position by the way of the platform inclination in the direction opposite to displacement, and in order to eliminate platform torsion it is suggested to use the method of backward wave which resides in sequential change of the platform inclination direction in each step of hoisting, as a result there appears a spiral motion of the forms in the direction opposite to torsion. This kind of control is based on the forms’ mathematical model, which performs connection of the complex condition parameters with controlling and disturbing influences.

3 THE MATHEMATICAL MODEL OF MSC

On the basis of the slip forms dynamic characteristics and disturbing effects a mathematical model of the complex has been developed (Figure 5).

It makes possible to perform analysis of dynamic characteristics and forecast the forms deviations during the process of its lifting. The mathematical model presents channels controlling the forms lifting and its radius changing, it also reflects connections between then. The controlling effects are voltages of the forms jacks control $U_h$ and radial displacement mechanisms control $U_r$. Coordinates of the forms
centre $Z_0$, $x_0$, $y_0$ and its radius $R$ are considered as adjustable values. While controlling the forms lifting the following external actions are taken into consideration: $F_r$ – the pressure of the lower gripper onto the jack bar; $F_w$ – the forms weight; $F_{fc}$ – friction of the forms shields; $F_v$ – wind load; $F_t$ – additional forces due to thermal gradients. Influence of the force loads on the forms is described by the transfer functions:

$$W_r^{(f)}(s) = k_f; \quad W_w^{(f)}(s) = \frac{k_{fw}}{T_{fw} s + 1}; \quad W_{fc}^{(f)}(s) = \frac{k_{fc}}{T_{fc} s + 1}.$$ 

![Figure 5: Mathematical model of the complex](image)

Influence of wind and thermal effects on the forms position can be represented by transfer functions:
The forms jacks displacement on the step \( \delta_j \) is described by the transfer function

\[
W^{(u)}(s) = \frac{k_{uh}}{(T_{uh} s + 1)s}.
\]

Coefficients matrix \( R \) has the dimensional representation of \( 3\times n \) and sets up the parameters interrelation. The values of its elements are determined from the formulae:

\[
k_{zi} = 1/n; k_{xi} = \left[ 2 \cos(2\pi i/n) \right]/R_h; k_{yi} = \left[ 2 \sin(2\pi i/n) \right]/R_h.
\]

While simulating the channel of mechanisms for radial displacement the following external effects are taken into consideration: \( F_{mp} \) – the mechanism reaction to the displacement forces; \( F_c \) – concrete reaction to the shields displacement; \( F_{pj} \) – elasticity force of jacks; \( F_r \) – shields friction force. The influence of these external effects is described by the transfer functions:

\[
W^{(f)}_{MR}(s) = \frac{k_{uh}}{(T_{uh} s + 1)s}, \quad W^{(f)}_{c}(s) = \frac{k_{uh}}{(T_{uh} s + 1)s}, \quad W^{(f)}_{pj}(s) = \frac{k_{uh}}{(T_{uh} s + 1)s}.
\]

The effect of the controlling voltage \( U_r \) on the operation of the radial displacement mechanisms is described by the transfer function \( W^{(f)}_c(s) = \frac{k_{uh}}{(T_{uh} s + 1)s} \). Transformation functions \( G \) and \( A \) represent matrices of coefficients describing effects of the shields radial displacement on the parameters of the state.

4 CONCLUSIONS AND RESULTS

The approaches and methods of the MSC control discussed in the paper are based on the investigations carried out by the authors in different periods for solving the tasks of monolith construction automation. The presented principles of the MSC control can be used when developing automation projects for erecting monolith objects with a variable radius (chimneys, TV and observation towers, cooling towers etc.). The suggested method of designing the complex lifting makes it possible to develop control algorithms with due account of restrictions for control and disturbing influences acting on the structure. Computer simulation of the described algorithms and laws of the MSC control has shown the efficiency of the suggested methods of movements design and controlling actions formation.

DEVELOPING FAILURE AGE PREDICTION MODEL OF HAZARDOUS LIQUID PIPELINES

L. Parvizsedghy\textsuperscript{1,2}, T. Zayed\textsuperscript{1}
\textsuperscript{1}Department of Building, Civil, and Environmental Engineering, Concordia University, Canada,
\textsuperscript{2}l.sedghy@yahoo.com

Abstract: Pipelines are the most common way of transporting the hazardous materials. They are considered to be the safest way of transporting petroleum products; however, there have been several failures with considerable consequences. As a result, the importance of studying failure of pipelines is not covert to anybody. Failure prediction of pipelines has been the subject of some studies from different perspectives. Estimation of failure age has also been studied from the specific points of view. Most of the studies have focused on producing models with data from inspection tools. These tools are very expensive; although, they are considerably accurate. This research aims to develop a model based on the basic attributes of pipelines without data from the inspection tools to predict the probability of failure. The model predicts the age of failure considering the historical data that was gathered on pipelines' failures. The effect of several variables on the frequency of failures in different age classes is studied in order to identify the effective variables on pipelines' failure. Then, a regression model is developed to estimate the age of failure. Pipe manufacture year, maximum operating pressure (MOP), specified minimum yield strength (SMYS) and pipe diameter over pipe wall thickness are the variables that are considered in the developed model after significant number of modeling iterations. Statistical parameters of the developed regression model prove its soundness. Validation results prove the accuracy of the model with over 80 percent.

1 INTRODUCTION

While pipelines are considered to be the most effective and safe way of transporting hazardous liquids there is probability of failure with monetary and safety consequences. The Pipelines and Hazardous Materials Safety Administration (PHMSA 2013) of US Department of Transportation has gathered data on the failures of oil and gas pipelines in three different date ranges. Over 7,300 failures are recorded from 1986 to 2013 in the United States of America which has resulted in almost 2.9 billion dollar property damages and the leakage of around 4.1 million barrels of hazardous liquids in the environment. Also, records prove the happening of 60 fatalities as well as 2,150 serious injuries which demands significant attention. Accordingly, failures of pipelines specially the ones carrying hazardous liquids (which will be called oil pipelines from now) has become the subject of interest for this study. Literature review proves the insufficiency of studies on the failures of oil pipelines; while, there are a few researches mostly focusing on the safety and reliability-based studies of such pipelines. This study tries to develop a model to predict the age of failure applying pre-mentioned data. The age of failure then will be applied to predict the probability of failure. Risk of failure will be calculated when probability of failure is combined with the consequences of failure. The age of failure can be used to plan the maintenance operations of the pipelines. In order to develop the model, existed data has been studied from different perspectives. Several diagrams have been drawn to analyze the effect of various variables in different classification.
Then, the trend has been studied to find the most effective variables. Data on the selected variables has been embedded to the regression model to produce predictive models of failure age. Then the efficiency of the produced models has been improved by changing the set of the variables considering their importance through analyzing the statistical parameters of the model. Error measuring methods have been used for validation applying test data which consists of randomly selected ten percent of data. Validation phase compares the estimated outputs of model with the actual data from the test dataset. A model has been selected finally which is proved to be the most effective, while reserving the simplicity of the model.

Objectives of this research are to (1) identify and study the most effective factors on the pipelines’ age of failure and (2) develop a model that predicts the age of failure to estimate the probability of failure of oil pipelines.

2 BACKGROUND

Several researchers have tried to model failures of oil and gas pipelines. Parvizsedghy & Zayed (2013) have developed a model for the prediction of failure consequences of oil and gas pipelines. This model has obtained data from the US Department of Transportation. It has identified a series of primary variables including the basic attributes of oil pipelines and some other variables related to the efficiency and quality of the inspection systems in the pipelines. Number of variables are optimized through comparing the efficiency of the produced Neural Networks. The final model is efficiently estimating the monetary consequences of the failures in oil and gas pipelines. Senouci et al. (2013) have developed a model to predict the failure type of oil and gas pipelines. The model benefits from data on the accidents of pipelines which has been published in European database (Davis et al. 2010). The model can predict the potential type of failure out of mechanical, operational, corrosion, third party and natural hazards. Validation results have proven accuracy of the model. Variables that have been applied in this model include product type, location of pipe and land use as categorical variables and pipe age and diameter as the numerical variables. The research gets use of Artificial Neural Network and regression analysis in developing the model. NOOR et al. (2011) have proposed a probabilistic method to forecast the remaining strength of offshore pipelines considering data from the Inline inspection tools. This method is developed based on the assessment rules of DNV’s Recommended Practice for Corroded Pipelines (DNV 2010) considering the standard deviation of inspection tools in determining the defect sizes. Bersani et al. (2010) have proposed a model to predict the probability of failures applying Artificial Neural Networks. For each cause of failure, a set of factors are proposed as the independent variables. Preliminary results on the prediction of third party failures’ probability have been presented; however, results do not prove the importance of the proposed factors and neither the soundness of the model. Caleyo et al. (2009) have developed probability distributions of corrosion depth and rate of growth applying Monte Carlo simulation. Different curves are proposed for underground pipelines considering properties of various soil types. Teixeira et al. (2008) have proposed a probabilistic model to evaluate the reliability of the pipelines under corrosion. The model employs experimental data and estimates the burst pressure of corroded pipelines. Bertolini and Bevilacqua (2006) have developed regression classification tree to predict the failure class of cross country oil pipelines. The model applies data from the CONCAWE (Davis et al. 2010) database in the training phase and aims to recognize the most risky pipelines to help the operators to decide about the maintence of their network of pipelines. A risk-based decision making support system is developed using Analytic Hierarchy Process (AHP) technique. This model applies expert opinions to obtain the weight of variables that have been identified important on the failures of pipelines. Variables are risk factors includig external and internal corrosion, construction and material defects and acts of God. Failure probability is estimated by the scores through the expert judgement. Dey (2004), Sinha (2002) and Ahammed (1998) have developed probabilistic models due to the uncertainties of pipeline parameters. Researches have obtained data from Inline inspection tools to predict the failure probability of oil and gas pipelines under corrosion. These tools are used to gather data on the condition of oil and gas pipelines. The models require data on defects depth and length from Inline inspection tools. Ahammed (1998) has applied reliability theory to estimate the remaining strength and integrity of pipelines.
This study proves deficiency of the researches on the estimation of failure probability of oil and gas pipelines. Current researches are either subjective and based on the expert opinion or have concentrated on physical models which require data from inspection tools. However, inspection tools are very expensive to run regularly and there is a need to develop predictive models based on the attributes of oil and gas pipelines.

2.1 Overview of regression modelling

Regression models are suitable for construction management problems and are used in a wide range of researches. Salman and Salem (2012) have used regression analysis to develop deterioration models for sewer pipelines, Wang et al. (2009) to forecast the annual break rates of water mains, Chughtai and Zayed (2008) to develop structural condition assessment models of sewer pipelines and Zayed et al. (2007) for productivity estimation models of horizontal directional drilling activities. These pattern recognition techniques can discover the relationship between the dependent and independent variables of historical data. Result of a linear regression model becomes in the form of the Equation 1 (Senouci, et al., 2013) where $Y_i$ represents the dependent variable, $x_1, x_2, \ldots$ and $x_n$ represent independent variables and $\beta_0, \beta_1, \ldots$ and $\beta_n$ are the parameters of the regression model.

\[ Y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \ldots + \beta_n x_n \]

This equation represents the best curve that fits the historical data assuming the error in each trial from the training data should be 1) independent of the predictor variable 2) the errors should be normally distributed around each value. (Senouci, et al. 2013) After developing the regression model, it should be assessed via different parameters. Significance of independent variables is evaluated through F-test, the results of which is presented as $P(f)$ values which should be less than alpha level. The acceptable amount of risk for F-test is the value that the user determines as alpha and is usually equal to 0.05. Accordingly, if the value of $P(f)$ for each variable is less than the amount of alpha then that variable is significant; otherwise, the variable should be removed. Then the regression modelling should be repeated with the new subset of the variables. The other parameter that should be assessed is R-squared of the regression model and the closer is the value of R-squared to 100% the more efficient is the regression model. (Wang, et al. 2009)

3 RESEARCH METHODOLOGY

In this section, the methodology of the model that is developed to estimate the age of failure of oil pipelines is described. Figure 1 presents the overall flowchart of the model development. It includes two major phases of pre-processing and regression analysis phases. Data is obtained from the Pipeline and Hazardous Materials Safety Administration (PHMSA 2013). Historical data will be analyzed to discover the variables which can affect the age of failure. Actually, this analysis will look for the trends that different variables can present in various classifications. After that, data will be prepared to be embedded into the model. Data preparation is comprised of removing missing and technically irrational data and combining existing categories of the database to produce new effective variables. Then data is normalized to make all in the same range of zero to one. In the next phase, training dataset which includes 90 percent of the data that is randomly selected from the prepared dataset is embedded to the regression analysis model. Then the produced models are assessed, based on the basic diagnostic parameters such as R-squared, $P(f)$ and $P(t)$. Different subsets of the primary variables are tested and the satisfactory models are selected. Selected models have gone through the residual analysis. This analysis plots residuals against the normal distribution and tests normality of residuals. This test tries to prove the assumption that the produced errors should be normally distributed around each value. After that, test dataset is applied to validate the satisfactory models. The validation step assesses the accuracy of the produced models against actual data via different methods.
Table 1 depicts frequency of the failures in each age class versus the failed pipelines’ wall thickness, pipe diameter, Specified Minimum Yield Strength (SMYS) and Maximum Operating Pressure (MOP) Classes. Age of failure is classified in seven groups, in the first ten years of pipelines’ life, number of failures increases due to the bathtub theory, as a result this period is divided into two groups of zero to five and six to ten years. The other classes include the groups of a decade till 50 years after which the older pipelines are classified in the same category. As it can be seen from the graph, there is a visible trend in all of the failure age classes versus pipe wall thickness except for the group of zero to 0.2 inches. The same happens to the total failures and number of failures is decreasing by growing the wall thickness of the pipes. That could be as a result of increasing strength of the pipes. Accordingly, pipe wall thickness is identified as a significant variable in the model. There is a clear trend in the frequency of the failures in the failure age classes versus pipe diameter classes. The number of failures in almost all of the failure age classes decreases by increasing the diameter of pipes. However, there is an exception for the group of pipes with diameter less than five inches in which the number of failures is less than the other groups of larger diameter. Semi-regular trend proves the importance of diameter of pipes in the age of failure. The same is true for the total number of failures in diameter classes which means by growing the pipe diameter, number of the failures are dropping meaningfully. Frequencies of failures in the failure age classes versus the classes of SMYS are also presented in table 1. A decreasing trend is visible in some of the age classes such as zero to five and six to ten. However, all of the failure classes do not display a similar pattern. Totally, the number of failures decrease from zero to 45,000 psi but the group of 45,000 to 55,000 psi does not follow the previous pattern and the number of failures increases. Then, the diminishing pattern continues in the next group. Although SMYS does not follow a very strong pattern in different classes, this variable will be inserted to the model and the significance of the variable will be determined through the statistical values of the regression model. Frequencies of failures in different age classes versus Maximum Operation Pressure classes have also been printed in the following table. As it can be predicted, increasing the operating pressure of the pipelines raises the number of failures in almost all of the failure age classes. There exists an exception of pipelines over 50 years when the
Operating pressure exceeds 950. In this group the number of failures drops; while, the previous groups confirm the increasing trend. An increasing trend of incident frequencies happens in the total failures of pipelines too. Muhlbauer (2004) suggests combining pipe diameter and wall thickness to form a new variable, namely pipe diameter over pipe wall thickness (D/th.). This variable can determine the crack potential or strength of the pipe.

Figure 2 illustrates the average age of failures in each diameter by wall thickness class versus the manufacturing year of pipelines. As it can be seen from the graph, there is a regular pattern in each diameter by wall thickness class. Actually, the average age of failure is decreasing in each classification by increasing the manufacturing year of pipelines. This fact reveals the importance of the factors of diameter over pipe wall thickness and pipe manufacturing year. Study of the other variables did not either result in any regular patterns or did not have enough data to be studied. Due to the results of these studies, manufacturing year of pipes (Man. Year), Diameter (D), wall thickness of pipe (th.), Diameter over pipe wall thickness (D/th.), Specified Minimum Yield Strength (SMYS) and maximum operating pressure (MOP) are identified as the primary effective variables in modeling the age of failure.
4 DATA COLLECTION

Pipeline and Hazardous Materials Safety Administration (PHMSA 2013) of US Department of Transportation has recorded data on the failures of the hazardous liquids and gas pipelines. PHMSA (2013) Data includes different date ranges from 1986 to 2001, 2002 to 2009 and 2010 to 2013. Each dataset includes different categories and the last dataset includes more categories than the previous ones. Data is also classified into the pipelines of hazardous liquids, gas distribution and gas transmission. This paper focuses on only hazardous liquid pipelines which includes the pipelines carrying liquid products such as crude oil and refined petroleum products. This database provides data on the basic attributes of pipelines such as pipe manufacturing year, pipeline installation year, incident date, Specified Minimum Yield Strength (SMYS) of pipe, Maximum Operating Pressure (MOP), pipe diameter as well as the pipe wall thickness. It also, includes data on the failures such as the cause of failures among internal and external corrosion, material and weld defect etc. Due to the existence of the missed data on some of the required variables, those data points with missing values have been removed. Then, data are normalized applying equation 2 in order to change the values of all of the variables to the range of zero to one.

\[ \text{VI} = \frac{V_i - V_{min}}{V_{max} - V_{min}} \]

Where \( V_i \) represents the value of each variable and \( V_{min} \) and \( V_{max} \) are the minimum and maximum value for that variable accordingly. After preparation of data and removing the missed datapoints, 2,236 data points remained that are divided into two datasets of training and test with the ratio of 90 to 10. Table 2 displays the minimum and maximum values of preliminary selected variables before normalisation.

5 MODEL DEVELOPMENT

The results of model development and the validation tests are illustrated in this section. As mentioned before, data is divided in two datasets of training and test data. Training data is embedded to the regression analysis and test data is preserved for the validation purposes. Different subsets of primary variables are considered for the models and regression analysis is iterated for the subsets. Regression
models are analyzed considering statistical values such as correlation coefficient ($R^2$), $P(f)$ and $P(t)$. Higher correlation coefficient values prove the efficiency of the regression models. F-test is carried out against alternate hypothesis ($H_a$). This hypothesis assumes that regression coefficients could be equal to zero the results of which are presented as $P(f)$ for each variable. Values less than alpha reject the alternate hypothesis which proves the significance of the variable. If more than one model is produced, the validation results determine the selected model. The higher validation parameters verify the efficiency of the model. In the next section, results of the regression analysis will be presented.

The training dataset is embedded to the Minitab 16 Statistical Software (Minitab 2013) and the regression analysis has been done with three different subsets of the primary variables. It has resulted in three models. Due to the satisfactory results of these models considering their statistical values, validation test has been done on all of them, the results of which are presented in Table 3. As it can be seen, Model No. 2 and 3 are very close in validation values and more efficient than Model No. 1. However, as the Model No. 3 is a non-linear quadratic model, it is recommended by (Kutner, et al. 2005) to select the linear model and preserve the model's simplicity.

</tr>
</tbody>
</table>

The results of the regression analysis for model No. 2 which is selected to predict the age of failure of oil pipelines is presented in Figure 3. This model includes four variables: pipe manufacturing year, MOP, SMYS and Diameter over pipe wall thickness. All of the variables are proved to be significant as the value of $P(f)$ for all of them is around zero which is smaller than the amount of alpha (0.05). As a result, it can be claimed that this model is the best model to represent the relationship between the age of failure and pre-mentioned variables. Correlation coefficient of the model equals 87.6% which verifies the efficiency of the model.

Regression Analysis: Age versus Man. Year, MOP, SMYS, D/Th.

The regression equation is

$\text{Age} = 0.859 - 0.899 \text{ Man. Year} - 0.131 \text{ MOP} + 0.0562 \text{ SMYS} - 0.0936 \text{ D/Th.}$

Figure 3: Regression Analysis Results

5.1 Residual Analysis

Satisfactory results of model’s statistical parameters, leads us to the next phase which is the residual analysis. Figure 4 illustrates histogram of the frequency of residuals along with the normal distribution

Figure 4
curve. Distribution of the residuals is almost normal with a small skew to the right. Results are satisfactory and acceptable as it is close to a normal distribution. Figure 5 presents normal probability plot of the residuals of the model. The same results are drawn from this graph as the results are almost linear, although showing some discrepancies in the tail of the plot. Discrepancy can be as a result of the outliers; however, historical data shows that they are not outliers and these scenarios are possible.

5.2 Validation of the model

Validation tests the estimated results of developed model against the actual data and it is done through utilizing four equations. In all of the equations, $E_i$ represents the $i_{th}$ estimated value through the model and $C_i$ represents the $i_{th}$ actual value of failure age; while, $n$ is the number of data in the test dataset. Equation related to the Root Mean Square Error (RMSE) is presented in equation 3. The closer is the value of RMSE to zero; the more efficient is the estimation function. Mean absolute error (MAE) is presented in equation 4 and as it can be predicted, the closer is the value of MAE to zero; the more accurate is the prediction. Equations related to the calculation of average invalidity percentage (AIP) and average validity percentage (AVP) are presented in equations 5 and 6 accordingly. In an accurate prediction the value of AIP should be closer to zero; while, the value of AVP is closer to one. AIP of the selected model equals to 19.5%, RMSE equals to 0.004, MAE equals to 0.056 and AVP equals 80.5% which prove the accuracy of the model.
Estimated ages of failure are plotted versus the actual ages of failures in the test dataset which is presented in figure 6. The best fit is depicted by the line drawn on the graph. The relationship of the estimated and actual values is presented with the function on the graph and the correlation coefficient of the generated values versus the actual ones equals to 87% which proves the efficiency of the prediction.

![Figure 6: Estimated age of failure versus actual age of failure](image)

### 5.3 Probability of Failure

Accuracy of the model is proved by the statistical parameters and the validation results. The model can predict the age of failure and it is possible to calculate the probability of failure over time. Equation 7 is proposed to forecast the failure probability assuming the failure probability increases linearly through the time. Failure age is the estimated value through the model and "t" represents the number of years from now before which the failure could happen. In this equation, individual failure probability in all of the years has been assumed to be identical.

\[
P(f(t)) = t \times 100^{ \frac{1}{(Pipe\ mana.\ year + Failure\ age) - Current\ Year}}
\]

### 6 CONCLUSION

The pipelines of Hazardous Liquids are considered to be the safest way of transporting these products. However, recorded data on the failures of these mega infrastructures has proved the importance of research on them. Literature review has also verified the shortage of studies in this field. Operators of these pipelines need inspection tools to predict the failures of their pipelines before happening of the incidents. Due to the fact that inspection tools are expensive to run regularly, predicting models are
required. This study has developed a model to predict the age of failure of these pipelines. The model benefits from the historical data (1986-2013) that is gathered through the PHMSA (2013). First, the effect of different factors is studied to identify the most effective variables on the age of failure. Four variables that have been recognized through this process are pipe manufacturing year, maximum operating pressure, diameter over pipe wall thickness and the Specified Minimum Yield Strength. Then, data is inserted into the regression analysis and several functions have been produced with different subsets of pre-defined variables. Functions are assessed through the statistical values such as R-squared and F-test values. Results proved the efficiency and appropriateness of some of the models. Selected functions are then compared by validation results. Validation is done through the test dataset which includes ten percent of the data. The best function is the most accurate one with the Average Validity Percentage (AVP) equal to 80.5%. Residual analysis over this regression function presents sound outcomes. Finally, the estimated values of failure ages are compared with the actual values in a graph and the best fit is determined. Correlation coefficient of the regression model equals to 87% which proves the efficiency of the model. Finally an equation is proposed to calculate the probability of failure applying failure age that is estimated through the model.

Abstract: The measurement and control of incident root causes allows for proactive actions to mitigate risk in advance. In practice, however, it is difficult to identify and collect data that represent the root causes due to the complexity of incident occurrence processes. Despite previous studies on incident causation modelling, the identification of root causes in practice still relies on the investigator's subjective opinion. This research presents a conceptual model that explains the causal relationships between the root causes and the site unsafe level, and eventually assesses incident investigation processes. A case study was conducted to evaluate the 13 root causes in a company's investigation practice. The causal relationship between the root causes was observed based on the company safety database, interviews, and literature review. Then, the detailed model, which explains the incident occurrence process, was explored. Additionally, a hypothetical simulation model that allows for evaluation of the influence of each root cause on the safety level was built and tested to discuss the potential use of the conceptual model. Based on the company database, this paper also suggests and discusses the types of data to measure the root causes in practice. The model demonstrates that not only do safety personal and safety strategies affect the site unsafe level, but other factors also do, such as procurement, engineering, human resources, etc. As a result, the proposed model can be used to help identify the root cause in incident investigation practice and to develop strategies to improve safety performance.

1 INTRODUCTION

Incidents in the construction industry can influence project cost, schedule and quality. According to the Association of Workers’ Compensation Boards of Canada (2012), the incident rate in the construction industry is 30% higher than in any other industry. Moreover, the fatality rate of the construction industry is approximately three times higher than the industry average. Incidents can affect the worker’s family, the community, and will also decrease the amount of worker resources available to the industry.

Incidents can generate accidents. According to Bird and Germain (1996), an accident is an event that results in unintended harm or damage, and when it is related to the worker, can result in injury. Any accident can be avoided; however, preventing accidents is difficult, mainly due to the difficulty of understanding accident causes, since several factors, such as worker and management commitment, schedule, and training, can affect it.
Construction companies usually perform an incident investigation to identify the root causes leading to an incident. Based on this investigation, the companies take actions (e.g. safety training, audits) that allow proactive management of safety performance by mitigating the risk in advance. Although several studies have developed accident causation models, the identification of the root causes in practice relies on investigator experience.

Besides identification of the root causes, the measure and control of the incident root causes can also contribute to improvement of the risk mitigation process. However, construction companies have difficulty identifying and collecting relevant data that represent the root causes due to the complexity of the incident occurrence process. Moreover, relevant data could be used to produce simulation models to better predict or estimate the site unsafe level.

The difficulties in identifying, measuring and controlling incident root causes could be due to the difficulty of understanding the causal relationship between them. Nevertheless, the relationship between the root causes should be determined, since projects usually have a limited safety budget, and better results can be achieved if the company can identify the best safety strategy to allocate the resources available (Wirth and Sigurdsson, 2008).

The objective of this research was to develop a conceptual accident causation model in order to explain the causal diagram between the root causes and the site unsafe level.

2 BACKGROUND

Accident causation models aim to “understand the factors and processes involved in accidents in order to develop strategies for accident prevention” (Arboleda and Abraham, 2004; Mitropoulos et al., 2005). According to Hovden et al. (2010), the main reasons for discussing the accident causation models are to: (1) create a common understanding of the accident phenomena; (2) help structure and communicate risk problems; (3) guide investigation on data collection and accident analyses; and (4) analyze the relationship between the factors.

Researchers have developed methodologies to identify incident root causes. Wagenaar and Schrier (1997) developed the TRIPOD model. This model classifies the causes for an incident into 11 General Failures Groups (e.g. design and training). Abdelhamid & Everett (2000) developed the Accident Root Causes Tracing Model (ARCTM). This model uses a decision tree to identify the main root cause of an incident. Suraji et al. (2001) developed a model that classifies the factors that cause an incident into distal and proximal factors. Leveson (2004) developed the Systems-Theoretic Accident Model and Process (STAMP). In this model, the accident occurs when external disturbances, component failures or dysfunctional interactions are not adequately controlled. However, these models are only able to pinpoint the main factors that cause the incident, not support the dynamic relationship between them.

As the previous models are not able to deal with the dynamic relationship between the factors, researchers have developed system dynamic models to understand how factors cause an incident. Cooke & Rohleder (2006) focus on how worker risky behavior and the learning process can cause an incident. Han et al. (2014) verified how the production pressure is related to incidents. Jiang et al. (2015) and Shin et al. (2014) developed models to understand the influence of the worker’s unsafe behavior on the incidents. It is possible to verify that these models are not able to deal with different root causes specified in practice by construction companies. Moreover, these models are generally conceptual and it is difficult to apply them to company safety routines.

The models and techniques presented have difficulties measuring the root causes that influence incidents. In practice, the incident investigation is usually only able to classify the occurrence of a pre-established root cause as Yes/No. The incident investigations utilized by construction companies usually collect information to describe the incident, but do not collect data to measure the influence of each root cause on the incident. Therefore, the companies have difficulty finding preventive actions to avoid further incidents.
3 METHODOLOGY

A case study was conducted to evaluate the root cause in a company's incident investigation practice. The incident root causes were identified. Although the root causes were established based on Bird and Germain (1996), there was no definition about how to classify each root cause during the incident investigation procedure. Therefore, the root causes were defined based on literature review and the company incident investigation.

After identifying and describing the root cause used by the construction company, the causal diagrams were developed. These diagrams were built based on the company's incident investigation, safety database, interviews, HSE Manual and further literature review.

The last step was to define empirical equations and build a hypothetical simulation model to understand the model behavior and evaluate the influence of each root cause on the site unsafe level. Moreover, data types were suggested to measure each root cause based on the safety database and the incident investigation.

4 IDENTIFY AND DEFINE THE ROOT CAUSES

According to the company safety policies, for every incident that occurs on the construction site, an incident investigation should be conducted. The company established 13 root causes of incidents, and the investigator should choose at least one cause based on his/her experience. A short description for each root cause is shown in Table 1.

Besides the incident root causes, the incident investigation defined by the construction company also collects information about the date and time of the incident, weather and lighting conditions, worker information, worker schedule, injury details, activity type, tools and equipment utilized in the incident, substandard act, substandard conditions, witness statement, etc.

5 CONCEPTUAL MODEL

The conceptual model established two main categories as the cause of the site unsafe level: worker behavior and site conditions. These categories were defined based on the incident investigation and literature review (Lingard and Rowlinson 2005). The site unsafe level can cause an incident. An incident, in this research, is every occurrence likely to lead to grave consequences. Accidents are every occurrence that decreases worker availability in the project. Therefore, incidents and accidents are positively correlated.

Three main loops were identified in the conceptual model. Loop R1 is related to the site condition. The company and some researchers (Mitropoulos et al. (2005) and Han et al. (2014)) stated that the accident affects the schedule pressure causing congestion, and increasing the site unsafe condition. Moreover, factors such as temperature, project type, activity type (Lee et al. 2012), and site layout (Anumba & Bishop, 1997), can also affect the site unsafe condition.

The other two loops (B1 and B2) are related to the worker behavior. The schedule pressure can affect the worker intention to work safe (Mitropoulos et al. 2005), and consequently, the worker safe behavior. Moreover, incident investigations can increase worker knowledge and also the perception of risk (Construction Industry Institute, 2002), improving the worker safe behavior (Han et al. 2014). Figure 1 shows a conceptual model of the influence of the worker safe behavior and site conditions on the site unsafe level.

![Basic conceptual model](image)

**Figure 1: Basic conceptual model**

The root causes defined by the construction company were categorized between the worker safe behavior and the site conditions categories. Each loop is explained in further detail below.

**Site Condition** (R1): Figure 3 shows the influence of the incident root causes on the site unsafe conditions. The site unsafe level increases the quantity of incidents and accidents. According to Han et al. (2014) and Mitropoulos et al. (2005), an accident can cause delays, increasing the schedule pressure. To compensate for the delay, the company can hire new workers. However, these workers increase the site congestion. The congestion increases the site unsafe condition because it increases workers' exposure to struck-by or struck-against incidents (Fortunato et al. 2012). According to the company safety investigation, the site safety conditions can also be affected by the root causes Environment (e.g.
temperature, lighting, and wind), Standard Operating Procedures, Site Specific Safety Plan and Security Emergence Response.

![Diagram](image)

**Figure 3: Influence of the root causes on the site unsafe conditions**

The site conditions are also affected by the root causes Engineering and Procurement. Both of these root causes can also contribute to the schedule pressure. Procurement can lead to material delay and poor design can increase rework.

**Hazard Identification (B1):** Figure 4 shows the influence of worker knowledge on the site unsafe level. If the investigation is able to identify the root causes and the results are shared with the workers, they will increase their knowledge. Workers' previous experience can also affect worker knowledge. According to the company safety database, worker experience and incidents are negatively correlated. Therefore, during the hiring process, it is important to identify workers with more experience. Furthermore, according to the company safety database, the quantity of pre-task meetings is negatively correlated with the quantity of incidents because it increases worker hazard perception (Construction Industry Institute, 2002). In this model, the root cause Safety Communication represents the pre-task meeting.

![Diagram](image)

**Figure 4: Worker knowledge influence on the site unsafe level**

The improvement of workers' knowledge facilitates worker perception of hazards (Jiang et al., 2015). However, worker perception can be affected by the root cause Hazard Identification and Control. This
root cause represents worker physical conditions such as work shift, worker’s age, health condition and other personal characteristics that can prevent the worker from recognizing a hazard.

Worker Intention (B2): Figure 5 shows the influence of the worker intention on the site unsafe condition. Because of the particularity of the worker intention, it was divided in two sub-loops: Fatigue (B2.1) and Safety Climate (B2.2).

Fatigue (B2.1): The schedule performance can make the company increase the workers’ shifts. According to Alvanchi et al. (2012), prolonged working hours can produce fatigue due to decrease in the muscular strength and mental stress. Fatigue can make the worker take shortcuts, not follow the safety recommendations, and consequently, decrease the worker’s intention to work safely (Jiang et al., 2015). Moreover, mental stress can cause distraction and decrease the worker’s capacity for hazard recognition (Hinze, 1997).

Safety Climate (B2.2): In this sub-loop, accidents increase the safety pressure and consequently increase management’s commitment to safety. However, Mitropoulos et al. (2005) stated that the schedule pressure may prevent management from providing and maintaining required safety measures, decreasing efforts to control the worker behavior. Moreover, management commitment is affected by the Leadership and Administration. According to the company HSE manual, the Leadership and Administration considers factors such as lack of discipline, lack of enforcement, lack of safety resources and lack of safety planning. The Management Commitment consequently affects the safety climate (Chinda & Mohamed, 2008). Although not specified as a root cause, safety climate is also affected by the Foreman Behavior (Choudhry and Fang, 2008). The root cause Sub-Contractor Management also affects Safety Climate.

The worker perception of safety (Han et al. 2014) is influenced by the safety climate and inspection and audits. One example of inspection is the Behavior-Based Observation (BBO) Card. The BBO improves worker safe behavior because the worker feels that he/she is being watched by the safety personnel (Vaughen et al., 2010).

Figure 6 shows the complete conceptual model.
6 MODEL EXPERIMENTS AND DISCUSSION

A hypothetical simulation model was built and four scenarios were tested to evaluate the influence of each root cause on the site unsafe level. In the first three scenarios, three different root causes were tested individually: 1) Environment, 2) Orientation and Training, and 3) Inspection and Audits. To better understand the influence of the root cause in each scenario, its value was set to 0 (worst condition), 0.5 and 1 (best condition). The other root causes had their values set at 0.5. The last graph compares the site unsafe level when all root causes are equal to 0.1 and 1. The time defined to visualize the root causes’ influence on the site unsafe level is 90 days. Figure 7 shows the site unsafe level obtained in each scenario.
It is possible to verify that the root causes defined by the construction company can affect the site unsafe level. The root causes defined in the model are inversely proportional with the site unsafe level. Moreover, it is possible to verify that after day 40, the site unsafe level is almost constant. This behavior is due to the schedule pressure, since the work hour overload and the crew size can compensate for the delay caused by incidents and rework. The similarity between the results of the three first graphs demonstrates that different root causes should be improved concurrently to decrease the site unsafe level (graph 4).

To improve the root causes, it is necessary to measure them. Furthermore, Table 2 suggests types of data to measure each root cause.

</table>

Besides the data types presented in Table 2, the company can also collect information about other factors used in the model, such as congestion (worker ramp up and ramp down), schedule pressure (delays), rework (project quality) and safety pressure (total recordable incident rate – TRIR).

The incident investigation can be improved to collect the data type suggested. Moreover, as some of the company’s incident investigations were not fully completed, the model could reinforce the importance of collecting all data requested by the investigation. In this case, the investigation will not be utilized just to describe an incident, but also to measure and control the incident root causes. The definition of the root cause can also help to better identify the incident causes, especially for those investigators who have to conduct the investigation.

The conceptual model was developed to identify the relationships between the root causes, but it is not recommended to be used to predict the site safety level. For this purpose, other simulation techniques, such as hybrid models combining discrete event simulation with system dynamics, or agent-based models, can achieve better results. According to Sawhney et al. (2003), an agent-based model “can be used to mimic the construction environment in which the worker [is] performing [his/her] work, along with
heterogeneous set of agents representing these workers to study various aspects of safety." Furthermore, root causes such as Environment, Procurement and Engineering can change values during the simulation and improvements are necessary to better predict the site unsafe level. However, the relationship between the root causes identified in this research can be used on other simulation models to improve the results.

Based on the model and the data type suggested to measure the incident root causes, construction companies can adopt strategies to improve the site safety level, such as improve the selection of engineering, suppliers, and sub-contractors in aspects related to safety; implement inspection procedures such as the BBO card and measure the supervisor’s commitment to safety.

7 CONCLUSION

The accident conceptual model developed in this research was able to demonstrate the relationship between the incident root causes defined by the construction company and the site unsafe level. It is also possible to conclude that not only are safety procedures, safety personnel, and field workers responsible to improve safety performance, but other company departments are as well. In this way, it was possible to conclude that, root causes such as project design, procurement, and HR/PD can affect the site unsafe level. Moreover, all departments that can cause project delays or influence the quality can influence the site unsafe level.

The company can improve the incident investigation procedures based on the conceptual model. Factors to measure each root cause were suggested and it is recommended to collect them during the incident investigation. Although this conceptual model cannot be used to predict the safety level, it is believed that the relationship defined in this research can be used in the future to develop a simulation model to measure and forecast how different safety strategies can affect the incident root cause and consequently the site unsafe level.

Ongoing research on the company safety database has been developed to validate the relationship between the root causes. Further steps are to define to which degree the different root causes affect the site unsafe level and validate the data type to measure the root causes with the safety managers.

Abstract: As the adoption and implementation of building information modeling (BIM) continues to gain momentum, the benefits and challenges of its implementation and use are becoming better defined. However, there still lacks an understanding into the reconfiguration of practice that is being induced by BIM within multi-disciplinary project teams. Part of this reconfiguration of practice involves the development of the model through the generation, authoring and exchange of project information. This paper presents the finding of a research project that investigated the evolution of a BIM developed by a vertically integrated project team on a large institutional project for design and construction purposes. The objective of the research project was to develop measures to investigate the evolution of a BIM in a collaborative and multi-disciplinary project setting. The research team analyzed the bi-weekly iterations of the models produced by the design team following a rigorous protocol. Timesheets were obtained for all project team members involved in the modeling process. The measures developed adopt both the product and the process perspective of BIM. These measures were tested to verify how they correlated to one another and to the overall time spent in the project and in BIM. Four categories of measure are developed: measures of information quantity, measures of information content, measures of information representation and measures of product evolution. These measures can serve as a benchmark to evaluate the efficiency of the modeling and ultimately the project delivery process.

1 INTRODUCTION

The transition to building information modeling (BIM) based practice in the Architecture, Engineering and Construction (AEC) industry promises considerable benefits over traditional practice mainly due to the possibility for project teams to co-develop, coordinate and optimize the digital prototype of a product (building, infrastructure, etc.) prior to its execution. This prototype is developed as a parametric model, acting as a database containing a product’s information available for reuse during its entire lifecycle (Eastman et al., 2011). These benefits are accrued through better information authoring, exchange, management and retrieval (Crotty, 2011); in theory BIM is allowing project teams to mitigate information chaos in the project lifecycle (Dubler et al., 2010). Considering that project teams can be considered information processing systems (Winch, 2010), this push to eliminate information chaos within the project team is central to one of the core tenants of BIM which is to improve the efficiency and performance of the AEC industry (Eastman et al., 2011). On the other hand, the transition to BIM constitutes a departure from traditional practice (Dossick and Neff, 2011). As such, organizations are currently caught in a period of disruption in the AEC industry: the promise of BIM is alluring to many and in this regard, they are
moving forward with its implementation. However, they are being confronted to deeply entrenched practices, hence the notion of paradigm shift and the need to reconfigure these practices to leverage the benefits of BIM (Taylor and Bernstein, 2009). While theoretical developments in the area of BIM implementation are taking root, there is still a need to define and assess how this shift is affecting practice and more precisely how it is impacting the generation, authoring, exchange and management of project information across a project’s lifecycle. From this perspective, this paper aims to increase our understanding of how a BIM evolves throughout a project and the factors that mediate its progression by developing measures to investigate its evolution in a collaborative and multi-disciplinary project setting. This paper specifically aims to answer the following questions: (1) what measures can be extracted from a BIM for its assessment, from both a product and a process perspective? (2) How do these measures correlate between themselves, across time and across disciplines? And (3) what do these measures tell us of how a BIM is evolving throughout the project? The case study of a new institutional building procured under a design-build delivery mode is used to develop these measures and answer these questions. Four categories of measure were developed: measures of information quantity, measures of information content, measures of information representation and measures of product evolution. Other measures that have been developed are discussed in the paper, however they were not operationalized. These measures are: measures of project complexity, measures of information quality and measures of information flow. The paper concludes with a discussion about the implications of these measures as well as opportunities for future work.

2 BACKGROUND

The transition to BIM is not without its set of challenges (eg. Eastman et al. 2011), chiefly amongst them, interoperability, or the ability of heterogeneous information systems to communicate (IEEE, 1990) is consistently ranked as a top barrier to BIM. Amongst the many dimensions of interoperability identified (Poirier et al., 2014), technological interoperability remains one of the most important issues which hinders the flow of information in current BIM-based project environments. While strategies to overcome these issues have been developed, namely the OpenBIM standards developed by buildingSMART International, they are still in development. Furthermore, organizational, procedural and contextual barriers, that have been documented in the past, prior to the emergence of BIM, (e.g.Egan, 1998) are still having as important, if not a bigger, impact on the flow of information within the project team than the newly introduced technological barriers. In light of these challenges, different approaches to formalize information handoffs in a BIM-based collaborative environment have been developed, namely the information delivery manual (IDM) part of the OpenBIM standard from buildingSMART International (ISO 29481-1, 2010), the model elements table developed by the American Institute of Architects (AIA) in 2008 (AIA, 2008), the Level of Development (LOD) Specifications developed by the BIMForum released in 2013 (BIM Forum, 2013), as well as the COBie data exchange format developed by the USACE in 2007 and in particular the Data Drops developed in conjunction with the BIM task group in the UK (East, 2007). While these approaches allow to either map out or align model based information authoring and exchanges expectations, they represent set points in time and are often aligned to the tradition project phases, further contradicting the required change in practice to move towards seamless information flow through BIM. Furthermore, these approaches do not allow to assess the dynamic nature of information throughout a project.

Sparse work has looked into the assessment of model evolution in the AEC industry. As such there are little metrics to perform a comprehensive evaluation. However, some work has been performed to investigate specific elements which touch on model-based information evolution. Leite et al. (2011) investigate the effort that it takes to develop a model from a LOD 400 to LOD 500. The main objective is to evaluate the modeling effort in relation to the level of detail. They then evaluate the impact of LoD in supporting MEP design coordination. The study shows that additional modeling effort can lead to more comprehensive analyses and better decision support during design and construction. Sacks et al. (2005) provide a set of benchmarks to evaluate the BIM implementation process in terms of productivity gains between a traditional 2D CAD workflow and a 3D modeling workflow. They go on to find that the transition to BIM has improved productivity between 15% and 41% for design and detailing in structural engineering practice (Sacks and Barak, 2008). East and Bogen (2012) propose an experimental platform and a
methodology to consistently evaluate building models. The tools proposed are experimental and mainly for research purposes. Du et al. (2014) propose a cloud-based BIM performance benchmarking application, called BIM Cloud Score, to allow an overall view of BIM utilization in the AEC industry and facilitate performance improvement for individual companies. The authors developed a series of 6 indicators and 21 measures for the assessment of both the process and the product (the model). The BIM Cloud Score is still a hypothetical tool and has yet to be commercialized. Furthermore, some of the metrics, information quality as an indicator of performance for instance, are summarily discussed and lack robustness. To that effect, Berard (2012) develops 8 specific metrics and describes a scale of observable phenomenon (akin to a maturity model) to evaluate information quality from the contractor's perspectives. He operationalizes these metrics to validate their applicability and usefulness in the AEC industry. While useful, the contractor perspective is narrow and the author doesn’t differentiate between quality of information processes and quality of the product information itself. Dubler et al. (2010) look into the question of process information and study information exchanges through BIM from a lean perspective. They develop the 7 types of waste identified in the Lean approach and map that to types of waste related to information exchanges through BIM. Manzione et al. (2011) develop a BIM Integrated Management Model (BIMM) comprised of four stages, called loops, and a total of 11 steps. In the control loop they operationalize the 6 indices (or measures) of information flow developed in Tribelsky and Sacks (2010) and based on lean concepts. These indices allow measurement of information flow in the process of detailed design where construction documents are prepared. The indices develop in Tribelsky and Sacks (2010) identify information flow bottlenecks, large batch sizes and accumulation of work with the objective of finding faults or bottlenecks in the project development process. They also developed an index for measuring rework which was later validated in Tribelsky and Sacks (2011). In this subsequent paper, the authors find that an unpredictable information flow results in unpredictable project outcomes. This body of work pertaining to evaluating information flow is highly relevant and speaks to the shift in practice from this perspective. In parallel, the BIMM offers a framework to structure how this information should be managed in a project delivery setting. However, certain areas of evaluation are lacking such as information quality, design evolution and productivity. Other domains have looked into assessing the evolution of design and production. Namely, the field of software engineering has developed many measures to evaluate the development (e.g. Ampatzoglou and Chatzigeorgiou, 2007) and quality of software design (e.g. Yacoub et al., 1999). In order to close the gap identified in terms of comprehensive evaluation of design development and evolution in the AECO industry in light of the reconfiguration of practice prompted by BIM, the developments in these fields could be leveraged and applied to the AEC industry. The table below presents various metrics to evaluate different aspects of design and product evolution (table 1)

Table 1: Measures to evaluate design and product evolution from various domains
3 RESEARCH METHODOLOGY

This research project is part of a larger more comprehensive research project aimed at studying the impact of BIM on project delivery in the AEC industry. The aim of this particular scope of the research project was to investigate the evolution of a BIM in a collaborative, multi-disciplinary project environment by answering the following questions: (1) what measures can be extracted from a BIM for its assessment, from both a product and a process perspective? (2) how do these measures correlate between themselves, across time and across disciplines? And (3) what do these measures tell us of how a BIM is evolving throughout a project? In light of this, the objective of this scope of the research project was to develop and test measures to evaluate the development of information through a BIM. To fulfill these objects, a mixed-method case study methodology was employed. The case studied is that of the new construction of a major institutional building in Edmonton, Alberta, Canada. The $260 million, 39,000 m², project was procured under a design-build contract with the government of Alberta. The project team was made up of 29 different stakeholder organizations.

For the scope of research described in this paper, the research team performed data collection over an 18 month period, which corresponded to the construction documentation phase of the project. More precisely, the research team collected the bi-weekly iterations of the models produced by the design team over this 18 month period and analyzed them following a rigorous protocol. 41 iterations of the model were analyzed for the four main disciplines: architecture, structural, mechanical and electrical, for a total of 164 models. The models were analyzed in their native format (Autodesk Revit 2012 & 2013) and in a model checking and coordination software (Autodesk Navisworks Manage 2014). The models were all purged to remove all unused elements prior to analysis to ensure consistency. Furthermore, Industry Foundation Class (IFC) files were produced for every model and analyzed using the text file, the NIST IFC Analysyser (Lipman, 2011) and Solibri Model Checker v.9.5. This was done to expand the scope of analysis to include measures such as Lines of Code in the IFC schema, number of entities, model components and model revisions. Table 3 presents these measures. Timesheets were obtained for all project team members involved in the design and model development process. The total hours spent on the project and the number of hours spent by BIM personnel (individuals who were working directly in the model) were compiled. The measures were analyzed in three ways: the correlation between the measures, the correlation of the measures between the disciplines and the evolution of the measure across time were calculated for all disciplines and between disciplines. The 'R' language and environment for statistical computing was used (R, 2008). Spearman's rank correlation coefficient (ρ) was used to evaluate the correlation between variables due to its sensitivity to monotonic relationships over linear relationships. A cluster analysis was also performed in R to evaluate the appropriateness of the measures developed. The analysis were run for both absolute values (cumulative, ρabs) and relative values (variance per time period, ρvar) for each measure.

3.1 Project setting

The context of the case studied was characterized by the following elements: it was a publicly funded project procured under a design-build agreement with the provincial government. The design team was from a vertically integrated firm offering architectural and engineering services. As such, the core design team was working on the same network in real-time. Bi-weekly updates of the models were published to a
cloud-based project management software to be distributed to the general contractor and sub-trades. Key sub trades were contracted in a design assist role and provided a gross maximum price upon completion of design development. The contracts with the sub-trades and with the client were based on 2D drawings and specifications. As such, the model represented the core database containing project information, however a lot of effort was put into preparing and distributing 2D documents, which themselves contained annotations and specifications that were not found in the model. Therefore, it cannot be said that the model contained all relevant project information. A BIM project execution plan (PxP) was prepared to outline the scope and uses of the model in the project. On key element that was introduced in the PxP was the “Statement of Collaboration Intent” which outlined the intentions of each project stakeholder with regards to BIM use in the project. This is where the level of development was detailed for all disciplines and for all model elements. For example, the statement of collaboration intent for the architectural discipline was the following: “Most elements will only have as much data as we need to produce a 2D set of drawings”. This particular statement was made because the contractual documents and all deliverables for the project were to be 2D documents. Any further modeling that was required for coordination and fabrication purposes would have to be performed by the trades. The active participants in the modeling process on the project were the following: architecture, interior design, structural engineer, mechanical engineer, electrical engineer, general contractor, structural steel contractor, mechanical contractor, electrical contractor. Furthermore, the project context was particular in that, even if this was a design-build project, the client still had considerable involvement during the design phase. The project team had to release progress documents at set milestones, both internally for costing updates and externally for project review by the client. Therefore, two parallel work streams were developed whereby part of the design and documentation effort was put on developing the model and part of that effort was put on producing the 2D documents. Despite this particular context, it is still possible to say that this project was a collaborative BIM-enabled, multi-disciplinary project, with early involvement of key trades and general contractor. In this regard, the evolution of the BIM was intimately tied to the evolution of the project. In the evaluation of the various models, it is assumed that the modeling process is consistent throughout the project and across the project team.

4 FINDINGS

4.1 Measures developed

All disciplinary models were thoroughly analyzed to answer the first question: what measures can be extracted from a BIM for its assessment, from both a product and a process perspective? The thorough investigation of the models allowed us to extract the 12 variables presented in the first two columns of table 3 and view their evolution across time for all four disciplines. Addressing the second question (how do these measures correlate between themselves, across time and across disciplines?) facilitated a categorization of the measures as follows: measures of information quantity, measures of information content, measures of information representation and measures of product evolution. Lastly, the third question (what do these measures tell us of how a BIM is evolving throughout a project?) was addressed for each category to evaluate how the measures identified vary in relation to time spent on BIM by the various disciplines in the project team. Figure 1 illustrates the relationships between the measures of model evolution. Figure 2 illustrates the percentage variance of the four measures at a given period for all disciplines. This percentage variance could be compared to the project average for each measure, compared against a given target, or in the case of a retrospective study such as this one, against the final model which serves as a benchmark.

4.1.1 Measures of information quantity: File size and lines of code in the schema

The measure of information size is a reflection of the overall information contained within the model in terms of bytes of encoded data or information. This measure is represented by file size (both from the purged native file and the IFC file) and the number of lines of code in the IFC schema (LOC) (from the IFC file). The main issue with file size as a measure is in the way the information is encoded by the software platform or how the model is created, with issues associated to the modeling process and elements included in the model. Native file size includes all geometry in the model, properties, relations, annotations, views, sheets, images or renders and other representations that would support the project.
development process, whereas the IFC files only contain the information that was processed at export, which in itself introduces variability due to the potential loss of information during export (Koch and Firmenich, 2011). It must be noted that a version upgrade was performed (from 2012 to 2013 version) for the native software used in the project, which could impact how the IFC files were exported. Regardless, IFC file sizes and LOC are very strongly positively correlated across all disciplines ($\rho_{var} = 0.898$ for architectural). There is a mid-positive correlation between purged native file size and IFC file size for mechanical ($\rho_{var} = 0.506$), while it is considerably lower for electrical ($\rho_{var} = 0.265$) and architectural ($\rho_{var} = 0.163$), which could be caused by information that is not directly included in the model, such as renders, or level of detail of model elements. A quasi-null, although negative, correlation was found for structural
While the number of entities in a model can be interpreted as a direct measure of the raw yet structured information contained in the IFC schema - there is a perfect correlation between LOC (consequently, IFC files size) and number of entities ($\rho_{var} = 1.000$) across all disciplines - the export to IFC process can introduce variability as mentioned. Therefore the measures of components and scheduled objects, which are attributable to model authoring and the project development process, would seem better suited for this measure. Indeed, individuals interact directly with these components in developing the model. The main difference between scheduled objects (extracted from the native file) and model components (extracted from the IFC file) are their practical use: scheduled objects are related to model uses whereas model components are related to model authoring. A mid to strong positive correlation was found between between the number of entities and the number of components for all disciplines ($0.655 < \rho_{var} < 0.810$). There was also a mid to strong positive correlation between the number of scheduled objects and the number of components for all disciplines ($0.415 < \rho_{var} < 0.688$) In the evaluation of the correlation of measures of information content between disciplines, specifically components, a low to mid positive correlation was found between all disciplines ($0.103 < \rho_{var} < 0.696$). A low to mid positive correlation was found between the time spent in BIM and the variation of number of views for all disciplines ($\rho_{var arch} = 0.309$, $\rho_{var struc} = 0.405$, $\rho_{var mech} = 0.702$, $\rho_{var elec} = 0.670$), which indicates a direct relationship between time spent in BIM and the purged native file size. The weaker correlations in architecture and structure could be in part due to the negative variations in size, for instance when certain elements in the model were rationalized. In investigating the evolution of measures of information quantity in relation to time spent in BIM over the course of the project, it was observed that the native file sizes for all disciplines progressed in a linear fashion whereas IFC files sizes jumped drastically at set points in time for both mechanical and structural.

### 4.1.2 Measures of information content: Entities, components, scheduled objects and quantities

The measure of information content relates to the geometry and properties of the elements in the model. While the number of entities in a model can be interpreted as a direct measure of the raw yet structured information contained in the IFC schema, there is a positive correlation between LOC (consequently, IFC files size) and number of entities ($\rho_{var} = 1.000$) across all disciplines - the export to IFC process can introduce variability as mentioned. Therefore the measures of components and scheduled objects, which are attributable to model authoring and the project development process, would seem better suited for this measure. Indeed, individuals interact directly with these components in developing the model. The main difference between scheduled objects (extracted from the native file) and model components (extracted from the IFC file) are their practical use: scheduled objects are related to model uses whereas model components are related to model authoring. A mid to strong positive correlation was found between between the number of entities and the number of components for all disciplines ($0.655 < \rho_{var} < 0.810$). There was also a mid to strong positive correlation between the number of scheduled objects and the number of components for all disciplines ($0.415 < \rho_{var} < 0.688$) In the evaluation of the correlation of measures of information content between disciplines, specifically components, a low to mid positive correlation was found between all disciplines ($0.103 < \rho_{var} < 0.696$). A low to mid positive correlation was found between the time spent in BIM and the variation of number of views for all disciplines ($\rho_{var arch} = 0.309$, $\rho_{var struc} = 0.405$, $\rho_{var mech} = 0.702$, $\rho_{var elec} = 0.670$), which indicates a direct relationship between time spent in BIM and the purged native file size. The weaker correlations in architecture and structure could be in part due to the negative variations in size, for instance when certain elements in the model were rationalized. In investigating the evolution of measures of information quantity in relation to time spent in BIM over the course of the project, it was observed that the native file sizes for all disciplines progressed in a linear fashion whereas IFC files sizes jumped drastically at set points in time for both mechanical and structural.

### 4.1.3 Measures of information representation: Views, sheets and annotations

The creation of views, sheets and annotation supports the design process and become the deliverables for the project. Views are embedded into sheets and annotated to create project documents. The presence of these elements are a characteristic of the parallel 2D – 3D modeling and documentation process. Whereas measures of information content tends to stabilize during the construction documentation workflows; the number of views and sheets continues to grow as the need for additional representations are required to translate and communicate project information to the various project team members. While the definition of what is represented on sheets is an industry standard (ie. plans, elevations, sections, details and schedules), views are highly contextual and not only discipline specific but subject to individual workflows, meaning that there is limited correlation between the number of views and sheets; each sheet will contain at least one view or schedule, but not all views and schedules will be included in a sheet. A low positive correlation was found between number of views and sheets across each disciplines ($0.181 < \rho_{var} < 0.277$); this measure is unrelated between disciplines. A low to mid positive correlation was found between the time spent in BIM and the variation of number of views for all disciplines ($\rho_{var arch} = 0.112$, $\rho_{var struc} = 0.101$, $\rho_{var mech} = 0.284$, $\rho_{var elec} = 0.446$). In the investigation the evolution of measures of information representation over the course of the project, the architectural discipline has the highest total number and the most rapid progression of views, however structural
discipline has the highest views to sheet ratio at 12.82 views per sheet on average. Understanding the rate of information representation progression can allow to evaluate the time spent on the production of 2D drawings, a relatively redundant procedure given the emerging uses of BIM directly on site and in facilities maintenance.

4.1.4 Measures of product evolution: Clashes and Revisions

The overall variation of the above measures (quantity, content and representation) over time will be measures of information evolution. Product evolution and information evolution are differentiated in this case. As such, the number of clashes and revisions in the model can be interpreted as a measure of the refinement of the model as design progresses. The measure of clashes is extracted through clash detection software and is a standard process in current BIM based practice. Three classes of clashes have been developed: true-positives (identified as a clash and is a clash), false-positives (not identified as a clash but is a clash) and false-negatives (identified as a clash but is not a clash) (Leite et al. 2011). In addition, clashes were totaled for each discipline. The number of revisions is extracted by directly comparing model iterations in a model checking software. Three classes of revisions were extracted: elements added, elements removed and elements modified (elements that have one or more characteristic modified). Evaluating the correlation of measures of product evolution between disciplines, the number of revisions showed mid positive correlation ($0.393 < \rho_{var} <0.641$), whereas the number of clashes show higher positive correlation ($0.608< \rho_{var} <0.915$). One element of note is that the design team did not start purposefully addressing clashes before the very end of construction documentation, therefore the measure of the evolution of clashes throughout the project is more or less a valid measure in this case. Furthermore, the models were released on a bi-weekly thus allowing the project team to complete any coordination cycle and thus the clashes that were found would be resolved in the upcoming cycle. Moreover, evaluating the correlation between the number of clashes and the number of revisions would seem a valid point of investigation, indeed this could indicated that clashes reduce as revisions increase, which would be a valid statement. The contrary however wouldn’t make sense. In evaluating this measure, the research team found a null to low correlation ($-0.214< \rho_{var} <0.227$), which confirms that the two measures are weakly related, if not unrelated. A null to mid correlation was found between the time spent in BIM and the variation of number of clashes ($\rho_{var arch} = 0.146$, $\rho_{var struc} = -0.073$, $\rho_{var mech} = 0.420$, $\rho_{var elec} = 0.494$) and the variation of the number of revisions ($\rho_{var arch} = -0.024$, $\rho_{var struc} = 0.230$, $\rho_{var mech} = 0.573$, $\rho_{var elec} = 0.370$). In the investigation the measures of product evolution over the course of the project, no clear trend was discernible for both number of revisions and number of clashes. It would be expected that both would tend towards 0 over time.

4.2 Additional measures: Measures of project complexity, information quality and flow

The measure of model complexity and of level of development are difficult to quantify. While specifications exist for level of development (eg. AIA, 2008), the exercise is carried out manually and remains somewhat subjective. In terms of complexity, some measures could be used such as use of generic model elements and place holders or number of objects per area (Du et al. 2014). Clevenger and Haymaker (2011) have developed some measures of complexity in the design process which could be further investigated in the context of model evolution. However, further work is required to develop measures of complexity that are relevant and directly computable as both measures of product and process in a BIM environment, namely in the investigation of complexity, coupling and cohesion in the IFC schema. Lastly, as discussed, measures of information quality and flow are core to the AEC industry. While the question of information flow has been tackled from various perspectives, the question of information quality is seemingly underrepresented in the AEC research domain. One could say that information flow is a subset of information quality as a measure of process efficiency and quality. The work performed by Dubler (2010) and Berard (2012) speak to these measures, however, they remain difficult to operationalize. For instances, measures of information accuracy and precision have to be validated in the field and compared to a suitable referent. Measures of information relevance are highly subjective and dependent on a stakeholder’s perspective. Trieblesky and Sack’s (2010, 2011) as well as Demian and Walters’ (2014) work tackled some of these issues with information flow, however, the authors acknowledge that the work performed was extremely onerous. Furthermore, while information exchanges can be more readily mapped and measure, information quality is highly subjective and
dependant on the stakeholder’s point of view. Information, its value and its quality in the model is a field of research that requires much more investigation.

5 DISCUSSION AND CONCLUSION

This paper presented the findings of a research project with the aim of investigating model evolution in a collaborative multi-disciplinary BIM-based project setting. Measures were developed to assess this evolution and allow a consistent empirical approach to information evolution in the project delivery process. The measures were tested for correlation between each other, across disciplines and their variation was evaluated across time. While most measures identified were correlated within their categories, further investigation is required to understand this implication across other project settings. Work is also necessary to understand proportionality in the evolution, for instance spending a lot of time on a particular 2D detail will not increase the weight of the model as adding or duplicating a specific component, say a piece of furniture, which takes a lot less time and contributes . Furthermore, in developing these measures and gaining access to data, the research team was faced with multiple challenges. A clear advantage was gained through BIM in this research project due to the possibility of querying project information in a structured manner. However, it would have been advantageous to have access to weekly iterations instead of bi-weekly iterations of the model. The exercise would have gained in precision. In addition, a main challenge was faced in developing a coherent measure of time spent in BIM versus time spent on the model. The research team did not have access to the file logs, nor did the time sheets completed by the employees contain relevant cost codes for various BIM activities. Time spent in BIM had to be extrapolated from the personnel that were identified as BIM users in the project. An additional challenge lay in exporting the IFC files in a consistent manner across different versions of the native software platform. IFC 2x3 was the standard format for export, and a special IFC export plug-in was used, however the mechanics behind the export were unknown to the research team and was seen to introduce a lot of variability between versions of the software platform. There is also some inherent loss in information in the transfer process (Koch and Firmenich, 2011) Moreover, while it was assumed the modeling process be consistent across the project team, each individual has their own way of working and interacting with the model, for instance creating 2D views to modify the model rather than working directly in 3D. This differences introduce variability in the investigation. In analysing the data, the research team was confronted with the choice between absolute values (ie. the compiled value or sum of values since the start of the project) and relative values (the variation between model iterations). Absolute values were used for correlation analysis in this paper whereas, the relative values were used in the time analysis. In the data extraction process, a rigorous protocol was required to replicate every step across the entire project. The research team is looking into automating this process for future work. It is also seeking to expand the scope of data extraction through the use of tools such as COBie data drops and the spreadsheets produced as a formal way to validate project progress. Further work is also required to replicate this evaluation across various project settings. However, in expanding this investigation to include different models, a considerable effort to normalize the data across the different project contexts will have to be carried out. For instance, the uses of BIM which impact the development of the model will have to be factored. The analysis of additional models would allow the regression analysis of multiple data sets to validate the evolution of the measures developed in this paper.

Acknowledgements

The authors are greatly indebted to all the members of the project team for the case studied. Their candor, transparency and openness are greatly appreciated and contributed immensely to this research project.

DO STRONG OR WEAK TIES MATTER IN KNOWLEDGE NETWORKS?

Cristina Poleacovschi¹, Amy N. Javernick-Will¹
¹ Department of Civil, Architectural, and Environmental Engineering, University of Colorado Boulder, USA

Abstract: Construction and engineering organizations have increasingly implemented knowledge exchange strategies with the goal to facilitate knowledge exchange across the organization. However, despite these efforts, many knowledge strategies fail in practice, as it is not well known when knowledge access is most beneficial. This research analyzes the correlation between group level knowledge exchange and perceived individual benefits. Specifically, we focus on the time saved (in hours per month) on work tasks as a result of accessing knowledge with others in the department. To conduct this research, we used social network analysis and a modularity optimization algorithm to identify the existing knowledge-based subgroups (KBS)—subgroups that share more knowledge internally than externally—within a large engineering and construction organization. To identify whether these knowledge-based subgroups offer time benefits, we compared the time benefits from receiving knowledge within these subgroups and outside these subgroups. Results found that individuals are more likely to perceive saving time on work tasks as a result of receiving knowledge within their subgroups. As a result, our results indicate that the type of benefit received matters to determine whether weak ties or strong ties are important.

1 INTRODUCTION

The importance of knowledge sharing in construction and engineering organizations has gained an unprecedented interest and many scholars view knowledge as the most important resource of the firm (Grant 1996). The efficient allocation of money and labor is not sufficient enough to gain competitive advantage anymore. Instead, knowledge and its use at the right place and time is what allows projects to achieve successful results (Argote and Ingram 2000).

While this view is shared largely in the literature, there are many debates about how and when knowledge exchange brings the most benefits. To address this debate, previous studies have focused on knowledge exchange primarily at the group level, with emerging studies at the individual level. At the group level, the literature has focused on the importance of knowledge exchange on group performance (Cummings 2004; Landaeta 2008; Tsai 2001). For instance, Tsai (2001) showed that business units which are more central are more likely to receive diverse knowledge from other business units which in turn affects innovation and performance. While studying the effects and benefits at the group level is important, it provides an incomplete understanding of how knowledge exchange adds value to outcomes. Specifically, aggregating group level outcomes offers a good understanding of the effect of group level attributes (e.g. size, composition) on final outcomes, but it neglects intra-group dynamics, which represent the core of group outcomes. To address the dearth of literature on individual level outcomes, Wanberg and Javernick-Will (2014) studied the relationship between frequency of individual knowledge exchange and
individual work outcomes in informal organizational groups. They found that infrequent interactions provided individuals with more unique knowledge than frequent knowledge interactions.

As such, individual level knowledge exchange has been analyzed for individual level performance and group level knowledge exchange has been analyzed for group level performance. As a result, the connection between the group level characteristics and individual level benefits has been largely neglected with the exception of Poleacovschi and Javernick-Will (under review) who found that individuals spanning knowledge across highly connected knowledge subgroups are more likely to receive higher individual performance evaluations in a construction and engineering organization.

This research proposes to further address the missed macro-micro link by analyzing the relationship between group knowledge exchange and individual level outcomes. Previous research has identified that individuals gain benefits from their position in the network structure. Nahapiet and Ghoshal (1998) found that individuals share intellectual advantages, such as knowledge exchange, as a result of being part of highly connected groups. Thus, we expect that individuals who are part of highly cohesive knowledge exchange groups will gain benefits from the network connectivity of their group. However, we expect that this relationship is sensitive to the type of relationship, or tie, between the individual and the group. This thinking is in line with the theory of weak ties (Granovetter 1973) which argues that the type of ties matter in a network. To translate Granovetter’s study at the level of subgroups, strong ties are part of highly connected groups while weak ties connect individuals from different subgroups. Considering the importance of project time in construction and engineering organizations, we define individual benefits as the time an individual saved (in hours per month) on work tasks as a result of receiving knowledge from other employees, whether within their knowledge based subgroup or outside of their knowledge based subgroup. Thus, this research asks: Do individuals save more time as a result of their weak or strong ties within knowledge exchange networks?

To answer this question we employed a unique method that identified knowledge-based subgroups (KBS) within a department of a large construction and engineering organization (Poleacovschi and Javernick-Will under review). The method used a social network optimization algorithm that identified subgroups that shared more knowledge internally than externally. Then, using survey data, we identified the perceived time savings as a result of receiving knowledge within their KBS as compared to receiving knowledge outside of their KBS.

This research is important both for theory and practice. To contribute to theory, this research links group and individual level constructs by testing the strength of weak ties theory in KBS. By translating weak and strong ties concepts to KBS, knowledge connections in KBS are strong ties because these subgroups are dense and cohesive, while connections outside KBS are weak ties. By focusing on the specific benefit of time savings, we contribute to theory by extending previous work on different types of benefits that can be received from strong or weak ties. In practice, construction and engineering organizations can choose to invest resources based upon the benefits they seek—in our research, this relates to saving time on work tasks.

2 THEORETICAL BACKGROUND

2.1 Knowledge-based subgroups

The interest in knowledge-based subgroups, or groups that share more knowledge internally than externally, is rooted in the knowledge-based theory of the firm (Grant 1996). In this view, the ability to efficiently exchange the “know what” and especially the “know how” is what differentiates organizations from markets (Kogut and Zander 1992). In other words, construction and engineering organizations exist because they successfully manage to integrate the knowledge of professionals from different disciplines (e.g. structural engineers, project managers) that can easily exchange knowledge, or “know how”, to achieve project goals. Another option is to look for professional knowledge (e.g. structural analysis and project management) on the market. However, this would be less efficient as separate transactions with different professionals would be costly. The knowledge-based theory of the firm also believes that an organization gains competitive advantage whenever it manages to coordinate knowledge exchange better
than other organizations (Argote and Ingram 2000; Grant 1996). Unfortunately, this is not easy as there are many organizational structures and boundaries that impede knowledge exchange (Wanberg et al. 2014; John Wanberg et al. 2014).

As a result of these boundaries, knowledge-based subgroups—subgroups that share more knowledge internally and less externally—can form. The common belief is that subgroups disrupt knowledge exchange, which may be detrimental for the larger performance of the group or organization. For instance, individuals are more densely connected to others within their subgroup and limited knowledge may flow between subgroups, resulting in a boundary that may impede members of the group to search and access knowledge outside their own subgroup. However, this assumes that knowledge exchange with others outside one’s own subgroup is actually valuable—which may not be true. More importantly, valuable in terms of what and valuable for whom? As previous research has mainly focused on the effects of subgroup formation on group level outcomes, we do not know the effect of subgroup formation on individual benefits in terms of time saved on work tasks. Using theory of weak ties we build our hypothesis about the relationship between network ties with KBS and individual time benefits.

2.2 Ties within and between knowledge-based subgroups

The most influential papers addressing individual benefits from network structure are the structural hole (Burt 1995) and the strength of weak ties (Granovetter 1973) theories. A structural hole means the absence of a relationship between two individuals in a network. The theory states that individuals who link two unconnected others are likely to gain benefits. The strength of weak ties theory was the antecedent of structural hole theory and focused on the types of ties and benefits results those ties (Granovetter 1973). Individuals who manage to create ties outside their own subgroup of close relationships (weak ties) gain benefits as a result of reaching for novel resources and information. For instance, in his thesis, Granovetter discovered that weak ties are the most beneficial connections for a job search. Figure 2 shows a visual representation of weak and strong ties. Straight lines represent strong ties while dotted lines represent weak ties.

While this theory is quite influential, it was initially conceptualized and tested in the context of people who were searching for jobs. The theory has been tested less in the context of knowledge networks or considering individual time benefits. KBS are subgroups whose members share more knowledge internally and less knowledge externally. Thus, ties in KBS are strong because of the high connectivity between members, while ties outside of, or between, KBS are weak as they connect distant subgroups, which are highly connected. In contrast to Granovetter’s study, we expect that highly connected subgroups will save individuals more time as a result of the short distance between subgroup members. Conversely, accessing a new subgroup of knowledge through weak ties requires many more steps. As such, individuals will save more time from accessing knowledge in their highly connected network then from accessing knowledge in other subgroups. For instance, member B will access member G’s knowledge easier than member D’s knowledge, although it takes the same number of steps (Figure 1). In other words, members of KBS will use their subgroup connectivity to access knowledge fast. Thus, we expect that the type of tie between the individual and the highly connected network further benefits the individual. If the tie is strong (within a KBS), we expect that the individual will gain more time benefits from accessing that knowledge.
Hypothesis: Individuals will save more time from accessing knowledge from strong ties (within subgroups) than from weak ties (between subgroups)

3 RESEARCH METHODS: DATA COLLECTION

We were provided access to a large set of network data within the department of a large construction and engineering consultancy. The organization has focused on improving their knowledge management strategies for the past decade. They initially implemented knowledge management in the IT department, which was where the data was collected. Survey questionnaires were administered to all employees within this department, with questions focused on with whom they share and receive knowledge and whether these connections help to save them time through the knowledge provided. The response rate for the knowledge network data was 88% (n=142). Non-respondents were excluded from the final analysis.

3.1 Knowledge sharing networks

Questionnaires were administered to all 161 employees in the department. Using definitions of knowledge as information and "know how" (Liebeskind 1996), employees were asked to indicate, on a 6-point scale, the level of knowledge that they receive from other departmental employees. Specifically, they were asked:

"Often we rely on the people we work with to provide us with information to get our work done. For example, people might provide us with simple routine administrative or technical information that we need to do our work. Alternatively, people might provide us with complex information or engage in problem solving with us to help us solve novel problem. Please indicate the extent to which people listed below provide you with information you use to accomplish your work?"

Response options included: 0 – I do not know this person/I have never met this person; 1 – Very infrequently; 2 – Infrequently; 3 – Somewhat infrequently; 4 – Somewhat frequently; 5 – Frequently; 6 – Very frequently.

The data was transferred into a matrix format where questionnaire respondents were listed as rows, and the level of knowledge sharing with each other departmental employee was indicated in columns. The data was then analyzed using social network analysis (SNA) software to determine the composition of knowledge-based subgroups.

3.2 Time Benefits

To identify time benefits accrued as a result of receiving knowledge within and outside KBS, individuals were asked to indicate the time they saved per month (in hours) as a result of receiving knowledge from each individual in the department. They responded to the prompt:

"Please provide an estimate for the typical time saved per month as a result of information, or other resources received from each person."

The respondents assessed the time benefits for each other departmental employee based on a 5-point scale, including: 0 – I do not know this person/I have never met this person; 1 – No time saved; 2 – 1-3 Hours per month; 3 – 4-8 Hours per month; 4 – 9-12 hours per month; to 5 – more than 13 hours per month.

3.3 Individual attributes: hierarchy, tenure and gender

To identify individual attributes, individuals were asked to identify their hierarchy level and tenure (in years) within the organization. Hierarchical levels were determined from a scale of one to five (1 – individual contributor/team member; 2 – supervisor/team leader; 3 – project manager/program manager; 4 – manager/BU [business unit] manager; 5 – director). For tenure, individuals mentioned the number of years they have spent with the organization. Finally, the department provided the data on gender. This
information was later used for the linear regression analysis as control variables. We controlled for hierarchy, tenure and gender as women and newcomers are not expected to gain the same benefits from their position in the network (Burt 1992), while individuals in higher hierarchy levels are expected to be central in networks and gain more benefits (Poleacovschi and Javernick-Will under review).

4 RESEARCH METHODS: DATA ANALYSIS

In this section we present methods used to analyze the collected data with the goal to identify KBS and the average time saved in versus outside of KBS.

4.1 Identifying Knowledge-based Subgroups

We analyzed structural aspects of the department by analyzing the knowledge sharing connections between individuals within the network. We used SNA to identify KBS, which is described in (Poleacovschi and Javernick-Will under review), using Gephi (Bastian et al. 2009), a visualization and network analysis software. Gephi includes a tool that uses the Louvain modularity optimization algorithm (Blondel et al. 2008) to determine groups within the network that share more knowledge internally and less knowledge externally. The algorithm is based on calculating the modularity gain, or, in our case, the change in the level of knowledge exchange within a group as a result of adding a new member to it, compared to the level of knowledge exchange outside the group once the member joins. This determined the number of KBS—which, for this network was four, and the composition of, or employees that belonged to, each of the four KBS. We validated the KBS by running a ‘blockmodel’ in Netminer (Netminer 2014). The blockmodel allowed us to calculate and compare the network density, or the ratio of existing connections to all possible connections, between different KBS. This helped to validate the algorithm, as higher network densities were observed within subgroups compared to network densities between subgroups.

4.2 Identifying Time Benefits in Knowledge-based Subgroups

After the KBS were determined, we analyzed whether individuals within the subgroups received greater time benefits (saving more hours per month) from the knowledge received from employees within their KBS or external to their KBS. To do this, we conducted several steps, outlined below.

1. We constructed a matrix of 142 rows by 142 columns (number of people who took the questionnaire). The rows represented questionnaire respondents, and the columns included the average amount of time they saved per month (on a scale from 0 to 5) based upon receiving knowledge from each other person.

2. We replaced the time benefit scores in the database with the minimum number of hours from questionnaires. For example, a rating of “1” was replaced with 0 hours, a rating of “5” was replaced with 13 hours, etc. This was done to obtain results that can be interpreted from linear regression analysis.

3. We divided the matrix data into four other matrices, which represented the number of subgroups identified in the knowledge network. Each matrix’s rows contained the identified members of one KBS and the columns contained each member’s perceptions of time saved from all 142 participants. We obtained four subgroups (further explained in the next section) which included 35, 33, 42 and 52 members each. Thus, the four matrices were a 35 by 142, a 33 by 142, a 42 by 142 and a 52 by 142 matrix.

4. In each matrix, the column scores were summed for each of the 142 participants in order to obtain perceptions of all members in one subgroup about time saved from receiving knowledge from each of the 142 employees. The 142 values in each of the four datasets were further used for the linear regression analysis.

5. A new variable was added to each of the 142 participants in each of the four datasets – entitled subgroup membership. If members belonged to the subgroup analyzed, then they were assigned a score of 1 and if they belonged to one of the three external subgroups then they were assigned a score of 0. This was done to differentiate between time benefits members gained in their subgroup (1) compared to time benefits gained between subgroups (0).
6. We conducted linear regression analysis using SPSS (SPSS 2013) to identify whether the time benefits were more likely to be associated with knowledge receiving in KBS or between KBS. The dependent variable included the time benefits in hours per month (continuous), while the independent variables included subgroup membership (dichotomous), hierarchy (continuous), tenure (continuous) and gender (dichotomous).

5 RESEARCH RESULTS

5.1 Identifying Knowledge-based Subgroups

Four subgroups were identified using Louivian modularity algorithm: KBS A, KBS B, KBS C and KBS D (Figure 2).

![Figure 2: Visual representation of KBS](image)

The size of the subgroups varied from 27 to 50 members (Table 1). KBS D was the largest subgroup and included 50 members, while KBS A was the smallest subgroup and included 27 members. The blockmodel analysis (Table 1) revealed that the subgroups’ internal density is higher than its external density, validating the existence of subgroups. In this case, members within subgroup A were connected 30% of the time to members within subgroup B while members within subgroup A were connected to 66% of other members within subgroup A. These results were especially meaningful due to the overall density of the network, which was 45%, meaning that of all possible knowledge connections within this department, 45% actually existed.

5.2 Time Benefits

Initially, we obtained descriptive statistics of all independent variables (Table 2). Then, we ran linear regression analysis to identify whether knowledge receiving in KBS brought more time benefit then across KBS (Table 3). All fours models found that receiving knowledge was perceived to be more beneficial within KBS. Specifically, members saved, on average, 46.5 hours per month more by receiving
knowledge from other members within KBS A then other subgroups, 56.2 hours per month in KBS B, 74.7 hours per month in KBS C, and 89.5 hours per month in KBS D. As a result, we found that strong ties were more likely to offer individual time benefits compared to weak ties.

Interestingly, increased network density (Table 1) within a KBS meant more hours saved in three cases (Table 3). Subgroup B had larger network density then Subgroup A (84% compared to 70%), and was more likely to save more hours (56.2 hours compared to 46.5 hours) from receiving knowledge. Subgroup D had a larger network density then Subgroup C (87% compared to 67%) and Subgroup B (87% compared to 84%), and was more likely to save more hours than Subgroup C (89.5 hours compared to 74.7 hours) and Subgroup B (89.5 hours compared to 56.2 hours) respectively. However, Subgroup C was an exception. While its network density was lower than Subgroup B’s network density (67% compared to 84%), individuals in that subgroup saved more time then Subgroup B (74.7 hours compared to 56.2 hours).

Another set of results show that individuals in higher hierarchy levels are more likely to offer time benefits to others. Three of the four KBS (KBS A, KBS C, and KBS D) were positive and significant in the amount of time they saved to others. For instance, an increase in one hierarchy level is likely to be associated with an increase of 2 hours a month (KBS A) and up to 7 hours a month (KBS D) time benefits. Other control variables such as tenure and gender were not significant in any of the four models.

### 6 DISCUSSION AND IMPLICATIONS

Our results found that members of KBS were more likely to report saving time as a result of receiving knowledge from others within their KBS compared to receiving knowledge from employees outside their KBS. While large engineering and construction organizations allocate resources to improve knowledge exchange, it is important to strategically identify when knowledge exchange is most efficient and results in benefits to the employees and organizations. Our results found that individuals are more likely to save
time, and thus benefit, from others within in their KBS. Specifically, we identified a statistically significant relationship in all KBS between group membership and time benefits. An individual is likely to save an average of 46.5 to 89.5 hours more a month as a result of receiving knowledge within their KBS then between KBS (Table 3).

A major implication from this study is linking group level characteristics with individual level benefits and testing the strength of weak ties theory (Granovetter 1973; Wanberg and Javernick-Will 2014). Previous research has focused primarily on either the effect of group level knowledge exchange on group level benefits (Cummings 2004; Landaeta 2008; Tsai 2001) or the effect of individual level knowledge exchange on individual level benefits (Wanberg and Javernick-Will 2014). Instead, this paper bridges the two levels of analysis. Specifically, we found that network connectivity and the type of tie (strong or weak) within a highly connected network play a role in individual time benefits. Strong ties are knowledge exchange connections that are part of a highly connected network (KBS) while weak ties are knowledge exchange connections that link two people of different knowledge based subgroups. As a result, they benefit individuals differently. Weak ties likely require more introduction and steps to access particular knowledge external to the knowledge seeker’s KBS. Conversely, strong ties likely require less steps for introduction as the connectivity between members (knowledge providers and knowledge seekers) is quite high. It is important to note, however, that our results do not suggest that weak ties are unimportant in knowledge networks. Instead they show that weak ties are less important when it comes to saving time on immediate project- and organizational- related tasks. In all likelihood, weak ties in KBS are important for innovation and accessing knowledge that differs from the knowledge seeker’s immediate KBS. As such, our study builds upon existing theory of strong and weak ties by different outcomes (time benefits).

Interestingly, we also found a relationship pattern between KBS density and time benefits. This suggests that network density may play a role in the level of time benefits obtained from knowledge receiving, which validates our previous propositions that a knowledge network’s connectivity mediates the effect of strong ties on time benefits. However, these results require further research and a larger subgroup sample for validation.

7  CONCLUSIONS

Many construction and engineering organizations increasingly understand the importance of intra-organizational knowledge sharing for achieving competitive advantage. However, few studies have studied the benefits of knowledge exchange, and even fewer have analyzed when receiving knowledge offers best individual benefits. Specifically, previous literature has focused on individual and group level outcomes separately, with a dearth of literature linking group level knowledge sharing and individual level benefits. Based upon the strength of weak ties theory (Granovetter 1973), we tested whether strong ties in knowledge-based subgroups (KBS) – subgroups that share more knowledge internally than externally – bring more time benefits, based upon the minimum hours per month saved on work tasks, than weak ties between members of different KBS. To do this, we used social network analysis and a modularity optimization algorithm (Blondel et al. 2008) to first identify knowledge-based subgroups (KBS). Then, we identified the hours saved from receiving knowledge within KBS and outside of KBS. We found that members of KBS are likely to perceive more time saved per month from receiving knowledge within, versus outside of their KBS. These results contradict previous theory on the importance of weak ties (Granovetter 1973) which showed that weak ties are more valuable than strong ties. Instead, we showed that strong ties are perceived as more important, specifically when it comes to saving time, in knowledge networks.

8  LIMITATIONS AND FUTURE WORK

There are several limitations in this work. First, this study was conducted in the department of one construction and engineering organization, making generalizations across other construction and engineering organizations more difficult. Second, while we have a large sample size, the analysis suggests
through correlations, the effects of weak and strong ties on obtaining time benefits, but is unable to show causation. To address these limitations, we propose reproducing this research across additional construction and engineering organizations and conducting qualitative analysis to better understand why weak and strong ties have differential effects on individual time benefits.

Abstract: Despite the progress made in the development of scheduling techniques and tools, the industrial construction sector is frequently characterized by informal and unstructured procedures during initial planning stages. This results in planning deliverables that are scarcely aligned across the different business divisions and poorly structured to support field operations. Advanced Work Packaging (AWP) methodology consists in an enhanced project breakdown structure that prescribes an organized planning approach, aiming at the alignment between construction, engineering, and procurement disciplines since the preliminary planning phase. AWP is an emerging planning approach in the industrial construction sector and the present article is aimed at exploring AWP impact on project performance. Research methodology is based on multiple case studies concerning two industrial construction projects. The case studies involved the construction of projects with identical scope, one with and one without AWP implementation. These case studies were performed at the same time, in neighboring sites, and by the same project participants, thus representing reliable units of analysis to investigate AWP impact. Findings show that AWP implementation is related to improved performance in terms of project cost, schedule, quality, and safety. The present article contributes to the validation of an emerging project planning methodology and highlights the criticality of the early planning phase, which systematic characterization represents a valuable and still under-explored research avenue.

1 INTRODUCTION

Recent research performed by the Construction Industry Institute has highlighted the poor execution performance in the industrial project sector, where almost 70\% of projects exceeded 10\% variation from expected cost and schedule values (CII, 2012). This poor performance is inescapably tied to the lack of reliability of the planning process (Gibson et al., 2006), which is not able to offer reliable estimates and to manage the increasing complexity of industrial projects (Bosch-Rekveldt et al., 2011).

Among the most common project planning concepts, work-packaging has been extensively used and recommended within Project Management theory to divide the scope of work into manageable units for execution (e.g., PMI, 2004). The erratic adoption and the lack of updated standards for existing work-packaging theory motivated a four-year research project by the Construction Industry Institute (CII) – together with the Construction Owner Association of Alberta (COAA) – aimed at defining and recollecting the current work-packaging best practices in the industrial construction sector. The efforts of this research resulted in a codified and systematic planning approach named Advanced Work Packaging (AWP).
The AWP approach provides a holistic process for work-packaging execution with a project lifecycle orientation, from preliminary planning to system turnover and commissioning (CII IR 272-2 Volume 1, 2012). AWP prescribes an organized planning approach through the continuous alignment between construction, engineering, and procurement disciplines, emphasizing the application of work-packaging concepts beyond field implementation to reach the initial phases of project development. AWP has still an emerging connotation within the industrial construction sector and further empirical evidence is required to demonstrate its beneficial impact and to corroborate the logics underlying this beneficial impact. The objective of present research is to explore AWP role in improving project performance. By pursuing this goal, the researchers started addressing two main challenges of current work-packaging literature, one conceptual and one methodological.

The first main challenge involves the limited attention paid by extant research to early integration between project participants (Yang, 2013). Hence, traditional concepts place most of the emphasis on schedule definition and field implementation activities, almost neglecting the importance of alignment practices during the preliminary planning stage. The present research addressed this challenge by emphasizing the traits and features of AWP that foster initial alignment and integration within the project management team. The second main challenge regards the difficulties of project management literature in providing reliable and replicable empirical evidence (Koskela and Howell, 2002). Isolating the impact of specific techniques or practices is a complex methodological issue that is a direct consequence of project uniqueness, characterized by distinctive environmental conditions, scope, and project participants’ interactions (e.g. Aloini et al., 2012). To minimize this issue, the present research identified and analyzed two projects with identical scope, project team, and location that are performed in parallel with- and without-AWP implementation.

The theoretical novelty of the present work resides in the emerging treats of AWP, which challenges the traditional work-packaging approaches towards a more integrated planning process. From a practical perspective, the present article can support construction managers implementing AWP with detailed insights throughout the various project stages.

This paper has the following structure. Section 2 introduces the AWP approach and formulates the research objective. Section 3 highlights research methodology. Section 4 offers and discusses the results. Finally Section 5 is dedicated to conclusions and future research developments.

2 THEORETICAL BACKGROUND

The term "work-packaging" is used to cover "any method of organizing work execution process within the scope of a construction project" (CII IR 272-2, 2013). Despite the widespread adoption of work-packaging principles in the construction industry, extant research has sporadically indicated systematic approaches that are able to effectively integrate the planning and the execution processes (Yeo and Ning, 2006). Previous research “has been devoted to examining the conceptual applicability of the work-packaging concept and applying it as a general managerial tool. Only limited attention has been paid to the actual work-packaging process” (Kim and Ibbs, 1995). This lack of empirical evidence is particularly marked for the industrial construction sector (Azambuja et al., 2014; Jacoby, 2012), so that the underlying work-packaging theory has been considered obsolete and inadequate to effectively execute projects in practice (Choo et al., 1999; Koskela and Howell, 2002). One of the main problems has been identified in the poor integration between the engineering, construction, and procurement disciplines (Goodman and Ignacio, 1999), mainly because of the delayed involvement of project participants during the initial project phases (Gibson et al., 2006).

Since 2009, a research project conducted by the joint effort of CII and COAA has been investigating the work-packaging issue through the analysis of current best practices in the industrial construction sector. The outcome was a framework for AWP that prescribes the breakdown structure of project scope into three main stages (Figure 1): Preliminary Planning/Design, Detailed Engineering, and Construction (O’Brien et al., 2013). Compared to previous work-packaging efforts for the industrial sector – most notably the WorkFace Planning concepts (Ryan, 2009) – AWP shifts the focus to the early planning stages and provides a holistic process for work-packaging execution with a project lifecycle orientation.
During the first stage – Preliminary Planning – the project management team identifies the critical planning elements to achieve a coordinated planning sequence. This sequence is obtained through the iterative definition of work-packaging deliverables. The project is initially broken into a set of Construction Work Packages (CWPs), which define the logical and manageable division of work within the construction scope. CWPs are aligned with the project execution plan and with engineering deliverables or Engineering Work Packages (EWPs). EWPs are enclosed within CWPs, so that engineering and procurement disciplines are delivered to support construction. The identification of EWPs is accomplished by system, eventually crossing CWP boundaries through the positioning of decoupling elements (e.g. valves).

The second stage – Detailed Engineering – builds on and refines the work started during preliminary planning. From an engineering and procurement perspective, the output of this phase includes the detailed specification of EWPs. The breakout of construction work hours for the project is provided at this stage and it enables the resource loading of a Level 3 schedule, which is prepared for engineering (by discipline), for procurement (by commodity and by construction need date), and for construction (by area). The different plans are constantly aligned to ensure consistency.

The third stage – Construction – includes the detailed planning and the execution of operational work-packages, named Installation Work Packages (IWPs) that contain all necessary and pertinent documents in support of the safe and efficient installation for a specific system portion. IWPs are developed by a dedicated AWP Planner, who collect the necessary documentation and ensures the resolution of operation constraints. IWPs are issued to the field three weeks before the starting date and they have to be approved by the frontline personnel, who become accountable for their execution. IWPs are pulled by the responsible superintendent/foreman, adhering in a dynamic manner to construction requirements. After execution, IWPs are controlled by owner representatives, who perform the quality check and update project estimates.

The AWP approach is gaining increasing attention from the industrial practitioners’ community in North America (i.e. through dedicated conferences and communities of practice). However, this approach still requires further rigorous analysis and empirical validation. As various scholars advocated a closer connection between theory and practice in project management (Koskela and Howell, 2002), the present research aims to:

- Provide in-depth insights on the AWP implementation process throughout the three project phases.
- Explore the impact of AWP on key project performance dimensions (cost, schedule, quality, safety).

3 RESEARCH METHODOLOGY

The explorative nature of this research has driven the methodological choice towards a qualitative approach (Yin, 2014). Case-based research has been selected as the most suitable technique to
empirically investigate the research objectives. Hence, multiple case studies are useful to obtain in-depth results on phenomena that are embedded in a complex and uncertain environment (McCutheon and Meredith, 1993), such as the industrial construction sector.

The unit of the analysis of the case studies is the project, which is analyzed from initial scope definition to the completion of field activities. Two industrial projects have been selected because involving the separate construction of identical systems as part of the same project. These systems were also executed in parallel, on contiguous sites, and by the same project companies (different crews but equivalent contractual and incentive structures). The systems can be considered identical apart from AWP adoption. AWP was adopted only for the execution of one system, while the other one was performed with traditional planning approaches. This duplication allowed using a replication logic (Yin, 2014) to isolate as much as possible the impact of AWP on project performance – increasing results reliability.

The first case study involved the construction of the necessary infrastructure to build twelve additional wells on two existing extraction sites in a North Eastern region of the United States. Construction activities were equally divided between the two sites and AWP was implemented only in one of them. The project had a duration of 4 months for a total of 160,000 construction hours. Project scope included also a modularization component for the construction of four pipe-racks. The remoteness of project locations, the limited duration of the construction season, and the high labor demand all necessitated effective integration between construction and engineering. This represented the main motivation for the Owner to test AWP effectiveness.

The second case study involved the construction of the necessary infrastructure to progress mining activities into two sites neighbouring an existing extraction facilities in Alberta, Canada. The project was mainly characterized by intensive civil and piping activities, which included the completion of two dykes and the partial development of a dedicated disposal area. As for the first case study, project activities were equally divided between the two sites and AWP was implemented in only one of them. The project had a duration of 12 months for approximately 1 million construction hours. The Owner decided to implement AWP to improve constraint mitigation during the upfront planning stage.

Table 1 highlights the main characteristics of the two case studies, namely: project sector, scope, construction hours, construction duration, and interviewees’ role.

*The role can be: Owner (O), Constructor (C), and Engineering (E).

The data collection process involved four main areas: AWP process; project performance; organizational implications; discussion on implementation challenges, and lessons learned. To increase the validity and reliability of the data collection process, the following measures have been adopted:

- The interviews were conducted through a semi-structured questionnaire (Voss et al., 2002). Each interview had a duration of approximately 1 hour. The questionnaire was sent in advance to the interviewees to increase the efficiency of the data collection process.
Multiple informants were consulted for each case study. Interviewees were selected to represent key project participants (see Table 1) – thus taking part to AWP implementation from different perspectives in order to triangulate the results and increase findings reliability (Gibbert et al., 2008).

Each interviewee provided a feedback on case study results to ensure data reliability (Creswell and Miller, 2000).

4 RESULTS AND DISCUSSION

Each case study is reported separately and focuses on:

- The AWP implementation process from preliminary planning to construction.
- The performance differences between the site with-AWP and the site without-AWP.

4.1 Case Study 1

In this first case study, the owner began the definition of AWP procedures during preliminary planning together with the Engineering and the Contractor companies. The goal of this early planning stage was to achieve AWP buy-in and obtain a reliable high-level scope decomposition in accordance with the construction sequence. The owner hired dedicated planners to provide constructability input during the engineering phase.

At the Level 2 Schedule, the project management team defined the deadlines for the development, issuance, and review of CWPs and EWPs. As detailed engineering neared completion, the project management team handed off the remaining planning efforts to the contractor’s planning team. Recognizing the value of pre-mobilization planning, the owner brought the contractor’s planning personnel to the home office two months prior the initial construction date.

The contractor did not utilize dedicated AWP planners – because of the limited project size – but rather traditional construction field personnel, who were responsible to perform the planning process. These personnel included superintendents and discipline foremen – such as electrical, instrumentation, piping, structural, and scaffolding – that were selected because they would be directly executing IWPAs and had substantial planning experience. The planning team dissected the scope of work in accordance to the separate parts of the construction assembly sequence and created IWPAs to support this sequence. IWPAs were developed to a Level 3 Schedule. IWPAs were broken-down by construction areas, module interfaces, and termination points. They were not homogeneous in terms of construction hours, so that different disciplines had IWPAs of different size. The project resulted into 40 IWPAs. As systems neared completion, the focus shifted from construction by area to system commissioning. Consequently, all IWPAs were designed to include turnover specifications.

After planning completion, IWPAs were sorted by discipline and issued in total to the responsible foremen. The issuance process was not in line with prescribed methodology that recommends to deliver the packages three weeks before the beginning of field activities. This lump IWP distribution generated a document control management issue, which arose when minor engineering specifications changed and then needed to be updated. The foremen became accountable for work completion and organized IWPAs execution into a logical construction sequence. To control working activities, foremen updated a weekly progress spread-sheet, by recording installed quantities. Planning meeting were held weekly between superintendents and project controls personnel to determine project progress. Upon completion, IWPAs were returned to the field office to incorporate lessons learned.

In terms of project performance, the interviewees reported various differences between the site with-AWP and the site without-AWP (see also Table 2):

- Cost. Although the project on the site without-AWP was completed on-budget, work stopped several times as a result of ineffective planning. Plans delivered to construction personnel were not
constraint-free and not developed at a sufficient level of detail. This led to inefficient field operations, which were often relocated across different construction areas, compromising field productivity. The site with-AWP completed the project under-budget and with a cost savings of $740,000 in labor. This result was obtained by minimizing the waiting time for materials and drawings for the crews. IWPs were effectively delivered to support construction activities. Moreover, the contractor reported that the inclusion of complete scope portions into specific IWPs allowed the crews focusing on one specific area at the time. As such, productivity was 20% higher than estimates.

- Schedule. The project without-AWP was delivered on-schedule. Crews were re-assigned to other tasks when their work was stopped, so that the overall project schedule was maintained. The project with-AWP was completed ahead of schedule, allowing the systems to be placed in service five days earlier than planned. Schedule savings were caused by the improved field productivity of construction operations, which allowed anticipating or parallelizing activities.

- Quality. For this project, welding activities represented the biggest portion of field activities so that quality is here measured in relation to this process. The site without-AWP highlighted a 2% weld reject rate, which was in line with contractor’s historical performance. The site with-AWP highlighted a 0% weld reject rate. This performance was linked to the more accurate planning process that is achieved through AWP. On the site without-AWP, welds were performed in the field under the influence of inclement weather, with little or no protection from the external environment. On the site with-AWP, the planning team was able to analyze the locations of field welds during IWP development. This analysis allowed grouping the weld areas together to perform the construction process under temporary shelters. These shelters provided better protection from the environment and, thus, improved process quality. In general, the owner qualitatively reported a reduction of reworks in the site with-AWP, mostly due to reduced scope and engineering changes. Most of the engineering changes were identified and mitigated during detailed engineering, rather than during construction when the impact of changes is higher.

- Safety. The site without-AWP reported one recordable injury. This injury was attributed to the re-direction of the crew to another area and to the worker’s self-imposed pressure to complete a scope of work that was unfeasible. The site with-AWP reported zero recordable injuries. This performance was attributed to improved risk identification and mitigation during IWP development and execution. Because the work was better planned, there was significantly less re-direction of crews on-site due to unforeseen constraints. Also, safety considerations were included into each IWP, so that the foremen were able to increase crew’s safety awareness during the daily briefing before operations started.

4.2 Case Study 2

In this second case study, the owner set up an AWP team together with members from the Owner, Engineering, and Contractor companies during the preliminary planning phase. The aim of the team was to obtain early alignment on AWP planning procedures and definitions. During the preliminary planning process, the AWP team divided the project scope into CWPs and integrated the various plans accordingly, checking for scope gaps and overlaps. Involving the contractor at this stage was fundamental to include constructability principles since the very beginning of the design process.
Subsequently, CWPs and EWPs were finalized and integrated in accordance with the scope and the complexity of construction activities. For example, the piping discipline allowed including many decoupling points across the construction areas (e.g. valves), so that one CWP typically included multiple EWPs. For other disciplines, such as electro-mechanical that is characterized by a larger amount of work-hours per system, boundary definition was more problematic and one CWP might have contained a single EWP. The planning team performed constraint minimization for every CWPs and EWPs, ensuring the definition of long-lead time items and turnover sequence. Also, major equipment requirements were identified and evaluated at this stage.

After the generation of EWPs, the detailed planning phase was managed by the contractor and supervised by the owner. Most involved organizational roles were: Superintendents, Materials Coordinators, and AWP Planners. The role of Owner’s AWP Planners was oriented at the support and coordination of the detailed planning process. CWPs were divided into multiple IWPs following the “one crew – one shift” principle. A shift included 10 working days and approximately 2000 working hours. IWPs were completed three weeks before the start of construction. Then, they were issued to Superintendents one week before the construction date to check and approve the documentation. The progress of each IWP was controlled on a daily basis by Foremen and Owner’s representatives through specific scorecards.

The comparison between the two sites (with- and without-AWP) highlighted substantial differences in each performance dimension. Results are described below and highlighted in Table 3:

- **Cost.** The trend for the project without-AWP resulted in budget overruns for $100,000. The project with-AWP was concluded 10% under budget. The owner reported that AWP allowed a more precise and accurate budget definition. The contractor highlighted an increased profitability related to AWP implementation. The profit for the project with-AWP was approximately three times higher (300% increase) compared to the project without-AWP. Such profit increase was mainly due to the better utilization of major equipment.

- **Schedule.** At the time of the interviews, the project with-AWP was concluded on schedule while the project without-AWP was still requiring three months of work. This delay was due to the unsophisticated schedule definition that took place only at a macro-level and that was supported by unsophisticated paper-based tools. The lack of transparency and the poor definition of details resulted in schedule overrun and to consequent reactive measures to cope with it. On the other site, AWP implementation required the contractor to provide accurate and reliable schedule estimates for IWPs. Hence, the contractors had to review, agree, and sign each IWP.

- **Quality.** The owner reported that the site without-AWP was characterized by a lack of consistent upfront planning that resulted in poor control over site activities. The contractor provided a large amount of Request For Information (RFIs), opposing the sequence and the feasibility of operations that resulted in widespread delays and reworks. The site with-AWP highlighted a smaller number of field reworks. Hence, the sequential release of IWPs allowed mitigating the effect of delays and errors by reducing the variability of field activities, so that each IWP was shielded by the variations occurring on other work-packages. The site with-AWP was also characterized by a smaller number of RFIs, which shifted from the execution to the planning phase when their impact on project cost and schedule is substantially minor.

- **Safety.** After one million hours, zero safety incidents were recorded for the project with-AWP. This result was particularly relevant if compared with the trend of the site without-AWP, which consisted of a recordable injury every month. The structure of IWPs constrained the workforce to focus on a single area, reducing useless and dangerous movements around the site. Also, IWPs prescribed that materials and equipment had to be cleared away from the working area after each shift, providing a cleaner and safer jobsite. AWP procedure was used to influence psychologically the workforce by highlighting safety rules and procedures at the very first chapter of each IWP. Superintendents and foremen got used to think to safety since the beginning of construction activities.

4.3 Discussion

The two case studies highlighted many commonalities but also differences with regard to AWP implementation procedures (e.g. lead-time before issuing IWPs to the field, level of owner involvement during IWPs development). In both case studies, however, AWP emerged as an important factor that contributed to achieve consistent project performance improvements. These improvements have been directly related to AWP adoption by the various interviewees, who stressed the importance of implementing systematic procedures to decompose project scope in a systematic and integrated since the initial planning phase.

Besides the quantitative improvements in terms of key performance dimensions, the interviewees reported additional “qualitative” benefits related to AWP:

- **Integration between Construction and Engineering.** The involvement of construction representatives since the initial planning phase allowed including consistent constructability input to the whole project sequence. The owners acknowledged higher collaboration between construction and engineering as well as between different construction disciplines (e.g. electrical and mechanical). The early involvement of engineering and construction representatives shaped a proactive team culture that benefited from the know-how of both departments especially during the constraint minimization process.

- **Execution Accountability.** AWP methodology required the contractors to provide accurate estimates for the execution of each IWP. Contractors, in exchange, received a complete and constraint-free documentation to execute IWPs. To foster accountability, Superintendents participated to the development of the same IWPs that they would execute in the field. They were able to edit, negotiate and correct the construction plans, taking ownership of scope execution by signing each IWP before the beginning of field activities.

- **Workforce Retention.** AWP was credited for lower employee turnover rates within craft personnel in both case studies. Lower turnover rates for the projects with-AWP were attributed to three main factors. First, the extensive training activities performed on AWP topics resulted in higher workforce engagement. Second, the development of a safe and organized construction environment enhanced workers’ satisfaction. Third, the early involvement of constructors made them feel part of the team, increasing their commitment to the project with a proactive role.

Both owner companies reported that the primary difference between AWP and traditional planning methods was the ability to identify and resolve construction constraints prior to field mobilization. However, AWP implementation did not come “effortless” and every company had to overcome consistent change resistance at the functional and at the inter-organizational level. In both case studies, the owner was the main driving subject to push for AWP adoption, which propagated from the final risk-taker (the owner) to other project participants (Engineering and contractors). Hence, interviewees underlined that AWP has to be fully supported at the various hierarchical levels to be effective, from top-management to craft personnel. The interviewees reported that the inclusion of AWP guidelines into the contractual terms fostered personnel buy-in. This contractual inclusiveness should be supported by a dedicated AWP training process in order to avoid that procedures are adopted only for bureaucratic purposes.
5 CONCLUSIONS

This research is aimed at providing empirical evidence of the performance improvements related to AWP implementation. The results of the case studies highlighted that the projects adopting AWP performed better than the projects without AWP in terms of cost, schedule, quality, and safety performance. The reason for this improvement can be traced back to the more systematic planning process undertaken since the initial project development phase. The early involvement of key stakeholders resulted in a reliable set of plans that are iteratively decomposed and delivered to support construction activities. Identifying and solving project constraints – such as materials and engineering drawings availability – fostered the productivity of field activities by reducing the amount of waiting time and the subsequent re-allocations of crews to unplanned activities.

From a theoretical perspective, the present article highlighted the shortcomings of current work-packaging literature and investigated the applicability of AWP as an emergent approach for the industrial construction sector. AWP contributes to previous research by extending the traditional work-packaging principles to the early planning stages. This approach enhances the development of collaborative relationship between project participants, providing further evidence on the importance of early integration practices for Construction Management literature. From a practical perspective, the present article provides in-depth details to Construction Managers on successful AWP implementation. This research highlights empirical results from real industrial projects that can be used to replicate AWP benefits. Lessons learned are drawn for every key participant: the owner should be the responsible and the most committed subject driving the implementation process; engineering should modify the traditional way of issuing deliverables to construction by providing complete and timely EWPs; contractors should proactively participate to the planning process and take accountability for the execution of field activities.

The main limitation of present article resides in the size of the case study sample. In-depth findings have been preferred to generalizability. Another limitation can be found in the assumption that the only difference between the site with-AWP and without-AWP was the planning approach itself. Although there might be additional factors explaining the performance variance (e.g. construction crews’ skills), every interviewee linked the root cause of performance improvement to AWP implementation, providing convincing and consistent justification.

Future research developments could be oriented at increasing findings generalizability by performing additional case studies in different construction sectors, such as power or commercial. A second potential development could involve the definition of specific performance metrics to measure the “goodness” or the “maturity” of AWP implementation. The comparison between different levels of AWP implementation with different levels of project performance would represent an important contribution to further validate this relationship. Finally, the case studies highlighted that AWP implementation is a complex and resource-consuming process that involves widespread change management implications. A third research development could investigate in details the implementation challenges related to AWP.

Abstract: The rapid development of Construction Method has posed a challenge for construction industry. This paper utilizes current Technological Innovation Method to accelerate the development of Construction Method. The Rapid Innovation Model is established based on the traditional technology innovation. This model contains four parts which can be divided into nine steps: definition of problem, fundamental reason analysis, selection of target technique, functional model analysis, scheme evaluation, experiment method, effect evaluation, summary and further application. Moreover, this paper introduces the process of SPIP Method which contains three phases: interpreting the problem according to basic reasons, seeking the answer by patent analysis and construction model and getting the solution by TRIZ and invention principle. In summary, the rapid innovation model meets both the speed and the quality requirements of Construction model development, pointing out a new way of developing construction model.

1 INTRODUCTION

The efficient and sustained, steady and rapid development of construction depends on the support of construction innovation technology. The current construction enterprise faces more challenging changes from market environment. Capability of rapid innovation in construction methods has become an important factor in determining the speed of enterprise development. Unlike other industries, the construction enterprise and its technology innovation has a strong characteristic. Construction business innovations can be classified by their functions, including engineering methods, customer service, design, construction, information technology, management, materials, occupational health and safety and ecological design and construction. Nam and Tatum(1989), based on the survey of the construction product innovation, pointed out that there were four key factors playing important roles in construction process: the owner's needs, problems, design of technical reserves, and the contractor's technology level. Dulaimi, Ling and Bajracharya(2004) discussed the possibility of construction projects to adopt innovative motivation and innovation activities interaction between participants in the organization based on two organizational theories regarding motivation and organizational relationship. Foreign scholars who specialized on the method of related studies have focused on the technical level of the specific construction methods, while the research of management mode of the method is limited. There is only a minimal amount of literature within the nation that comes from the perspective of qualitative description in connotation of methods, characteristics and significance and etc. Such literature stays in the summary of universal knowledge, and there is no further discussion of construction management in the method development process and the principle and constructive problem in the development of innovative
models. Overall, the existing research results are unable to provide guidance and examples to further support or strengthen the construction management innovation.

In the field of construction, the technology innovation is slower than other industries mainly due to the lack of innovative tools and systematic approaches. At the same time, along with the uncertainty of construction environment increasing, the innovation of construction method itself and the methods for construction method developed is needed; some new ideas are in great demand in the study of problem related to the development of engineering methods. How to develop a complex method as soon as possible has become a hot topic both in theories and practices, since the modern construction technology is no longer a traditional simple technique, but rather a complex integrated system. Based on the current situation, this paper developed a model of complex systematic engineering methods in order to rapidly develop innovative process (SPIP) for technology application. Combining with existing innovative approaches, this paper proposed a SPIP system model for rapid development of construction method.

2 CONSTRUCTION METHOD INNOVATIVE SYSTEM PROCESS MODELS

As the owners’ expectation and demands for the safety, quality and time cost of the project raised, advanced construction methods are required due to the needs of higher construction speed and quality. In this scenario, the speed of technique innovation has become as important as other business factors such as cost and quality strategy.

2.1 Traditional Construction Process Engineering Methods Developed

Method development should not only focus on building products, but also on resolving all sorts of building problems in the process of overall consideration. Therefore, the method development is a complex and innovative process, a mature product from construction enterprises accelerating their scientific and technological achievements. It is also a planned and organized activity of study, improvement and promotion of construction methods. Method management of construction enterprises includes new understanding of the power of innovation and opportunities, generation of innovative atmosphere and development of the necessary skills, providing the construction enterprises new construction technologies after testing, refinement and implementation.

Today, the implementation of the method system in China is still a novel thing. Generally, enterprise develops construction method from summaries after action, of which the main work includes: the development of construction method and establishment of management system, technical data collection, decision of development theme, novel finding in construction method theme, redacting construction method materials according to the writing code of construction technique, construction method declaration, construction method validation, engineering methods application, and summarization and improvement. The traditional development method of construction methods is a management-driven and consolidation-based development model. It recreates and formulates new construction methods through studying and refining the experiences accumulated in the past.

With the progress of technology and social development, the great uncertainty of the external and internal environment of projects lead to enormous challenges in traditional construction method development model. Construction method belongs to the category of construction enterprise standards. It is an important component of enterprise standard, which is a standardizing description of the stable and deterministic content in the project. Therefore, the precondition of the method development is the certainty and repeatability of the construction content itself. However, the fluidity of the construction process, the one-piece quality and type-diversity of the construction product and the complexity of the construction production process have determined that the construction method in construction production process is uncertain. Traditional hindsight paradigm has become insufficient to meet the increasing personalized needs of the construction, unable to bring sustainable competitive advantage for construction companies.
2.2 The Process Model of Construction Method Innovative System

The rapid-develop approaches of complex construction method include comprehensive transplantation type, development-oriented type, unearthing type, local modification type and reverse development of type. Comprehensive transplantation type means to transplant the existing soft and hard technology to create a new technology or to improve existing technology function significantly; development-oriented type is the result of the use of new technologies, new materials, new processes and new equipment; unearthing type refers to study, refine and demonstrate the experience accumulated in the past or the approaches for new situations encountered in the field, and then create a new construction methods; local modification type refers to a partial improvement of existing engineering methods in the promotion of the application shortcomings; reverse development type refers to the introduction of engineering methods to decipher analysis, combining with corporate and project circumstances absorption and transformation. Based on the common feature of all the types mentioned above, this paper extracts the process model of complex construction method innovative system (Figure 1). Complex method process model of innovation system includes four parts which can be divided into. The four parts are subject inspection method, evaluation, design, methods and diffusion method. The nine steps include the definition of method design problem, root cause analysis, target technology selection, function model analysis and correction, scheme evaluation, test, evaluation, summarize the method and application.

![Figure 1: The Systematic Process Model of Complex Construction Method Innovation](image)

3 DETERMINATION AND ASSESSMENT OF METHOD INNOVATION TOPIC SELECTION

The topic scope and differences of the construction method directly affect the development and popularization of method. Construction method topic is not only the fist step for developers to think about and prepare for the method, but also an important factor affecting the quality of construction method. Topic selection is the foundation of technique innovation. The pertinence of the topic to a certain extent
determines the success or failure of technique innovation. In the method management, it is clear that topic selection should be combined with technical research, scientific and technological achievements, promoting the transformation of scientific and technological achievements. In the actual development process, the method choice should emphasize not only advancement but also practicability. Therefore it is an important link during which decisions are difficult to make.

### 3.1 Methods Determination of Topic Selection

The purpose of construction method development is to accelerate the application of scientific and technological achievements to realistic productivity and advanced construction experience, to transform conventional technology with advanced technology, to replace the retiring method with advanced experience and to replace empirical evidence with scientific process. Therefore, we cannot use the construction method for the sake of using it; instead, we should be able to summarize and extract from the construction methods, improve construction skills and management system. Principles for theme selection of construction method include opportunity evaluation, importance evaluation and controllability evaluation. The opportunity evaluation refers to the company's business activity levels and company personnel that determine the corporate vision to explore construction methods. The importance evaluation includes innovation and practicality. According to the construction method, it must be proven by practice of the mature technology, and controllability evaluation includes two aspects: research and development strength and construction project performance.

![Figure 2: The Funnel Model of Selecting Construction Method Theme](image)

General construction method development process is divided into technical data collection, development theme determination, theme method research, construction methods writing, the examination and approval of application of method, method declaration, method application and summarization and improvement. The method filter funnel is formulated by the possibility of phase optimization in the construction method theme as the phases proceed (Figure 2). Funnel model refers to the fact that during the development process, the construction technique (also called latent construction method) is gradually transformed into the actual working model law. The model vividly describes the process and the mechanism of making choice.

In addition, for complex method, it also needs to apply value-engineering methods to determine the development of specific targets. Because it is difficult to accurately select the object of innovation in scheme design, we can use the coefficient of function evaluation as basis and select value as evaluation yardstick to develop construction method target. By means of quantitative evaluation on each constitutional element in the system, there are many levels to choose developing object of construction methods for developers, pointing out the direction for further improvement.
3.2 The Root Cause Analysis of Topic Selection Evaluation Method

For the development of construction methods, the first step is to figure out what construction question is and what is the cause of the problem. Method emphasizes the application as the guidance and chose the problem in the construction process as a starting point. There are many reasons that have caused the problems, but the root cause is the key. The problem can be solved fundamentally merely through identifying and troubleshooting the root cause.

Most difficult problems in the construction have more than one single coping method. These different solutions pose different resource requirements for the construction enterprises. Root cause analysis of the problems (Root Cause Analysis, abbreviated as RCA) is a structured problem solving approach that gradually identifies the root cause of the problem and resolves it, which includes analysis to determine the cause of the problem, solutions to problems and preventative measures to the problems.

Generally there are various causes of problems, such as physical conditions, human factors and system behavior or process factors. But the root cause, as the most fundamental cause of the problem, should be mostly concerned. RCA includes: problem identification (what), root cause analysis (why), corrective and preventive actions (any way to prevent problems from happening again).

For example, the pipeline leakage in multiple high-rise buildings will induce secondary damage to building structure and interior decoration. There are many reasons of leakage, and the establishment of RCA model is shown in Figure 3. Through it we can find out the key causes of pipeline leakage. Figure 3 shows that the root cause of pipeline leakage is "concrete crack" or "rupture". The reasons for these two fundamental factors include earthquakes, corrosion and temperature. RCA model also shows that if these two fundamental reasons are resolved, pipeline leakage can be repaired. Therefore, according to the RCA model, the possible rehabilitation program can be "concrete block gap" and "fix broken pipes."

![Figure 3: The RCA Model of Pipeline Leakage](image)

3.3 The Project Technology of the Selected Topic Selection Evaluation Method

Since the construction method has become a new method that construction techniques, new materials and new equipment are combined with, innovative ingredients in the construction method are also increasing. Patents and construction methods that were once separated are now combined, and the combination has become tighter and tighter. As a result, there has been construction method patents and patent method that are of mutual transformation trend. Therefore, analysis and patent analysis should be strengthened in the topic selection evaluation method in order to enhance innovative method.
3.3.1 Engineering Method Analysis

Construction method of science and technology novelty search has become the precondition of the construction enterprise technology development and the first step. Compared to other professional science and technology novelty search, construction method of science and technology novelty has some common characteristics as well as its unique features. Novelty searching work is based on the literature, and the method of novelty search is the same. It is retrieved from the method directory, which has been released by the nation or the province, and find out whether the same method exists. Even if the construction project is the same, as long as there is a new operation method or the construction technology, new method development can be achieved. The pioneering research of shield construction methods of Sany Group, for example, set up a professional team on the shield construction methods that include wide sets of shield construction methods and cases both at home and abroad, summarizing previous construction experience and forming a huge shield method database that contains thousands of shield construction method, construction cases, failure model and solving scheme, and etc.

During the process of construction method of science and technology novelty search, based mainly on statistical analysis of construction method, the current status, level and the future of Chinese construction method are understood. This paper, summarizing the method published by the national and provincial in decades, has extracted and refined the keywords as shown in Table 1, Table 2 and Table 3 below. From keyword density (frequency), the hotspot of construction method development comes out.

Method keyword analysis can be used in the long term. As new data added each year, it will be able to observe the changes along with time and its trends of development. Method keywords play a connecting role in information analysis work and it is the base for the analysis of construction method information. Through the construction method of comparative analysis and keyword research, we can make predictions and judgments and extract valuable information about development level, status and trend, providing a reference for the development of construction method decisions.

3.3.2 Patent Analysis

With the emergence of complex construction systems, the construction method that includes patents emerges in large numbers. For example, in Wuhan’s China Petroleum Building project, China Metallurgical used a "major axis diameter of 56 meters, 48 meters in diameter in the minor axis of the ellipse combination of structural support, within two oval combination of vertical structural support" construction method for the world’s first, remarkably shorting the construction period. The construction method has also resolved the deformation control, strength increase, water seepage reduction and other technical problems. A complete set of methods includes four patent technologies of China Metallurgical. If
a construction method can meet the novelty, inventive and practical features, it can be declared for patent protection. Therefore, when assessing topics in construction methods, patent analysis strengthen is needed. Since the patent has the characteristics of creativity, novelty and practicability, patent information becomes an important source for scientific research of new product and research results on the social and enterprise level. Patent analysis refers to searching the relevant patent literature, statistics, analysis and screening, and turning the patent into available information for construction method.

For example, leakage repairing of pipeline embedded in the reinforced concrete, the alternative repair plan can be "block concrete crack" and "fix a broken pipe". From existing evidence in the United States patent search, the related patents are shown in table 4.

After studying the patent directory, Yu, Wu and Lien (2008) found that US4758295 (method to stop leakage phenomenon in concrete structures) used in foaming agent as the repair material can be an innovative option.

4 TRIZ ANALYSIS IN THE DESIGN OF CONSTRUCTION METHODS

Theory of inventive problem solving, also known as TRIZ theory, is a theory developed by the former Soviet Union inventor Altshuller GS. It is a theoretical system that builds an integrated multi-disciplinary field of methods and studies solutions of various technical issues and the methods and algorithms to achieve innovation development.

The core of construction method is the key technology in construction process, and the entire process is working around key technologies. The key technology in construction method may be advanced technology, intermediate technology, or even a junior one. The choice of construction methods topics is made from integrating a large number of existing materials, technology and techniques and extracting the key principles. The idea is established from the key technology or the expansion, divergence and construction process of key technologies structures. The basic idea of TRIZ to solve the problem of innovation is studying the basic condition deeply, combined with system evolution model to confirm the problem of ideal solution and the contradictions of system, and then find the resources available to eliminate contradictions so as to solve the problem.

4.1 Problem Description

To analyze a given problem, the first thing is transforming the practical problems into TRIZ. TRIZ theory believes that the core of the invention is to solve the problem of contradiction. In the repairing of pipe embedded in reinforced concrete structure, the problem can be defined as a technology contradiction, the parameter intending to improve is "moving object area" and the degraded parameter is "structural stability". The parameters intend to improve and degrade consist of the contradiction in the technical system. In other words, construction parameter (EP) 5 (Area of Moving Object) needs to be changed under the condition of degraded EP 21. The contradiction matrix for reference is shown in table 5.
To Help users to optimize and accelerate the process of technological innovation, a funerary wares company has developed a unique tool that effectively combines innovation process called the Goldfire Innovator™. Goldfire Innovator supports product and process innovation, and can be used to determine the need to analyze systematically the question, confirm the innovation concept and examine the innovation concept by its methods and some application examples. The conceptual solutions developed through Goldfire Innovator™’s proposed Innovative solution generator (ISG) tools include the principles of the invention (IPs): (1) IP19: "regular operation"; (2) IP10: "initial actions"; (3) IP32: "vibration characteristics change"; (4) IP18: "mechanical vibration."

4.2 The Solution

Solving the problem of the invention is the core of product innovation design. Goldfire Innovator™ offers two built-in databases (scientific impact and patent database) to generate solutions. After entering the following requirements: 1. How to stop / repair leaking water permeating into concrete; 2. How to improve liquid / fluid flow / permeability, science influence database gives four solutions: (1) increase the pressure difference between the molecular energy to improve mobile liquid; (2) derive droplets from the mixture of soda capillary water; (3) use sound to increase the diameter of bubble in water; (4) bubbles dissolve the air in the water. According to the four solutions, the model in Figure 4 obtained to modify the proposed pipeline leak method from US4758295 shown in Table 4.

4.3 The key technical scheme design

Nominal design is the way to solve conventional problem, and innovative design is the way to solve invention problem. Innovative technology is based on the conceptual solution development. Compared with traditional construction technology, engineering construction key technology should achieve...
technology innovation, technology maturation, project quality assurance, construction efficiency improvement, engineering cost reduction, remarkable achievements in energy conservation and environmental protection, and etc. The final innovation of the technology solution to fix the pipeline embedded in reinforced concrete structures is as follows: put the liquid sealing material into an open mixer; open the air compressor to provide compressed air for mixing vessel; open the ultrasonic generator vibration for mixer; under the action of air pressure and vibration, the liquid sealing material gradually flow into the crack in concrete and repair the broken pipe.

5 CONCLUSION

The current focus of competition in construction enterprises usually is not the ability to manufacture engineering products, but being capable in developing a new method meeting the project requirements, using competitive new construction method in a faster speed, lower costs and higher quality to complete the construction process. In view of the method in the demand of the rapid development for the current construction enterprise and the organic combination of the innovation of the existing methods, this paper presents a system model for rapid development of the complex construction methods. The model includes: problem definition, root cause analysis, target technology selection, functional model analysis and modification, program evaluation, laboratory testing, impact assessment, construction method application and summary. Root cause analysis (RCA) model is used to describe the problem. The solution to the problem is obtained through patent analysis and method analysis. TRIZ theory and principles of the invention are also used to generate innovative solutions. System process model can satisfy both the speed and quality requirement of the new method development, and it also points out a new way to develop method.

Since the construction method is combined with advanced technology and scientific management, the process and pattern of construction method development is different from the general technological innovation. Due to limited time and data, this paper was not thorough enough in practical studies of construction method. Further research can be implemented by choosing some representative enterprises, tracking their construction method development process to obtain appropriate data and analyze the development process of construction methods. The understanding of meaning and significance of the rapid development of construction method will be more clearly.

A MODEL TO EVALUATE THE MATURITY OF CONSTRUCTION ORGANIZATIONS’ DISABILITY MANAGEMENT PRACTICES

Rhoda A. Quaigrain\textsuperscript{1,2} and Mohamed H. Issa\textsuperscript{1}
\textsuperscript{1} Department of Civil Engineering, University of Manitoba, Canada
\textsuperscript{2} quaigrra@myumanitoba.ca

Abstract: Evidence exists as to what constitutes successful disability management (DM), with many describing recent upsurge in the area as a major paradigm shift. Despite the benefits of return-to-work (RTW) programs in reducing costs and improving workplace morale, many workplaces appear unwilling or unable to develop and implement successful RTW programs. A review of the literature reveals a lack of coherent theoretical frameworks for implementing DM. This paper presents a model developed to assess the maturity of DM practices in construction organizations. The model is part of an overall research project aiming to evaluate DM in the Manitoban construction industry and its relation to health and safety performance. This project is conducted by the University of Manitoba Construction Engineering and Management Group and funded by the Workers’ Compensation Board of Manitoba. The proposed model is based on existing construction industry maturity models and the concept of process improvement and relies on leading and lagging indicators of performance at the organizational level, thus enabling a thorough evaluation of it. Once validated, the model should help construction organizations evaluate their DM practices against best practices, identify and address areas where improvements are needed, and assess and benchmark DM performance on a regular basis, thus providing a framework to guide the advancement of DM. Similarly, the model can be used by Worker’s Compensation Boards, safety associations and other regulatory bodies across Canada and elsewhere for auditing purposes.

1 INTRODUCTION

Disability management (DM) performance has traditionally been at odds with project and organizational performance. Research in the field (Amick et al. 2000; Rosenthal, 2003; Shrey, 1995; Millington and Strauser, 1998; Ngai et al. 2013) has traditionally argued that disability management (DM) practices used up organizational resources and weakened organizations’ competitiveness. With the advancement of knowledge in the field, researchers have begun to realize the benefits of DM practices (Reynolds et al. 2006). A study by Geisen et al. (2008) on workplace DM shows not only economic incentives but also corporate culture and external incentives for establishing in-house DM. With proactive DM practices, companies are able to generate additional business opportunities, and reduce DM costs (Amick et al. 2000; Ngai et al. 2013). Despite the advancement of knowledge in the field, DM in the construction industry receives limited research attention (Lingard and Saunders, 2004: Omerald and Newton, 2013). A review of the literature shows a lack of clear and coherent frameworks for managing disability management, especially in the construction industry (Lucas, 2010). There is in particular a lack of frameworks for the implementation, monitoring and evaluation of DM practices (Tshobotlwane, 2005). This makes it difficult for construction organizations to evaluate the maturity of their DM programs and by
extension improve them; leading to a situation wherein the potential benefits of FM cannot be fully realized in the construction workplace.

This research, currently in progress aims to develop and validate a disability management maturity model called the Construction Disability Management Maturity Model (CDM3) for use in the construction industry. The model has two major functions. First, CDM3 provides an assessment framework with five maturity levels for analyzing construction organizations’ DM maturity. Second, it provides a progressive framework to guide organizational advancement in the field.

This paper reports on the work that has been done so far by the Construction Engineering and Management (CEM) Group at the University of Manitoba and funded by the Workers Compensation Board of Manitoba as part of this research. This work aims to: 1) review the use of maturity modeling in construction, 2) present an overview of the CDM3, its features and theoretical underpinnings, and 3) describe its proposed implementation. The paper concludes by highlighting the strengths of the CDM3, and future work associated with it. Construction organizations should be able to use the tool/paper as a basis to assess their performance and address issues regarding their DM performance. The tool will be flexible enough to allow for its modification to accommodate changing guidance in the future and thus allow for a more accurate evaluation of existing practices against those changing best practices. The paper additionally provides a foundation from which further investigations can be impelled.

2 LITERATURE REVIEW

This section includes a review of the concept of maturity modelling in general, and as it applies to the construction industry in particular.

2.1 Disability Management

Disability Management originated from the concept of older vocational rehabilitation programs for injured workers and gradually evolved to incorporate the return to work (RTW) model. It incorporates three key domains: prevention, early intervention and proactive RTW interventions to reduce the impact of injury and disability and to accommodate those experiencing functional work limitations (Quaigrain and Issa, 2014). DM a model integrates protection from work hazards and promotes improvement in personal health behaviours (Angeloni, 2013); however this aspect is hardly harmonized and considered in implementing DM in workplaces. Despite the benefits of RTW programs in reducing costs and improving workplace morale (Shrey and Hursh, 1999), many workplaces appear unwilling or unable to implement and sustain successful RTW programs (Brooker et al, 2012). A systematic literature review of evaluative studies of modified work (Krauset al. 1998) noted little documentation of program implementation or the strengths and weaknesses of RTW programs. According to Tshobotlwane (2005) employers have frequently overstated the cost of adjustments in respect to accommodating disabled persons in their workplaces as an excuse to discreetly discriminate in the workplace. A comprehensive DM program enables early preventative actions and intervention, helping to alleviate many of the concerns experienced by injured or ill employees. Most employees want to be able to return to work, whether or not they would is dependent on the comprehensiveness of the DM program (Quaigrain and Issa, 2014).

2.2 Conceptualization

Maturity modeling emanated from the software manufacturing industry (Finnemore et al, 2000) in response to the poor performance of software manufacturers working on US Department of Defense Projects (Pauluk et al. 1995). It is based on the earlier concepts of process improvements such as Philip Crosby's quality management maturity grid describing "five evolutionary stages in adopting quality practices" (Crosby, 1979) and the Shewhart plan-do-check-act cycle (Pauluk et al. 1995). Process maturity modeling consists of various stages of progression which, when adhered to increases the effectiveness of a process. One of the earlier models is the Capability Maturity Model (CMM) developed by researchers at Carnegie Mellon University (Pauluk et al. 1995). CMM uses the original framework of maturity modeling and defines five thresholds or levels of maturity for a given process (Pauluk et al. 1995). At the first level, a process is primarily chaotic or ad-hoc. It is made repeatable at the second level, after which it becomes
defined or standardized. At the fourth level, a process is usually measured or controlled, before it is optimized at its highest level by subjecting it to continuous improvement and feedback cycles.

Assessing the maturity of a process involves investigating the degree to which the process is defined, managed, measured and controlled (Dorfman and Thayer, 1997). This is usually accomplished by analyzing the policies and practices existing within the process (Paulk et al. 1995). Process maturity modelling was found to reduce the overall software development cycle in the field of software development (Harter et al. 2000) and improve project performance in the field of project management (Ibbs and Kwak 2000). It also improves the forecasting and meeting of goals, costs and performance (Lockamy and McCormack, 2004).

2.3 Maturity Modelling in Construction

In construction, the concept has been applied to develop maturity models such as the Standardized Process Improvement for Construction Enterprises Model (Sarshar et al. 1998), the Construction Supply Chain Maturity Model (Vaidyanathan and Howell, 2007) and the Construction Industry Macro Maturity Model (CIM3) (Willis and Rankin, 2011). A number of maturity models have been developed for project management specifically, with the Project Management Maturity Model being the most notable of all (PMI, 2005) and the Fuzzy Industry Maturity Grid being the most used at the macro level. Only one model has so far been developed for health and safety in construction: the Health and safety Maturity Model (Goggin and Rankin, 2009). The DM model currently being developed builds on these five existing models which are reviewed below. It should be noted that although five models are reviewed in the paper, the model (CDM3) still being developed will incorporate other relevant maturity models not outlined in this paper.

CMM integration (CMMI) is an extension of CMM composed of a collection of the best practices in the areas of product and service development; service establishment, management, and delivery; and product and service acquisition (Ngai et al, 2013). CMMI provides guidance for continuous organizational improvement by integrating inter-organizational functions, setting process improvement goals and priorities, providing guidelines for quality processes, and establishing a reference point for appraising current processes (Mani et al., 2010). CMMI has two different representations of maturity, namely, staged representation and continuous representation. CMMI representation uses six capability levels ("incomplete," "performed," "managed," "defined," "quantitatively managed," and "optimizing") which enable organizations to track, evaluate, and demonstrate organizational improvement within process areas (Ngai et al, 2013). Staged representation is a more appropriate reference framework for CDM3 because it provides a highly generic measurement of the maturity of DM practices as a whole and not according to the maturity level of each specific process area (Mani et al., 2010).

The Standardized Process Improvement for Construction Enterprises (SPICE) Maturity Model was developed by researchers at Salford University to improve the management of construction processes, as called for in the Latham report on the performance of the UK construction industry (Sharshar et al., 1998). The framework consists of five maturity levels. It involves testing an organization’s key processes against five process enablers (Finnemore et al. 2000). They applied the SPICE maturity model to four construction organizations, while Amaratunga et al. (2002) tested it on a facilities management organization. Both studies found its assessment to be based on facts rather than perceptions. They also found that the model identified process strengths as well as weaknesses, and enabled the development of improvement and implementation plans. Its main limitation is that it does not account for the multi-organizational nature of construction work (Vaidyanathan and Howell, 2007).

The Construction Supply Chain Maturity Model (CSCMM) is based on the concept of process maturity as used in the CMM and consists of four levels of maturity. The CSCMM assumes that for a construction firm to grow with respect to supply chain maturity it must do so along three dimensions: functional, project and firm. The model was proposed with the objective to offer a roadmap for supply chain members to improve performance through operation excellence of process, technology, strategy, and value (Vaidyanathan and Howell, 2007). Although model does address multi-enterprise supply chain aspect of construction, but it does not handle the maturity of other aspects such as BMI and hence cannot be directly applied.
The Construction Industry Macro Maturity Model (CIM3) is based on an adaptation of the concept of process improvement as used in the CMM. The CIM3 assesses the maturity of the construction industry at the macro level and provides leading indicators of project performance. There are three possible maturity levels associated with each key practice. The evaluation of each key practice is based on the presence of specific outcomes/indicators. It utilizes the analytical hierarchy process (AHP) and questionnaires to conduct the assessment. The utilized detailed levels of maturity adopted may be appropriate for use at the macro level given the characteristics of the industry, however from the organizational level perspective may be deemed inadequate and over simplification of the growth process (Willis and Rankin, 2011).

Finally, the Health and Safety maturity model (Goggin and Rankin, 2010) assesses maturity partly through AHP and questionnaires based on six key safety factors. Its scale is restricted to three maturity levels to simplify the data collection and analysis process. The model however inadequately takes into covers injury management and preventive practices.

A specific comparison can be made of the differences in cumulativeness of the models. In general, a specific trait of maturity models is that levels are assumed to be cumulative. That is, achieving level z implies that level z1 is also fulfilled. Interestingly, although existing construction maturity models provide leading indicators of construction industry performance both at the macro levels and organisational levels, none of them provides a context in which to interpret the performance of the construction industry in relation to its DM practices and subsequently correlated it to its overall health and safety performance. The development of the CDM3 is based on adapting and combining various aspects from the methodologies of the five aforementioned maturity models, although not entirely limited to them. Such aspects include the CIM3 and the safety model’s use of AHP as well as SPICE’s definition of progressive thresholds or levels of maturity and its five maturity levels. Based on the five specific models reviewed, we are currently developing an integrated framework. This framework incorporates contents of many models as well as our specific findings with respect to model scope, domain focus, and the number of levels.

3 METHODOLOGY

This section provides an overview of the CDM3, its assessment indicators at the individual and organizational levels.

3.1 Model Overview

The CDM3 reflects the perspectives of the DM or Case manager's practical work context. The CDM3 adapts the concept of process improvement epitomized in the process maturity framework, taking into account key DM practices identified in existing DM guidance. It enables the identification of the DM activities currently in place within an organization and the development of a process of iterative improvement for those activities. The goal of the model is to benchmark an organization’s existing DM practices against best practices. Its objectives are to:

- Define key DM best practices.
- Evaluate the maturity of construction organizations’ DM practices using leading indicators of performance.
- Provide guidance and make recommendations on improving construction organizations’ management of DM.

3.2 Assessment Indicators

Assessment indicators represent clusters of related activities and regulations, which when performed and adhered to enable the achievement of performance goals. They also identify areas of concern that need to be addressed to achieve these goals. Many of the indicators of DM in construction are related to the parameters of project performance as well as construction project management knowledge areas. They cover employer-based strategies aimed at preventing and managing injuries and represent leading
indicators of performance. They are divided to two main categories based on their level of implementation and applicability.

3.2.1 Individual Level Indicators

Communication practices: Related practices cover information provided to all employees about the organisation’s strategy with respect to DM, and accommodations provided at all levels in support of those with disabilities.

Case management practices: These practices deal with the individual employee once an injury occurs with the aim of managing the injury and rehabilitating the employee. Case management is a term used to describe a variety of strategies aiming to manage the health and social services provided to injured employees and their families (Brooker et al, 2012).

Return to work and accommodation practices: These practices involve the completion of a job needs assessment to determine how the DM program can best meet the needs of employees with disabilities and bring them back to work. A comprehensive analysis of employees' skills is conducted to modify their original jobs or identify alternate jobs for which they would be more suited.

Claims management practices: Related practices deal with managing claims related to occupational and non-occupational injuries or illnesses that may entitle the individual employee to long-term disability (LTD) benefits.

3.2.2 Organizational Level Indicators

Disability and injury prevention practices: These practices cover the preventative aspects of DM programs, which have matured considerably in recent years and are critical to the overall performance of these programs and to controlling related costs. DM programs should educate employees on these aspects before the occurrence of disabling injuries.

Transitional program management practices: These practices cover the development of a generic DM program for injured employees, which can be customized to the individual employee during the individualized case management.
Physical accessibility management practices: These practices aim to improve the physical accessibility of construction workplaces to people with disabilities and as such cover physical workplace accessibility requirements.

Senior Management and leadership support practices: These practices involve getting continuous and consistent support at the senior management level to ensure the effective implementation of DM programs.

Program evaluation practices: These practices encompass the continuous evaluation of DM programs, customized individual RTW programs and injury and illness statistics to identify necessary program modifications and improvements and justify these programs’ costs and benefits as well.

Regulatory and compliance policies: These practices cover existing policies both at the federal and provincial levels. Additionally it delves into specific policies developed by the organization in relation to accommodating injured and disabled workers. Policies can cover issues as salary replacement, job accommodation, transitional employment, budgetary responsibility and vocational training when necessary.

Recruitment and retention policies: Practices cover the recruitment process of employees in the construction workplace as well the procedures undertaken to ensure the retention of injured workers. The principle of non-discrimination should be respected throughout the process, to ensure maximal benefit to the employer and equitable opportunities to candidates with and without disabilities.

Ergonomic practices: Related practices should ensure the design of work processes and spaces that minimize injuries, complaints, staff turnover and work absenteeism; meet employers’ social and legal obligations and improve employees’ health and safety.

3.3 Measurement and Scale

An assessment tool was developed to enable organizations to determine the maturity of a comprehensive range of DM practices under twelve different categories. Responding organizations are expected to rate their level of implementation of these practices using a five-point Likert scale, ranging from 1 (Strongly Disagree) to 5 (Strongly Agree). The tool enables respondents to add additional practices to the ones existing as part of the model and rate them accordingly.

3.3.1 Scaling Framework

This study uses the CMMI and SPICE as reference frameworks for the development of the maturity scale for the CDM3. Similar to the CMMI and SPICE, the CDM3 has five well-defined maturity levels that enable continuous monitoring and improvement with the aim of approaching the highest level of process maturity. The rationale for opting for five levels instead of three or four is to provide a more comprehensive breakdown of the growth process, and avoid overlaps and oversimplification of it. Each maturity level represents a well-defined stage that institutionalizes new process areas for disability management process maturation. The characteristics of each stage are described below.
At maturity level 1, organizational processes are usually ad hoc and chaotic (CMMI Product Team, 2002). No procedures or policies are defined or performed. Organizations’ DM performance usually depends on the competence of organizational members rather than the application of specific DM practices.

At maturity level 2, processes are planned, performed, measured, and controlled. This level implies that DM requirements and programs as well as monitoring, control, and measurement mechanisms are managed, with DM practices and results visible to management.

At maturity level 3, a set of standard organizational DM procedures and processes are defined, implemented, managed and used to establish consistency across the organization.

At maturity level 4, organizations perform DM processes accurately and efficiently, practicing standard quality and performance measurement control. Human resource management performance data are collected and evaluated against internal and external benchmarks to identify causes of process variation.

At maturity level 5, organizational DM processes are continually enhanced through technological improvement and the establishment of quantitative objectives and targets.

### 3.3.2 AHP Implementation

Disability Management (DM) performance measurement will be partly determined using the concept of absolute comparison in analytical hierarchy process (AHP) (Islam and Rasad, 2006; Saaty, 1987). The AHP will provide a controlled and systematic way for determining the weights of importance of the construction industry’s indicators for DM and determining the accuracy and reliability of these weights. It is an analytic decision making method used to select the best alternative from a number of alternatives using several criteria.

The indicators will be prioritised by determining the relative weights of the twelve primary indicators using pairwise comparison. A focus group encompassing a minimum of four experts will be set up to determine the indicators weights for the twelve defined leading indicators. The comparisons will be performed using the fundamental scale for pairwise comparison developed by Saaty (1987). A minimum of four such pairwise comparisons will be completed for each indicator and aggregated using geometric means (Yee-Ching and Elea, 1991). The comparisons of indicators will be done using a nine point fundamental scale of values instead of an abbreviated five point scale to reduce the level of fuzziness associated with the pairwise comparison judgements made by the experts. In its use of AHP, the CDM3 considers the indicators (practice areas) as being the decision alternatives that are being compared, with the criteria for comparison being the relative importance of an indicator relative to another to the performance of DM.
The aggregated pairwise comparison values will be normalized by dividing each column value (each indicator) by the sum of column values such that the sum of each column’s values will be 1. A consistency check will be conducted to test the consistency of the rating of the various indicators (Saaty, 1987). The pairwise comparison will be repeated if the consistency ratio is greater than or equal to 0.1.

Each construction expert will assess the primary parameters as shown in figure 1 with respect to the methods described in table 1. When comparing the indicators, each expert will ask himself or herself which indicator is more important to the overall performance of the DM. All will be rated on a nine point scale from “Strongly Disagree” (1) to “Strongly Agree” (9). These subjective ratings will be quantified using the same pairwise comparison procedure that is, the same AHP process explained above to determine parameter weights to obtain quantified subjective ratings.

For each indicator, the pairwise comparisons conducted by an expert produce a matrix referred to as a pairwise comparison matrix (Yee-Ching and Elea, 1991). The values of the pairwise comparison matrix are known as pairwise comparison judgments and reflect the relative importance of the indicators as perceived by an expert (Saaty, 1987). The study adopts the scale developed by Saaty (1987) instead of developing its own scale because Saaty’s (1987) scale has been adopted and validated by many studies, and was found to produce consistent and uniform results in each. The pairwise comparison judgments which comprise the pairwise comparison matrix are normalized, producing ratio scales in the form of principal eigenvectors or Eigen functions (Saaty, 1987). These eigenvectors or Eigen functions represent the weights of importance of the various assessment indicators.

<table>

<tr>
<td>Reciprocal</td>
<td>If activity i has one of the above numbers assigned to it when compared with activity j, then j has the reciprocal value when compared with i</td>
<td></td>
</tr>
</tbody>
</table>

The second part of implementing the CDM3: the assessment worksheet is based on a set of close ended questions which require a rating ranging from “Disagree” to “Strongly Agree” response, and which represent specific practice areas under each indicator. This technique is the central technique for implementing maturity modelling. It has been validated for use in a number of maturity models and was therefore adopted for the study. Scoring an organization using the assessment worksheet is straightforward. After answering the questions, evaluate the answer column to determine the maturity level. It is indicated by affirmative answers on all questions above the markers to the right of the answer column. The questions seek to determine the existence of specific outcomes/indicators within the organization and thus the implementation of specific practices. The CDM3 requires that the assessment
worksheet be administered to the relevant members of the organization by the researchers. As a check on the accuracy of the responses, the CDM3 requires that random verification be conducted to increase the rigour and validity of the assessment through a review of project and organizational documents, as well as through direct observations and follow up interviews. After completion of the assessment worksheets, additional audit work will be performed to check the organization to ensure the activities prescribed by each practice are in place.

4 CONCLUSION

The paper outlines the development and theoretical underpinnings of the Construction Disability Management Maturity Model or CDM3 and describes its proposed implementation. The primary purpose of the CDM3 is to provide a framework for benchmarking the disability management (DM) performance of the construction industry over time and across countries and regions. Empirical studies on the use of the CDM3 as a tool for continuous improvements should contribute to the development of a better understanding of the problems associated with the implementation of DM programs.

The research, once complete should have research and practical contributions. Theoretically, this research extends the application of CMMI to DM in the construction industry. Furthermore, it develops a progressive framework that defines the advancement of the process of DM from one maturity level to another, thereby helping researchers advance knowledge in the field and helping practitioners implement DM successfully in practice. Once complete, the model will be implemented in practice by applying it to ten construction organizations with the aim of validating it.

Abstract: This paper describes a research study entitled Enhancing the Performance and Productivity of the Canadian Construction Industry through Appropriate Digital Technology Adoption. The study was completed by researchers from four regions across Canada over the period of August 2013 to March 2014. The underlying purpose of the study was to assist in the development of decision-making tools to support the construction industry in the successfully adoption and implementation of new technologies. The study was accomplished by completion of the following steps: (1) an existing framework for the assessment of management practices at the project level for general contractors in the construction industry was refined and extended; (2) a standard assessment tool was developed and administered to 25 small to medium sized commercial/institutional building general contractor organizations, resulting in the identification of potential opportunities for improvement; (3) opportunities for improvement were validated with organizations; and (4) the assessment results were aggregated to provide an initial benchmark of the level of implementation of management practices. The assessment included 117 practices, across nine practice areas, and grouped as planning and control. The aggregated assessment results are indicating that at an industry level, the management practices in need of improvement that relate more directly to digital technologies are becoming clearer and include: Time - better utilization of the capabilities of existing scheduling software; Cost - improve the integration between time management and cost management software; Scope - improve the capture of as-built information and the management of warranty and operation and maintenance information; Quality - capture and categorize rework and non-conforming work; Materials - implement materials tracking and on-site management; and Information and Communication - implement processes to assess the performance of information and communication processes and use structured forms for information capture. The study built on previous work and extended it with respect to gaining insight on practices from the perspectives of the level of implementation and the consistency with which a practice is employed. To further extend this work, partnerships are being developed with national industry organizations to broaden the application of the assessment framework, thereby expanding the benchmarking dataset.
INTRODUCTION

Impediments to increasing the rate of innovation and improving productivity in the Canadian Construction Industry are related to accessing knowledge in the appropriate form to support decision making, and realizing the necessary capacity to successfully adopt and implement new technologies (or methodologies). This research project continues efforts to provide solutions to overcoming these barriers in support of digital technologies adoption. The project was undertaken with the support of the Digital Technologies Adoption Pilot Program administered by National Research Council Canada’s Industrial Research Assistance Program (NRC IRAP). This paper also represents an abbreviated version of the final results of this project (UNB CEM 2014).

The project builds on a method for a comprehensive assessment of construction companies’ operational processes and identifies areas with the potential to improve performance and productivity through successful adoption. The enhanced methodology is applied in a series of diagnostic projects with construction companies in four geographical regions (the Canadian Provinces of British Columbia, Manitoba, Ontario, and Nova Scotia) with the intention of: 1) identifying candidates for technology adoption projects, and 2) adding to an existing benchmarking dataset of management practices for the construction industry.

The project was accomplished by completion of the following objectives:

1. Critique and further refinement of an existing framework for conducting a diagnostic assessment of digital technologies in the construction industry at an organization level.
2. Identify regions for application and willing companies that will form a representative group in the construction industry.
3. Assess each individual representative company to determine both current capabilities and opportunities for improvement (identifying practices and processes that are lacking, and those that could be enhanced through digital technology adoption).
4. Aggregate the analysis of the individual assessment to an industry level to identify current capabilities and trends in management practices.

The intended audience for this paper is practitioners that are considering a benchmarking of their construction management practices and, more broadly, those attempting efforts in establishing benchmarking programs within the construction industry.

1.1 Refinements to Framework for Diagnostics Assessment

The first step in the research project was to complete a critique and refine the existing framework from a previous study (UNB CEM 2013) for conducting a diagnostic assessment of digital technologies in the construction industry at an organization level. The existing framework was developed based on the foundation provided by previous work in the assessment of organizational management practices within the construction industry. In summary, the following efforts were used to support the development of the framework:

2. The Nova Scotia Construction Sector Council’s Functional Information Technology Project (Rankin 2010).
3. The researchers’ previous research in assessing management practice maturity (Goggin et al. 2010, Willis and Rankin 2012).
The result was the adoption of nine management practice areas. Each area of management practices is a synthesis of numerous sources of commonly employed best practices within the construction industry. The following notes describe the scope and context of the practices:

1. Practices are intended within the scope of a design-bid-build type project versus any form of design-build-operation project (e.g., less emphasis on financial management).

2. Practices being examined are common to general contractors in commercial, institutional and infrastructure projects (e.g., equipment management is excluded as it is considered heavy-civil specific).

3. Although some practices are normally performed in a home-office scenario (i.e., planning practices), the emphasis is project (site)-level practices.

With this as a starting point, a broader search on assessment methodologies in the context of digital technologies and organizational management practices was completed at each research location. Materials reviewed included existing international standards for organizational project management practices and techniques for their application to an assessment framework:

1. PMI’s Construction Extension to the Project Management Body of Knowledge (PMI 2003).

2. UK’s PRINCE2, PRojects IN Controlled Environments, Version 2 (OGC 2002).

The results were used as the basis of identifying opportunities to improve the existing framework. The following summarizes the areas for improvement and actions undertaken to complete the refinement.

1. The scope of management areas, and project practices.
   - The existing framework is based on practices derived from PMI PMBOK and its management processes where some areas (e.g., integrated, risk, procurement) have been incorporated into others (e.g., cost, scope). This is a reasonable structure to continue with and can be cross-referenced with other standards if required for comparisons.
   - It is anticipated that the structure will work in the future as additional practices emerge.
   - There is consensus that the area of information practices needs to be improved.
   - There is consensus that direct assessment of project performance should remain outside the scope of the framework.

2. The capture of the level of maturity of a practice and the influence of the complexity of a project.
   - Modifications were made in order to gain more insight in the level of implementation of practices with respect to the concept of the “maturity of practice” (e.g., how formal it is) and the influence of the complexity of an application (e.g., size of project). A project complexity metric is proposed for use with each company to establish a type of best-typical-worst scale and then collect these for each practice.
   - Using multiple participants in the same company for the assessment will provide more insight on opportunities and increase the validity of the results.
   - If there are instances where it makes sense from a company perspective to collect data from multiple participants, consideration will be given to collect these separately and then reconcile these multiple responses in a group setting.

3. Capturing the motivation behind the use or non-use of a practice.
• A categorization of practices based on their source of motivation (e.g., voluntary, owner driven, legislated) was considered as an addition to the survey questionnaire.

1.2 Project Complexity

Project management practices vary with the complexity of an organization’s projects. Project complexity is measured by comparing it to other projects within the same industry sector. This study adopts the project complexity definitions used by the Construction Industry Institute (CII)’s Benchmarking and Metrics Program (CII 2008), which measures project complexity on a scale of 1 to 7 (low to high) by asking companies to rate their projects’ complexity compared to other typical projects within the same industry sector (e.g. commercial, institutional, infrastructure, etc.). The level of complexity for typical projects undertaken by a company is assessed with the following definitions:

1. Low complexity: projects are categorized by the use of well-established, proven technology, a relatively small number of process steps, a relatively small facility size or process capacity, a facility configuration or geometry that your company has used before, and well-established, proven construction methods.

2. Average complexity: projects are categorized by the use of established technology, a moderate number of process steps, a moderate facility size or process capacity, a facility configuration or geometry that your company has used before, and established, proven construction methods.

3. High complexity: projects are categorized by the use of new, “unproven” technology, an unusually large number of process steps, large facility size or process capacity, new facility configuration or geometry, and new construction methods.

2 PRACTICES

Table 1 is a summary of the nine practice areas and the grouping of practices under the basic management categories of planning and controlling. Each grouping contains multiple practices.

2.1 Protocols for Data Collection

Within the management areas, each practice is assessed for two factors:

1. The level of implementation (how often is the process used?) for a typical project performed by your organization, on a scale of: never; rarely; sometimes; often; or always.

2. The level of consistency (how formally is the process defined and managed?) for a typical project performed by your organization in which the practice is applied, on the scale of: ad-hoc (the process is determined as needed); repeatable (the process is carried out consistently from one occurrence to the next); defined (the process is formally defined and documented); standard (the process is formally standardized throughout the company); or improving (the process undergoes formal review and ongoing improvement).

Additionally, open-ended questions invite information about additional management practices within each area, and situations where there are significant exceptions to the implementation or consistency of a typical practice.

The practices were then converted to a survey format to serve as a script for face-to-face interviews for data collection. Table 2 summarizes the format of the survey and provides examples of the questions.

Table 2: Overview of survey questions for initial data collection.

For the following statements of management practices, please indicate the level of implementation (how often is the process used?) and the level of consistency (how formally is the process defined and managed?) for a typical project performed by your organization.

Schedule development

1. A standard work breakdown structure (e.g., CSI MasterFormat) is used to define the activities/tasks for project schedules.

</table>

The data collection protocols (i.e., basis of the study, method of data collection, and survey questions) were reviewed and approved by the UNB Research Ethics Board, per the Canadian Tri-Council (CIHR, NSERC, SSHRC) policies for research involving humans.

3 INITIAL ASSESSMENT

At each geographical location an initial list of general contractors was identified as potential participants for assessment. In most cases, the cooperation of local construction associations was solicited to assist in developing these lists. Upon first contact with each organization the general intent of the project was explained and survey/interview respondents identified. This was sometimes followed by a face-to-face meeting to further describe the study but in most cases the next step was administering the scripted interview for initial data collection on practices. All participants in the interview were senior managers in the organization with direct experience in the execution of all management practices at the project level. Each scripted interview session lasted between three to four hours and was conducted by the same researcher (either face-to-face or by phone) in each geographical location for consistency. To protect the confidentiality of participating organizations, none are directly or indirectly identified. A total of 25 companies were assessed.

3.1 Overall Assessment

Subsequent to the completion of the initial data collection a summary analysis was provided to each participant in the form of a “box and whisker” diagram. The results provided are an aggregation of scores...
based on the initial assessment of all organizations. The results in Figure 1 are summarized by
management areas to give a general overview of the average level of implementation. Each practice is
weighted equally with a maximum score of 5 corresponding with the highest level of implementation and a
score of 1 corresponding to the lowest level of implementation. The maximum and minimum scores
correspond to practices within each area and the boxes indicate the variance across companies within
each management area. Figure 2 provides additional insight with a breakdown of the management step
within each area.

In general, the traditional management areas of time, cost, and scope, are performed at a higher level. As
expected, safety is at the highest level of implementation. Next are quality, human resources, and
information and communication. The lower levels of implementation are practices in materials, and
environmental and waste. As depicted in Figure 3, planning practices are implemented at a higher level.
However, this is not the case for both scope and quality (with higher scores of implementation for control
practices).

Figure 1: Aggregated implementation score for practices by nine management areas.

Figure 2: Aggregated implementation for all practices by management area and step.
3.2 Individual First Stage Analysis

At the same time the overall summary of practices was provided, each company also received an overview of their scores at the management area level and a more detailed description of where opportunities for improvement were identified. This was captured in a single page, which contained a radar chart (Figure 4) that measured the company against the average of all companies and a summary of opportunities for improvement. These results were used to further engage each company on their practices and to validate the opportunities for improvement.

The opportunities for improvement were aggregated under each management area with the frequency of common opportunities also indicated. The most frequently identified opportunities in each management area are summarized as follows:

1. **Time**: incorporate uncertainty in project schedules during planning; use short-term look ahead scheduling during project execution; communicate the project schedule to all project participants; better utilize the capabilities of existing scheduling software.

2. **Cost**: improve the integration between time management and cost management software; improve internal reviews of estimates; improve the use of expertise in the development of estimates.

3. **Scope**: improve project risk identification and management; improve the capture of as-built information and the management of warranty and operation and maintenance information.

4. **Quality**: capture and categorize rework and non-conforming work; perform internal analyses of common work processes for improvement.

5. **Safety**: improve the hazard planning and inspection planning processes; improve the management of safety equipment, materials and resources management.

6. **Human Resources**: implement team building practices on projects; implement performance assessment on a project basis.

7. **Materials**: implement materials tracking and on-site management; integrate procurement of materials with project scheduling.

8. **Information and Communication**: implement processes to assess the performance of information and communication processes; use structured forms for information capture.
9. *Environmental and waste*: overall the practices in this area are the least mature; therefore in general, consideration should be given to the overall management approach.

![Radar Chart of Initial Assessment](image)

**Figure 4: Example of radar chart of initial assessment.**

### 3.3 Validation and Final Analysis

Validation of the results and opportunities for improvement identified was completed by either a face-to-face meeting or phone call, at which the overall results were reviewed and additional insights provided, followed by a discussion of each individual opportunity. Each validation meeting was completed in a single session of one to two hours.

In general, for each company, the initial opportunities were classified into three groups:

- identified as an opportunity and ready to pursue
- identified as an opportunity but not ready to pursue
- at this point not able to rationalize the investment to improve in the area identified
- currently satisfied with practices in the management area identified

Of the 25 organizations that completed the initial assessment, twelve were available to further validate the results and opportunities for improvement identified.

### 4 AGGREGATION AS A BENCHMARK

As noted, Figures 1 and 2 summarize the average score for an aggregation of practices in each management area. This was used for the purpose of validating opportunities for improvement. These commonly used descriptive statistics in benchmarking can provide additional insight with respect to the practices assessed. It should be noted that at this point the results are not considered statistically significant due to the current sample size.

Figure 3 provides the aggregated practices per a management step classification of practices (i.e., planning and controlling). At this aggregated level, the assessment indicates that overall there are higher scores for the level of implementation for planning practices and conversely overall more variance in the scores for level of implementation of controlling practices.
The assessment of management practices reported at an aggregate level for each management area is provided in Figure 4. Apart from the observations noted earlier on the average values for each management area, general observations on the variance of the resulting scores is offered. Management areas with lower variance in the scoring of their level of implementation include scope and safety, groupings of management areas with higher variance include quality, human resources, and materials. Although not depicted in this paper, general observations for planning practices are that there are higher variances in the scoring of level of implementation for quality and materials. Whereas for the controlling practices, there are a number of management areas with higher variance in the scoring of level of implementation including: cost, quality, materials, and human resources. As part of the final analysis, each individual organization was also provided with a more detailed comparison of their practices against the aggregated group. Figure 5 depicts an example of this comparison.

![Box plot of Company A](image)

**Figure 5:** Descriptive statistics example indicating an individual organization.

### 5 CONCLUSIONS AND FURTHER STEPS

The project resulted in knowledge in a form that is usable to the potential adopter (industry practitioners) for decision making purposes. When aggregated with a previous project, we now have assessment results from 33 (8 from the previous study and 25 from this most recent one) small-to-medium sized general contractors in five geographical regions. The results demonstrate evidence of the common issues that need to be addressed at an industry level.

Also to note is the challenge presented in developing a mechanism of assessment with a common structure while also providing enough depth to be useful for each organization. One of the more positive aspects of the research project was the reaction of members of the construction industry to the research project. Although there were some challenges due to timing, all participants were quite willing to participate and saw the value in having an independent review of their practices, as well as an opportunity to consider exploiting technological solutions to address their needs.
5.1 Next Steps

The refined assessment framework and subsequent data collected and aggregated, serve as an initial benchmarking mechanism for industry management practices at the project level. Results are now available to move forward with a broader dissemination of the framework and its potential to assist in the identification of opportunities for organizational improvements. It is the researchers’ intent to further the application of the framework by adding additional participants on a regional basis, as well as exploring its application in other regions.

Dissemination of the current results is being pursued through partnerships with local and regional construction associations in the form of industry briefs and presentations. In addition, further application of the framework is being explored through partnerships with national level construction industry organizations (e.g., BuildForce).

Abstract: Motivation is a critical factor affecting construction crew performance. Motivation arises from various internal and external factors such as self-efficacy, assigned goals, and other sources. On construction and industrial projects, workers usually work in crews; thus, performance factors such as productivity are mostly measurable at the crew level. Crew motivation is one factor impacting crew performance. However, it is difficult to define and measure crew motivation in construction, due to the uniqueness and dynamism of the construction environment. Additionally, motivational factors may be described in the form of subjective or objective data. Therefore, a method of measurement is required to systematically and explicitly measure each factor affecting crew motivation and therefore performance. This paper reviews theories and models of motivation that have been developed in research domains other than construction. Next, it overviews motivation literature within the construction domain, and discusses shortcomings of these current approaches. From the literature review, the key factors affecting crew motivation are identified. Finally, the paper proposes a method of measuring crew motivation. The findings and methods presented in this paper will help to define and measure construction crew motivation which will contribute to better predictions of performance.

1 INTRODUCTION AND PROBLEM STATEMENT

There are different definitions of the term “motivation” in existing literature. Colquitt et al. (2013) trace the word to its Latin roots: “motivation” derives from the Latin word for movement, movere. Motivated people usually move or work faster and for longer periods of time than unmotivated people, which makes this Latin root particularly representative of the concept of motivation (Colquitt et al. 2013). Based on Latham and Pinder’s (2005) definition, for an employee, motivation is a set of internal and external energetic forces. Motivation triggers the effort to perform a task. Motivation also determines the three characteristics of such effort: direction, intensity, and persistence (Latham and Pinder 2005). Campbell (1970) defined motivation as “the extent to which persistent effort is directed toward a goal".
Motivation is a critical factor affecting construction crew performance. An effective job performance often requires high levels of both ability and motivation; therefore, motivation is a critical consideration (Maier 1955). However, there is a lack of research on factors affecting motivation in the construction area. Motivation is a major area of research in domains other than construction. Much research has been done in business, management, psychology, industrial psychology, and organizational behavior. In this paper, research in these domains is reviewed. There are some gaps and shortcomings in the research done on motivation; most theories of motivation consider motivation on an individual level. Some theories, like equity theory, recognize that the individual may compare himself or herself to others (e.g., to another group member or another company personnel). As workers mostly work in crews on construction sites, there is a need to evaluate the motivation of workers at the crew level.

Research on motivation in the construction domain suffers from many gaps and shortcomings. The objective of this paper is to define a method to measure crew motivation based on factors that have been derived from literature in both non-construction and construction domains. This paper is organized as follows: First, a comprehensive review of past research is presented on theories of motivation in general domains (e.g. general management, social psychology, applied psychology, personnel psychology, occupational and organizational psychology, and organizational behavior). Secondly, the paper provides a review of motivation literature specifically in the construction domain. Factors that affect construction crew motivation are identified from the reviewed literature. A model of crew motivation is then proposed based on the factors that have been derived from the literature in both non-construction and construction domains. Lastly, a method is proposed to measure the factors affecting construction crew motivation and to measure the overall crew motivation. The findings of this paper will help to define and measure construction crew motivation, which will contribute to better prediction and management of construction labour productivity and project performance. The findings of this paper also provide a basis for future research on construction crew motivation.

2 REVIEW OF MOTIVATION THEORIES IN NON-CONSTRUCTION DOMAINS

Theories of work motivation can be categorized broadly into two groups: (1) content (need) theories of work motivation and (2) process theories of work motivation. Content theories focus on human needs as the main source of motivation and specify the types of needs people have. Psychologists have spent several decades studying types of human needs and have proposed different need structures. Three prominent need theories of motivation are Maslow's hierarchy of needs, Alderfer's ERG theory, and McClelland's need theory. Process theories provide information about how motivation occurs by presenting the factors that affect the motivation and describing the causal relationship between such factors and motivation. Process theories and need theories are not contradictory but complementary (Johns and Saks 2011). However, since this paper ultimately proposes metrics for construction crew motivation and the factors that contribute to it (i.e., it focuses on causal relationships between motivational factors and motivation), it relates most directly to process theories of motivation, the most prominent of which are summarized here. In 1964, psychologist Victor Vroom introduced the first complete version of expectancy theory. Based on the expectancy theory, motivation is determined by the outcomes that people expect to occur as a result of their actions on the job (Vroom 1964). Equity theory was introduced by Adams in 1965. Unlike expectancy theory, equity theory poses that motivation does not depend only on employee beliefs about himself or herself and on personal circumstances, but also on employee beliefs about other people. Bandura (1986) defined perceived self-efficacy as "people’s judgment of their capabilities to organize and execute courses of action required to attain designated type of performance". Bandura proposes that perceived self-efficacy works as the motivational force to take an action. In goal-setting theory, goals are viewed as the primary drivers of an effort (Locke 1968). Goal-setting theory suggests that assigning specific and difficult goals to employees will result in higher levels of performance compared to assigning no goals or easy goals (Locke and Latham 1990). In 1991, Ajzen proposed the theory of planned behaviour. This theory suggests that “intentions to perform behaviour of different kinds can be predicted with high accuracy from attitude toward behaviour, subjective norms, and perceived behavioral control” (Ajzen 1991). Self-determination theory (SDT) suggests that people are motivated to pursue behaviours that lead to the satisfaction of three innate psychological needs: competence, autonomy, and relatedness. According to SDT, the nature of one’s motivational experience
varies along a continuum of internal versus external control (Ryan and Deci 2000). In primary models of goal setting, the focus was on the effect of an assigned goal on personal goals and also the effect of personal goals on performance (Locke 1968; Locke and Latham 1990). More recently, Mitchell et al. (2000) proposed an integrative model of the effect of goals on performance, in which self-efficacy and personal goals are determinants of performance in addition to ability and other factors. In 2001, Locke proposed an integrative model of motivation around the concept of the motivation hub. The motivation hub model consolidates two previously described models: goal-setting theory (Locke 1968; Locke and Latham 1990) and social cognitive theory (Locke 2001). Johns and Saks (2011) proposed another integrative model of motivation that considers expectancy theory (Vroom 1964), goal-setting theory, equity theory (Adams 1965), and need theories.

The above review conveys how different theories and models of motivation in the general domain have developed over time. It also shows which motivational factors have been considered by psychologists and other experts in domains other than construction. Comparing the motivation literature in the general domain to that which exists in construction will help identify the gaps in and shortcomings of motivation research in the construction domain. Thus, the next step is to review the motivation literature in construction in order to understand which motivational factors and motivation theories have not been considered in this area so that the factors affecting crew motivation can be better defined.

3 REVIEW OF MOTIVATION LITERATURE IN THE CONSTRUCTION DOMAIN

Early research on motivation in the construction domain was mostly related to the definition of motivation, with a focus on expectancy theory. Maloney (1981) reviewed studies about construction worker motivation and discovered a lack of empirical research. Soon after, use of the expectancy theory of motivation and performance was proposed in the construction area following the surveys administered to construction workers on the importance and satisfaction of various job-related factors. This research introduced three worker motivational factors: work, supervisor or leader behavior, and incentives (Maloney and McFillen 1986). Questionnaire responses and data collected from different trades were analyzed in order to determine the impact of the work crew on individual worker motivation; this analysis resulted in the conclusion that contractors must manage their work crews in terms of planning, organizing, staffing, directing, and controlling in order to increase worker performance and satisfaction (Maloney 1987). Overall, these early research efforts lacked clarity and rigour in selecting factors, used a limited number of factors, or, in some cases, demonstrated a misunderstanding of motivation theories and concepts. In the following years, researchers expanded on the identification of motivational factors in construction, although such research varied in terms of rigour and comprehensiveness. Carrier (1992) briefly introduced general motivational factors in the workplace. Khan (1993), after reviewing popular motivation theories, concluded that “each theory deals with selected aspects of human behavior that, if managed carefully, motivate people and thus improve productivity” (Khan 1993). Shoura and Singh (1999) used a questionnaire to quantitatively assess motivational parameters of engineering managers. These studies defined motivational factors very generally and based their definitions on the suggestions of previous authors without providing original data analysis. Recently, researchers investigated motivational factors relating to specific types of employees in the construction industry. For example, Cox et al. (2006) identified factors that promote positive motivational behavior in construction subcontractor crews. Šajeva (2007) summarized research done in defining knowledge workers and identifying factors affecting their motivation and loyalty. She identified five motivator categories: work, personal growth and continuous learning, autonomy and personal freedom, status and recognition, and monetary motivators. Siriwardana and Ruwanpura (2012) specified motivational factors as one category of factors affecting productivity in addition to management, supervisor’s assessment, and technical skills. However, their study includes a limited number of factors, provides no ranking between the different factor categories, and is not based on job-site data collection.

In summary, this review of motivation literature in construction shows that there are major shortcomings in this research area: studies largely relied on expectancy theory without integrating other and more recent motivation theories, lacked data analysis and therefore based recommendations only on authors' personal perceptions, and were performed based on questionnaires with no job-site (field) data collection. Comparing the Section 3 review of motivation literature in construction with the Section 2 review of
motivation literature in general reveals many gaps in construction motivation research that should be addressed. One such gap is defining all factors affecting crew motivation in construction. These factors should be identified from developed theories and models of motivation in the general domain. While previous studies have identified some motivational factors in construction, researchers have yet to produce a comprehensive list of factors that adequately addresses all possible sources of motivation. Section 4 addresses this gap by defining a list of motivational factors affecting crew motivation.

4 IDENTIFICATION OF KEY FACTORS AFFECTING CREW MOTIVATION

In this section, factors affecting crew motivation are identified from the motivation literature in both construction and non-construction domains. To accomplish this task, two major issues must be kept in mind. One issue is that theories of motivation have developed and evolved over the last 80 years. Some theories dominated for a period of time before declining in prominence at the arrival of new theories. However, recent literature published in the last decade has tended to integrate numerous earlier theories to propose more comprehensive meta-theories of motivation that overcome the limitations of any of their component approaches alone. Another issue is that existing motivation theories are concerned with the motivation of individuals. However, in construction, individuals usually work in a crew whose performance (e.g., productivity) can only be measured as an aggregate of the individuals' performances (i.e., at the crew level). Therefore, factors affecting motivation in the construction context should also be measurable at the crew level and should include factors affecting crew motivation as a result of peer influence.

Among motivation theories, expectancy theory and self-determination theory are more related to individual motivation, while goal-setting theory and equity theory are more related to team or crew motivation. As the motivation of a worker who is working in a crew results from a combination of different factors related to both the individual and the group, it is important to consider all possible sources of motivation in developing a base model of motivation for the construction domain. For example, a worker may be motivated by goals assigned by the foreman; at the same time, the worker may be motivated by the perception that the ratio of his or her output (e.g., income) to input (e.g., time spent on tasks) compares favourably to co-workers. The recent, integrative theories of motivation (e.g., Johns and Saks 2011) are useful in accounting for these multiple, distinct, interacting motivational factors. In this paper, we group factors affecting crew motivation into five different categories: individual factors, crew factors, project factors, industry factors, and context factors. In each category, we identify factors affecting crew motivation from the motivation theories discussed in previous sections.

4.1 Individual Factors

Factors affecting crew motivation at the level of the individual are those which concern individual workers' self-efficacy and self-set goals. We use the motivation hub model (Locke 2001) to identify factors affecting crew motivation in this category. Based on the motivation hub model, self-set goals (i.e., personal goals or intentions) and self-efficacy (i.e., task-specific self-confidence) are two factors affecting motivation. Although these factors are measured at the individual level, in our model they are grouped together and evaluated at the crew level so that they can be used to assess crew performance.

4.2 Crew Factors

Factors affecting crew motivation at the level of the crew are those which concern the effects of working in a group. We use equity theory (Adams 1965) and the theory of planned behaviour (Ajzen 1991) to identify factors affecting crew motivation this category. Equity theory deals with peer influence by recognizing that employees compare themselves to other referent persons. These referent persons may be in the group, in the company, or outside. Employees compare their own work inputs and resulting outcomes to the perceived inputs and outcomes of their referent persons—their peers—and they adjust their ratio of inputs to outcomes (performance) so that it equals that which they perceive of their peers. Based on this theory, equity perception is a factor that affects worker motivation and therefore crew motivation. According to the theory of planned behaviour, attitude (personality), subjective norms (e.g., social pressures), and perceived behavioural control (perceived ability) are factors that define motivation. While working in a crew a worker may feel social pressure from other crew members. This felt social
pressure (subjective norms among crew members) affects the worker’s motivation. In other words, based on the theory of planned behaviour, crew norms are another factor affecting crew motivation. To identify factors affecting motivation in this category, in addition to using theories and models of motivation, the influence of group processes (i.e., the effect of working in a group on an individual in the group) must also be considered. Our model therefore considers crew characteristics (e.g., crew size) and crew similarity (e.g., the extent to which workers’ ethnicities are similar) as factors affecting crew motivation.

4.3 Project Factors

Factors affecting crew motivation at the project level are those which concern the effect of working on a project or for a company. Our model considers equity theory (Adams 1965), the theory of planned behaviour (Ajzen 1991), and self-determination theory (Ryan and Deci 2000) in identifying project factors affecting crew motivation. Based on equity theory, the equity perception of a worker in relation to other company employees is a factor that affects crew motivation. Based on the theory of planned behaviour, a worker may feel social pressure (company norms) from other company members. Therefore, company norms are another factor affecting crew motivation. Based of self-determination theory, motivation types vary according to regulatory styles (i.e., different methods of control) that exist in a company.

4.4 Industry Factors

Factors affecting crew motivation at the industry level are those which concern the effect of working in an industry sector, as a member of a labour group, or in a regional economy (e.g., as a member of a union or in a specific provincial economy). Our model considers equity theory (Adams 1965) and the theory of planned behaviour (Ajzen 1991) in identifying factors affecting crew motivation in this category.

4.5 Context Factors

Factors affecting crew motivation at the context level are those which derive from the context in which the work is being done. For example, market conditions are a context factor that may affect crew motivation. Table 1 summarizes key factors affecting crew motivation in these categories.

5 PROPOSED MODEL FOR PREDICTING CREW METRICS FROM CREW MOTIVATIONAL FACTORS

Based on the identified factors affecting crew motivation, we propose a model for predicting crew metrics from crew motivational factors in Figure 1. As shown in the model, factors affecting crew motivation in the different categories (individual, crew, project, industry, and context) are organized in a hierarchical structure. These factors are defined and discussed in Section 4. In the proposed model, crew metrics include: crew overall performance, turnover, absenteeism, and safety (e.g., incidents). Crew overall performance is further divided into three categories: task performance (e.g., productivity, rework), contextual performance (i.e., organizational citizenship behaviour [OCB], either interpersonal or organizational, such as helping others or following rules), and counterproductive behaviour of an interpersonal or organizational nature (e.g., gossiping, wasting resources).
Figure 1: Model for Predicting Crew Metrics from Crew Motivational Factors
These metrics (i.e., crew overall performance, turnover, absenteeism, and crew safety) are included in the model because each is affected by crew motivation. In addition to the identified factors affecting crew motivation, the model also includes other factors affecting crew metrics: ability, work-setting conditions (e.g., factors such as distance to lunchroom, access to tools and equipment, and noise level in working area), environmental factors, and resource availability. Since performance in construction is usually measured at the crew level, motivational factors affecting crew performance should also be measurable at the crew level. Measurement of motivational factors and crew motivation are discussed in the next section. However, this paper only focuses on defining and measuring motivational factors and crew motivation; crew metrics will be defined in future research.

6 METHOD OF MEASURING MOTIVATIONAL FACTORS AND CREW MOTIVATION

This section describes how to measure both the motivational factors and the crew motivation. According to our model, the first concepts to be measured are factors affecting crew motivation. Measurement should be designed for each factor in order to appropriately quantify that factor. Factors may be in the form of quantitative data (e.g., crew size is three workers) or qualitative data (e.g., crew similarity is high). Therefore, both quantitative and qualitative types of data should be collected. The second concept to be measured is crew motivation; an overall measure for crew motivation should be defined. In the following sections we describe the measurement of these two concepts (motivational factors and crew motivation).

6.1 Identifying and Selecting Measures of Motivational Factors

Identification of measures in this research depends on the type of data that is to be collected. The data type may be quantitative (e.g., an objective attribute such as crew size or weather conditions) or qualitative (e.g., a subjective attribute such as crew similarity and company norms). As our model includes both subjective and objective variables, we need to collect both qualitative and quantitative data. Weather conditions, as an objective input variable, can be measured by objective attribute values (e.g., temperature: 28°C, humidity: 52% humidity, wind speed: 10 km/hr). Crew similarity, as a subjective input variable, can be measured by subjective terms of its attributes (e.g., high similarity in crew members’ ethnicity, medium similarity in number of languages spoken in crew, very low similarity among crew members in years of experience). Subjective terms like “very low”, “low”, “medium”, “high”, and “very high” can be used as linguistic descriptors in a predetermined rating scale. The advantage of using predetermined rating scales is that they provide better definitions for factors and thus lead to more consistency in the collected data. Our model requires the collection of both subjective and objective data. However, we define and use predetermined rating scales for the subjective data. Table 2 shows an example of how measures for one factor—crew similarity—are identified and selected.

For measuring motivational factors, different types of data collection tools and techniques may be used such as company (project) databases and documents, questionnaire surveys (self-reports), interview surveys, and work sampling. Depending on the project under study, the availability and suitability of a potential source of information should be investigated. For example, factors such as company norms (e.g., having a good attitude toward colleagues is mandatory; following manager-imposed rules and disciplines is mandatory) may be available in the company or project database. However, many of the factors that affect worker motivation are based on individual perception. For example, self-efficacy is a worker’s perception of his or her ability to do a job. Similarly, perceived equity to other members of the crew is a factor that relates to a worker’s own perception. For these types of factors, there is a need to obtain the opinions of workers through questionnaire surveys or interview surveys. An advantage of interview surveys is that this method of data collection provides a better understanding of the research situations for the respondents and probably more accurate and useful responses as compared to self-reports. Therefore, structured interview surveys are the most suitable method for collecting motivational factors because they allow researchers to capture the advantages of both face-to-face interviews and structured survey questionnaires.

### 6.2 Measurement of Crew Motivation

Once the factors affecting crew motivation have been measured, the overall motivation level of the crew must be measured so that it can be related to the factors affecting crew motivation for model development (as shown in Figure 1). When attempting to measure crew motivation, experts often find it difficult to express a score using exact numbers because of inherent uncertainty. For this reason, the use of linguistic terms makes expert judgments more reliable and informative, which is why we have chosen to express crew motivation scores in this way. The first step in measuring overall crew motivation is to define evaluation criteria for crew motivation. As mentioned in Section 1, motivation is concerned with the intensity, persistence, and direction of effort (Johns and Saks 2011). Accordingly, in our model, these three attributes are evaluated and measured on a rating scale in order to define crew motivation. The second step is to measure crew motivation based on the defined measurement criteria. The available sources of this measurement data are the crew workers themselves, the foreman, and direct supervisors. It is possible to ask the workers, foreman, and supervisor about the crew motivation in form of a survey; however, this method poses some challenges for aggregating the respondents’ opinions. As some of the crew metrics attributes (e.g., crew productivity) are measureable only at the crew level, it is important that in these cases the relevant measurement is also taken at the crew level. In other words, all motivation attributes should be measured for the crew as a whole (e.g., How intense is the effort of crew workers? How persistent is the effort of crew workers? To what extent did the crew direct their effort toward their tasks?). The challenge here is related to aggregation of different expert opinions about crew motivation.

The aggregation of individual judgments into a group opinion requires a measured level of consensus. Omar and Robinson (2014) proposed a framework for measuring competencies for construction projects. In their work they used OWA (Ordered Weighted Averaging) to aggregate different expert opinions. Ben-Arie and Chen (2006) introduced a new linguistic-labels aggregation operation for handling an autocratic group decision-making process under linguistic assessments. They proposed a FLOWA (Fuzzy Linguistic OWA) algorithm. The methodology they presented has two outcomes: a group-based recommendation and a score for each expert reflecting the expert’s contribution towards the group recommendation (Ben-Arie and Chen 2006). Both methods (OWA and FLOWA) can be implemented here to define a score for
crew motivation. The difference is that OWA provides a point score as representative of each expert judgment of crew motivation while FLOWA provides a fuzzy set for each expert judgment of crew motivation. After implementing either OWA or FLOWA, all scores experts assigned for various crew motivation attributes are aggregated to define the crew’s motivation. Ben-Arieh and Chen (2006) considered applying the classic aggregation method, in which each expert’s importance is multiplied by their expert opinion score. Following this method, a crew motivation score is defined including a combination of different opinions of crew motivation.

Measuring crew motivation and the factors affecting it will help in modeling and identifying the most critical factors that affect crew motivation. By determining the strength of the links between motivational factors and crew motivation, a model for predicting and improving crew motivation can be developed. Future work on assessing and measuring crew metrics will be done to complete the proposed model shown in Figure 1. The model will be validated with actual data and used to determine crew performance based on motivational and other factors affecting crew performance. Agent-based modeling will be used to further implement the concepts in order to show the relationships between the individuals on the crew and crew performance, and to thus gain a better understanding of the dynamics of the crew as they relate to motivation.

7 CONCLUSIONS AND FUTURE RESEARCH

The first contribution of this paper is in providing a comprehensive review of motivation literature in both the construction and non-construction domains, identifying the shortcomings of construction literature about motivation, and identifying factors affecting crew motivation in construction. Identifying these motivational factors enables their effects on crew motivation to be analysed, which in turn leads to better prediction of crew performance. We reviewed past research on motivation in the general domain followed by a review of motivation literature in construction. We then provided a list of key factors that affect crew motivation based on the reviewed literature. Previous research in construction failed to provide a comprehensive review of motivational factors affecting crew workers even though the need for such a consideration has only been increasing in order to better predict crew performance. The second contribution of this paper is the presentation of a method for measuring crew motivation. We illustrate how it is possible to measure both motivational factors and crew motivation quantitatively. Quantifying crew motivation will help in analysing and evaluating crew motivation models, such as models for understanding the relationship between motivational factors, crew motivation, and crew performance.

This paper is part of a broader research study that intends to understand the effect of motivational factors on crew metrics. In future, the research presented here will be extended to develop crew metrics including not only crew performance indicators (e.g. productivity) but also other crew behavioral outputs (e.g. turnover, absenteeism, and safety [incidents]). Through our study, we will try to find the relationship between crew motivation and other crew performance metrics. A model of such relationships is presented in this paper. Future research will also focus on further analysing the relationships between motivational factors, crew motivation, and crew metrics by developing suitable theoretical models such as fuzzy agent-based models. Agent-based modeling and simulation (ABMS) is a powerful technique when dealing with attributes like human behaviour. On the other hand, fuzzy techniques are powerful when dealing with subjective data. Thus, future research will examine the possibility of developing fuzzy agent-based models to model the relationships between motivational factors, crew motivation, and crew metrics. Such models will allow the construction industry to achieve better predictions of crew performance.

Abstract: This paper reports on the results of field studies of seven transportation infrastructure projects. The results of two road projects are compared to four street and utility projects and to a commercial building project. The study results show that road construction emits a much higher quantity of emissions than building construction; that the emissions calculated with published data are higher than those from field data; and that backhoes, motor graders, and bulldozers produce the highest total emissions. This paper adds to our understanding of emissions estimates from multiple project types and data sources.

1 INTRODUCTION

Typically, an infrastructure project is studied from different perspectives during planning and design phases to assess the impact the project will have on the community, the existing infrastructure system, and the environment. Such analysis is particularly intense during the development of highly visible transportation projects, especially highway projects. The impacts of these types of projects are visible and obvious to the general public.

Air pollution emissions are one of the effects that are of special interest because of the dangers they pose to health. The impact of future emissions from passenger cars, heavy-duty trucks, and other vehicles that use transportation infrastructure is an important area of study during the early phases of a project. However, such study does not typically include construction equipment emissions assessments, leaving a full understanding of the emissions produced during the infrastructure development processes as a void in the body of knowledge.

This paper addresses that knowledge void. Seven actual construction projects located in central North Carolina were studied in numerous ways to assess their emissions generation. This paper compares those projects, reports some of the key findings of these studies, and makes observations about their significance.

The research question addressed in this particular paper is, “to what extent, if any, do different project types vary in their emissions during construction?” To answer this question we compared emissions forecasts from two road projects, to four street and utility construction projects, and to a building construction project.
Results from the different types of projects can be used to understand how the emissions profiles change, not only between projects but also between different activities and schedules, over time. These comparisons begin to reveal general emissions patterns and rates. This enables us to calculate emissions factors per dollar or per productivity unit and these factors can then be used to forecast emissions for numerous other projects during their early planning stages, thus improving design alternative selection. At this point the research question “are there metrics by which emissions forecasts can be compared across various project sizes and types?” is addressed.

1.1 Scope

This paper focuses on forecasting emissions from the exhaust system of nonroad construction equipment during the construction process. The six pollutants studied are hydrocarbons (HC), nitrogen oxide (NO\textsubscript{x}), carbon monoxide (CO), particulate matter (PM), sulfur dioxide (SO\textsubscript{2}), and carbon dioxide (CO\textsubscript{2}). Emissions from other parts of the equipment such as the braking system are not included. This paper also does not include other air pollution produced during the construction project such as fugitive dust.

The equipment used for the calculations in this paper was categorized using the tier system derived from the US Environmental Protection Agency (EPA) regulations. Engine tier is a categorization of equipment by age and by regulated emissions quantities for that age. Engines can be identified by the emissions levels that were in place for that model year with each subsequent tier being more restrictive with respect to allowable emissions quantities [EPA 2010].

2 LITERATURE REVIEW

One interesting recent study focused on greenhouse gas (GHG) emissions during the construction of transportation projects in Korea [Kim et al. 2012]. The paper focused on CO\textsubscript{2}, methane, and nitrous oxide emissions presented as CO\textsubscript{2} equivalent. The paper presented an estimation of GHG emissions for two highway projects. The key finding was that earthwork activities consumed more fuel than any other activity and that dump trucks (on-road equipment) are the highest emitters of pollutants. Using these results, the authors calculated emissions during earthwork activities. The optimal equipment fleet for each activity was determined using typical equipment combinations. The activities and emissions quantities were determined using the design documents for each project. Thus, the estimates produced by the authors are based on published data.

Cui and Zhu [2011] surveyed the use of green contracting strategies by state DOTs. The survey was completed by 39 states of which 25 reported using some type of green strategy. The findings indicated that New York, California, Washington, Oregon, and Illinois have green strategy programs that are enforced either by the state government or by DOT. This paper also mentioned that EPA recommends the use of the Pavement Life-Cycle Assessment Tool for Environmental and Economic Effects (PaLATE) to calculate the economic and environmental effects of an existing, proposed, or hypothetical highway construction projects. The output of the tool includes the energy use and emissions produced during the construction and maintenance phases of a project, including material transportation. However, PaLATE is currently only applicable to roadway construction, it only operates at the project level, and it does not assess the impact of individual construction project activities, which is a critical element addressed herein.

A paper by Avetisyan et al. [2012] presented a decision model to select construction equipment for transportation projects. The authors assert that the model can be used for any type, location, and conditions of construction projects. The inputs for the model are derived from information provided by the contractor and included the amount of work and time available for each activity, details about equipment capacity and compatibility, operational and maintenance cost, engine tier specifications, and emissions rates. The model can be used to optimize equipment selection by cost and emissions production. The result of the model is a list of equipment that should be used for the project and the tier for each item of equipment. However, it is not clear from the paper which factors were used to determine the equipment fleet and which equipment characteristics were studied. Only one case study was used to test the model. Finally, there is no way to benchmark their model.
In summary, research has been conducted in auto emissions, other on road vehicle emissions, life cycle emissions, standards development, emissions regulations, sustainability, and green infrastructure. However, other than previous work examining four street and utility projects [Arocho et al. 2014] and the project by Kim et al. (2012) (that looked at GHG emissions during the earthwork activities of highway construction projects) little has been done in measuring and benchmarking emissions from nonroad construction equipment performing actual highway construction work. This paper makes a contribution toward filling a part of that void. Furthermore, it is worth noting that life cycle analyses estimate the quantity of emissions produced during the construction process. The work described herein provides quantification for the construction process to fill that void (replace the estimate) in existing life cycle models.

3 PROJECT DESCRIPTIONS

This section presents brief descriptions of the two highway, the four street and utility, and the building projects analyzed herein. Table 1 shows the basic characteristics of these seven projects. The first four projects are the street and utility projects. Apex and Wake Forest are the two road construction projects. The Building project was a 13,400 square foot commercial building that included parking and site work.

Table 2 shows the construction activities associated with the transportation projects. The building project was not added to Table 2 because the activities needed for it (e.g., earth movement and excavation for the utility connection and foundation, and grading and paving needed for the landscaping and parking area) do not correspond well with the activities for the transportation projects.

4 RESULTS

In this section the paper compares the emissions from the three distinct project types (road, street and utility, and building) for all of the seven projects.

4.1 Project Type Comparison with Tier 3 Equipment

This section shows the emissions results using Tier 3 as the reference for all equipment used. In Table 3 the average daily emissions for the four street and utility projects are lower than the average daily emissions for the building project. The emissions for the two road projects (calculated using the field data) are almost double the emissions for the street and utility and building projects for all the pollutants. The emissions estimates for the road projects using published data (RS Means) are even higher than those using field data (with the exception of PM).

4.2 Comparison Between Field and RS Means Results

To better understand the differences between field and published data the total emissions calculated using field data were compared to those calculated using RS Means data for the Apex and Wake Forest projects. We found that the difference in the equipment fleet between the two data sources is the largest contributor to the total emissions difference shown in Tables 3 and 4. To illustrate this finding Table 5 shows the field and RS Means fleets for the Apex project and clearly shows the difference in equipment used.

The emissions per activity were also calculated using both data sources for both projects. Tables 6 and 7 show total emissions per activity for the Apex project for field data and RS Means, respectively. The activities with the largest contribution to emissions were consistent for field and RS Means data with earthmoving and paving activities on the top of the list for both. These activities are performed by simultaneously using many different items of equipment that results in a large quantity of emissions.

Another metric used to compare the two different data sources is emissions per day. Figure 1 shows CO₂ emissions by day for both field and RS Means for the Apex Project. The RS Means calculation resulted in shorter project durations than the actual duration but matched up well in emissions quantities per day. The emissions per day metric for the field data was 8.55x10⁶ grams of CO₂ while the RS Means data resulted in 8.82x10⁶ grams of CO₂. The results for the other pollutants are also comparable between the two data sources. Figure 1 shows that the project schedule for the field data was 124 days while the schedule for the RS Means data was 77 days. The difference in duration between the two is due to the difference in equipment fleet. The difference in productivity of the different equipment resulted in different activity durations even when the same quantity of work was used for both.

![Figure 1. Apex CO₂ Emissions for Field and RS Means](image)

5 CONCLUSIONS

Our seven projects clearly indicate that RS Means data often produces a different emissions estimate than the results obtained using field data. Where these differences exist they are largely due to the differences in fleet composition recommended by RS Means versus the fleet composition a contractor might actually use. However, on an emissions per day basis, published and field data matched well thus...
verifying the utility of this emissions metric. Finally, we also found that earthmoving and paving activities are by far the largest polluting activities.

The projects compared in this paper have differences not only in type but also in size and complexity. The Wake Forest project was a simple and small road widening project that lasted 13 days. The Apex project included the relocation of a road and an intersection and lasted 124 days. The street and utility projects included the installation of water distribution, sewer, and storm water systems, while the building project was a medium-sized commercial structure. These projects are typical of different construction projects types, although we readily acknowledge that they are not fully representative of all construction project sizes and types. Still, they do provide insight.

Our first research goals was to determine the extent to which project type affects the total quantity of emissions produced. The comparison presented on this paper shows that it is possible to calculate emissions metrics to compare different types of projects.

Another research goal was to determine how different project types vary in their emissions during construction. The results showed that the Apex and Wake Forest projects had similar emissions profiles with large amounts of emissions produced during earth movement and paving activities. This emissions pattern was similar to the one presented by the street and utility projects. Furthermore, the road and street projects produced pollutant emissions throughout the entire duration of the project. In contrast, the building project produced the majority of its emissions at the beginning of the project with almost all the emissions produced during the first two thirds of the project and two thirds of the emissions were produced before the project was even half completed.

More work is needed to increase the number of projects for which forecasts have been produced. However, this very small sample shows that it is possible to identify patterns of emissions production for different types of projects, thus enabling us to begin to develop an inventory and a hierarchy of project type emissions production, thereby alerting designers, in early project stages, of potentially dangerous emissions situations that are a function of project type.

The third research goal addressed whether or not emissions metrics could be used to compare different project types. One such metric was emissions per day. The results showed that all highway projects had higher emissions than the building. However, emissions per day may not be a good method to compare different projects because this metric can vary depending on schedule changes that do not affect total emissions. A better metric for comparison is emissions per unit, but the building project did not have a production unit comparable to the road and street projects. When the street and utility and the road projects are compared using emissions per square foot the results showed that road construction produced more emissions than street and utility projects.

Calculations presented herein included total emissions, emissions per activity, and emissions per equipment type. Activities with a larger contribution to total emissions include earth movement and paving. The activities with the largest contribution for the Apex project were clearing and grubbing, grading, and aggregate base course (ABC) and paving. Gravel subgrade and backfill were the activities with the largest emissions for the Wake Forest project. The emissions for these activities were the highest for both the field and RS Means estimation methods and are all similar in nature.

The equipment types with the largest contribution to total emissions were motor graders, backhoes, front-end loaders, and bulldozers. The large contribution of some of these types of equipment is linked to their high emissions factors. For other equipment types, such as bulldozers, their large quantity of emissions is due to the long hours of use of the equipment for a variety of different activities.

This study shows that it is possible to use published data to obtain a forecast of total emissions at the early stages of the project, making it possible to have emissions forecasts earlier in the project process. An early forecast can be used during the planning process to compare alternatives or to estimate the environmental impact of a potential project. As with any forecast, the accuracy of the numbers can be improved when additional information is available.
Contractors can use a forecasting model during the construction process to assess their emissions production. The actual equipment type and hours of use can be used as inputs rather than the planned (and potentially highly variable) schedule. The forecast could be used to monitor their equipment use and productivity in addition to monitoring emissions produced. Improving productivity could reduce hours of operation for each item of equipment and could result on lower total emissions for the project.

The data collected during construction could be used to calculate a final total emissions quantity for the entire project. This total could be viewed as an equivalent to an “as-built” emissions total that owners can use to evaluate total effect or future activities to offset this effect. Researchers could use the equipment use and total emissions information to improve emissions metrics for different equipment types.

Abstract: To improve the performance of the increasingly deteriorating infrastructure, effective strategic policies must be combined with optimum tactical rehabilitation plans. In the literature, limited efforts have focused on strategic policy analysis and its integration with tactical/operational planning. This paper, therefore, presents a framework that combines the strategic and tactical dimensions of infrastructure rehabilitation. At the strategic level, the System Dynamics (SD) modeling technique has been used to simulate the long-term effect of different policy scenarios on physical performance and backlog accumulation. The optimum policies are then used as inputs to a detailed tactical planning model. The objective of such model is to provide detailed fund allocation plans for the assets that need rehabilitation on a yearly basis. The proposed tactical model deals with large number of asset components over a 5-year plan to determine the best possible combination of repair types and timings. The paper compares the processing time and solution quality of three models that use different optimization approaches: Genetic Algorithms (GA); mathematical mixed integer programming; and Microeconomic-based heuristics. The paper discusses the conceptual formulation of the proposed integrated framework, the developments made so far, present limitations, and future enhancements.

1 INTRODUCTION

A major challenge for asset managers is to determine the appropriate actions needed to preserve the performance of rapidly deteriorating civil infrastructure, over a long service life. Adequately budgeting and planning of infrastructure rehabilitation programs is of extreme importance in achieving this objective (Hudson et al. 1997). Budgeting and planning, however, are complex tasks that require many details about each asset, including present condition, multi-criteria performance, deterioration pattern, possible rehabilitation actions, and rehabilitation impacts. All these are then used to formulate a detailed life cycle cost analysis (LCCA) model of the whole network of assets to facilitate the appropriate allocation of limited rehabilitation funds among the assets (Frangopol et al., 2012). In the literature, infrastructure rehabilitation has been extensively studied and a number of life cycle optimization models have been introduced for different asset domains. Examples are: pavements (De la Garza et al. 2011); water and sewer (Halfawy et al. 2008); bridges (Frangopol et al. 2012); buildings (Rashedi and Hegazy 2014). Most of the existing models, however, suffer from performance degradation when facing large-scale and complex life cycle optimization problems, yet the results are also difficult to explain or economically interpret (Rashedi and Hegazy 2014; Hegazy and Saad 2014).

While existing efforts provide useful life cycle cost models, they do not provide an overall understanding of the rehabilitation dynamics in large networks of assets, over a long period of time. Some efforts
focused on individual assets over a long period (more than 50 years) (e.g., Frangopol and Liu 2007) while others focused on a large number of assets over a short period (5 years) (e.g., Rashedi and Hegazy 2014). These efforts do not provide a comprehensive view that examines strategic decisions and their impact on the life cycle dynamics over a long span of time. Such a comprehensive view, however, is essential for strategic decision-making. This paper therefore attempts to combine the long-term strategic perspective that relates to the setting of budget policies with the short-term tactical perspective that relates to detailed allocation of a decided budget among asset components. The paper explores the potential of the system dynamics (SD) technique as an effective tool for modeling and analysis of the dynamic processes within infrastructure rehabilitation at the strategic level. Also it compares various optimization techniques that can be used to optimize tactical fund allocation decisions. The combination of the two levels of decisions creates a more comprehensive framework for analyzing infrastructure rehabilitation plans.

2 PROPOSED FRAMEWORK FOR REHABILITATION PLANNING

A proposed policy optimization framework is illustrated in Figure 1. The overall objective of this framework is to understand the dynamic interactions among different aspects of asset management, generate various ‘what-if’ scenarios, and optimize strategic policies. The framework’s initial inputs can be categorized into two groups: asset information and organizational information. Asset information is mainly determined using inspection and condition assessment methods. They include asset inventory data, current conditions, historical condition indices, deterioration rates, maintenance costs, and costs of rehabilitation alternatives. Organizational information, on the other hand, includes key performance indicators (KPIs), strategic objectives, and different policies such as budget allocation strategy. To develop the strategic and tactical models of this comprehensive framework, the asset inventory of the Toronto District School Board (TDSB), which administrates a network of more than 550 school buildings, has been used. Also, in this study the key strategic variables have been identified based on reviewing the literature, previous research on TDSB assets, and other guidelines obtained from the TDSB and the Ontario Ministry of Education (OME). The two main components of the proposed framework are as follows:

![Figure 1: Proposed framework for rehabilitation planning](image-url)
Strategic System Dynamics (SD) Model: The strategic SD model investigates the long-term organizational objectives and seeks to examine the impact of different strategic policies, such as rehabilitation budgeting, sustainability policy, or public private partnership (PPP), on asset performance and backlog accumulation. As shown in the conceptual framework of Figure 1, the proposed SD model has four integrated modules: 1) the central policy analysis module; 2) physical condition; (3) backlog accumulation; and (4) sustainability performance. Accordingly, the SD model simulates the dynamic interactions within and among these modules, and can be used to provide policymakers with a clearer understanding of the long-term impact of their policies.

Tactical Optimization Model: After performing the strategic SD analysis, the outputs of the model, such as budget policy, is used as an input to the tactical optimization model to perform a detailed fund allocation analysis over a tactical planning horizon. At the tactical level, three approaches: genetic algorithms (GA), mathematical optimization, and microeconomics-based heuristics are used to achieve the most optimum fund allocation plan.

3 STRATEGIC SD MODEL

System dynamics (SD) is perhaps one of the most promising simulation methods in the area of policy optimization and strategic decision-making (Forrester 1961). Sterman (2000) describes it as “a method to enhance learning in complex systems. Just as an airline uses flight simulators to help pilots learn, system dynamics is, partly, a method for developing management flight simulators, often computer simulation models, to help us learn about dynamic complexity, understand the sources of policy resistance, and design more effective policies.” SD has been applied to a variety of domains from construction to politics, HIV control, and even warfare. In all of its applications, SD has proved to be capable of capturing the dynamics and interactions within complex systems from a holistic perspective, thus making it effective for top-level management (Sterman 2000). In the asset management domain, Rehan at al. (2011) developed an SD model for estimating the financial sustainability of water and wastewater systems and the impact of pricing policies on users. In another effort, Xu and Coors (2012) combined SD with GIS and 3D visualization to examine the sustainability of urban residential development. Other applications have also established the significant potential of system dynamics with respect to the development of holistic models for macro-level management.

To examine the dynamics within complex systems, SD models are developed through three main steps: (1) creating causal loop diagrams (CLDs) to capture the dynamic interactions among the key variables/parameters; (2) mapping the developed CLDs into stock-and-flow simulation components; and (3) running the simulation, testing the model, and analysing the long-term impact of various parameters. These steps, along with the proposed rehabilitation analysis model, are discussed in the next section.

3.1 Casual Loop Diagramming

The development of the proposed strategic SD model starts with identifying the interactions among four main groups of key strategic variables (as shown in Figure 1), related to: policy aspects of asset management, physical condition, backlog accumulation, and sustainability performance. Figure 2 depicts the proposed causal loop diagram (CLD) that captures the dynamic interactions among the key strategic variables. In system dynamics, Causal Loop Diagrams (CLDs) are tools for capturing SD hypotheses about the interactions among different variables/parameters, causes of dynamics, and determining the important feedbacks in the strategic model. A causal loop diagram consists of variables connected by links denoting the causal influences among them. Casual links show effects of variables on each other by link polarities. A positive link, i.e., (+) polarity, implies that the cause and effect are moving in the same direction meaning if a cause increases, the effect increases and if a cause decreases, the effect decreases. A negative link, i.e., (-) polarity, means if the cause increases, the effect decreases and vice versa (Sterman 2000). As and example, a CLD is highlighted in Figure 2 that involves two variables: “asset condition” and “asset deterioration”. In this CLD, “asset deterioration” is linked to “asset condition” by a negative link polarity, which models the fact that higher deterioration typically results in lower condition. Similarly, another negative link in the same loop represents the causal relationship in which higher condition leads to lower deterioration. The combination of these two links then creates a positive
(or reinforcing) feedback loop as highlighted in Figure 2. This positive loop models the dynamic behavior of infrastructure deterioration in which growing deterioration rates results in decaying physical condition in a continuous cycle. With time, such a reinforcing loop exhibits an accelerated rate of deterioration and lower condition indices, until other parameters take part to influence these dynamics.

Figure 2: Causal loop diagram for the proposed SD model

3.2 Stock-And-Flow Modeling

After identifying the dynamic interactions among the parameters that are impacted by strategic policy, the developed causal loop diagram (CLD) has been mapped into a stock and flow simulation model. While the CLD shows the underlying feedback structure of the model, the stock and flow diagram captures the physical dynamic structure of the system. Stocks, represented by rectangles, are accumulations that characterize the state of key system variables over the simulation time. Flows, on the other hand, represent system variables that generate quantities accumulated into (inflows) or out of (outflows) the stocks over time. Figure 3 shows a partial screen capture of the SD simulation model, which has been developed in the VENSIM software. The model includes around 100 decision variables and equations including key and intermediate parameters. Developing the stock and flow diagram of Figure 3 and its underlying simulation model was a demanding process of translating all the loops in the CLD diagram one by one into stocks and flows and writing the related equations. This iterative process includes numerous rounds of modifications of the stock and flow diagram and performing various tests to verify model relationships and the accuracy of results.
3.3 Analyzing Budget Policy

As an example to show the application of the proposed model in determining different strategic policies, a set of experiments was performed to investigate the effect of government investment on asset condition and backlog accumulation, to determine a proper annual budget level. Four scenarios have been generated based on different investment values. Scenario 1 allows assets to deteriorate over time without any rehabilitation (i.e., $0/year), and the next three scenarios (Scenario 2, 3, and 4) investigate the effect of increasing the annual government investment from 0 to $2, $3, and $4 million, respectively. Figure 4 shows the backlog and condition results. As expected, the no rehabilitation scenario causes significant backlog accumulation (almost 7 times more than the $4 million/year scenario at year 50) and results in a decaying overall asset condition (Figure 4). Increasing government investment, as shown in Figure 4, can significantly reduce backlog accumulation and improve asset condition. Sustainable performance results also indicated that increasing the annual budget by only $1 million (e.g., form $3 to $4 million/year) can improve the sustainable performance by 39%. The positive effect of increasing investment on condition and backlog might be obvious, however, the presented analysis can be very useful for the TDSB administrators (or other asset owners) to justify the required budget and its impact on their inventory while negotiating with the ministry of education (or other authorities).
4 TACTICAL OPTIMIZATION

With a budget level imposed on a public agency as a constraint on rehabilitation work (as a result of strategic analysis), tactical decisions are concerned with determining the optimum rehabilitation type (project-level decisions) and rehabilitation timing within a planning horizon (network-level decisions). At the tactical level, this paper utilizes a fund allocation method that integrates both project and network levels of decision. The method is built upon the Multiple Optimization and Segmentation Technique (MOST) of Hegazy and Elhakeem (2011) that reduce problem size to handle large-scale problems. In the MOST technique, the project-level analysis is done first, one year at a time, to determine the most cost-effective rehabilitation scenario (e.g., minor, major, or full replacement) for each asset that maximizes overall condition. This analysis provides a pool of best potential repair strategies, and their associated costs. This information is then used as a lookup input table to simplify the network-level analysis. At the network-level, the problem is segmented into yearly smaller-size optimizations to determine optimum renewal timings (facilitated only by the pre-analysis at the project level) using genetic algorithm (GA), as shown below in Figure 5.

![Figure 5: Schematic of MOST and its adaptation to the network-level fund allocation model](image)

The performance of GAs, however, is highly sensitive to problem size, problem formulation and other operational parameters that govern the GA evolutionary process. As such, a steep degradation of solution quality has been noticed from experimenting with GA on larger problems (Rashedi and Hegazy 2014). Thus, at the network-level, this paper presents three different models to improve solution quality: 1) GA + Segmentation optimization, 2) Mathematical optimization, and 3) Microeconomic Enhanced benefit-cost analysis (EBCA) heuristic. To compare solution quality, the three models are applied to a base case involving 800 school building asset components. The models have a planning horizon of 5 years, an assumed $10M annual budget yielding from the strategic-level SD model, and the objective function of maximizing the overall network condition.

4.1 GA + Segmentation Model

To suit real-life problems that are much larger in size, a segmentation method by Hegazy and Rashedi (2013) has been applied to enhance the performance of GAs. The GA+Segmentation process divides the original network-level problem into smaller sub-problems (segments), handles them separately, and combines their results to produce the final solution. To implement the segmentation process within the tactical model, the available budget, decision variables and optimization constraints have been segmented, without compromising the integrity of the model. Also, the model has been modified to
accommodate the redistribution of unallocated (leftover) money from one segment to the next. Considering these aspects, the GA+Segmentation approach has been fully automated, which makes it practical for real-life applications. In the GA+Segmentation method, the budget is divided among segments (e.g., size of 200 assets) based on the relative criticality (RC) of each segment, which is calculated as a function of the relative importance and the deterioration behaviour of the components within each segment. Subsequently, the budget constraint in year j for the components within a segment is proportional to the segment’s RC value divided by the sum of RCs for all segments. Application of the GA+Segmentation model on the building case study showed significant improvement to solution quality in comparison to the traditional GAs (comparison is shown in Table 1), and effectiveness in handling large-scale problems. The major drawback of this approach, however, was its processing time that showed exponential increase on larger size problems.

**4.2 Mathematical Optimization Model**

To reduce processing time and to find globally optimum solutions, Rashedi and Hegazy (2014) developed a mathematical optimization model that utilizes an advanced mathematical optimization tool, General Algebraic Modeling System (GAMS), which consists of an array of integrated high-performance built-in solvers. The model uses CPLEX solver engine, a powerful mathematical optimization solver that uses advanced algorithms for variety of optimization problems, including mixed-integer programming. The optimization model is designed to be generic enough to accommodate any type of data. The model’s objective function is to maximize the assets’ overall network condition index, which is an aggregation of one or more performance parameters of all individual assets. Each asset can be selected in a year over the planning horizon using a binary decision variable (e.g., \( X_{ij} \)). If \( X_{ij} \) for a certain asset \( i \) and year \( j \) is equal to 1, then the asset is selected for rehabilitation at this year, and the associated rehabilitation cost and benefit would be retrieved from the appropriate lookup tables (value of zero represents no action). The Objective function is set to maximize the network overall condition index, which is the weighted sum of all assets’ condition, considering the relative importance factor of each asset. The total rehabilitation cost, which is the sum of all assets’ costs in any year \( j \), is another constraint that is limited by the available budget for that year. Also, each asset can only be selected once for rehabilitation within the planning horizon to satisfy a single-visit criterion (Rashedi and Hegazy 2014). The GAMS/CPLEX model proves to be promising in terms of both solution quality and processing time and can be effectively used by asset managers for tactical optimization solutions. Using this model a network of more than 50,000 asset components, that is close to the real size of the problem, has been optimized in a matter of minutes resulting in a close to global optimum network condition of 31.71 as shown in Table 1.
4.3 Microeconomic EBCA Heuristic Model

While the previous two models are effective in handling large-scale tactical optimization problems, their development was not simple, thus it is difficult to provide an economical interpretation for the optimization results. The results are typically a set of decisions (usually binary, i.e., a combination of \([0, 0, 1, 0, 0]\) represents a decision to repair an asset in year 3 of a 5-year plan). In case of thousands of assets, which is typical, the combination of zeroes and ones is not easy to interpret or justify economically. Several combinations of zeroes and ones might lead to close-to-optimum solutions, and thus it is not easy to determine the logic behind those solutions.

To handle this issue, an Enhanced Benefit-Cost Analysis (EBCA) heuristic approach has been introduced that uses the microeconomic consumer theory of equal marginal utility per dollar, to arrive at near optimum balanced fund-allocation decisions in a structured way, while providing an economic justification behind decisions (Saad 2014). This theory of equal marginal utility per dollar has been proven, in the microeconomics literature (Chugh 2014), to arrive at optimum allocation of a limited fund by targeting equilibrium (equality) among the marginal utility per dollar spent on the different consumption categories, rather than the typical approach of maximizing benefits or minimizing costs. The basic premise of this approach is an analogy between a consumer who has a limited income to spend on various expenditure categories, and a public agency with a limited budget, from taxpayers’ money, to allocate to various rehabilitation expenditures. As such, optimum fund-allocation is represented by an equilibrium state at which the marginal utilities (benefits) per dollar (MU/$) associated with the rehabilitation of the last selected asset from each category (e.g., Architectural, Mechanical, etc.) are equal. This approach involves a five-step process that is applied one year \((j)\) at a time to facilitate mapping the consumer case in each year in the planning horizon. To arrive at the optimum decision that maintains equilibrium state among the different asset categories the heuristic process is applied to the building case study as follows:

1. For each year in the planning horizon group unfunded assets into their categories (Architectural, Mechanical, and Electrical);  
2. List the performance improvement and the renewal cost for each asset based on the LCCA calculations, assuming all assets will be funded this year;  
3. Compute the Marginal utility per dollar (MU/$) for each asset by dividing the performance improvement by the renewal cost;  
4. Sort the assets in a descending order, according to the MU/$; and  
5. Select assets for funding starting from the top of the sorted list in each category till the MU/$ value of the last selected asset in each category is almost equal, and the budget for this year is fully exhausted. Move unfunded assets beyond this equilibrium point to the next year in the planning horizon.

![Figure 6: Sample of selected assets in first year using EBCA approach](image-url)
Figure 6 shows the application of the heuristic process steps to the school building case study in first year. The assets are grouped according to their system-level categories (Architectural, Mechanical, and Electrical), and sorted in a descending order according to their marginal utility per dollar values. The “Cum. Cost” column represents the total cumulative rehabilitation costs that correspond to a total number of allocated assets in each category. The shaded part shows the optimum (equilibrium) combination of assets for year 1, which is 124 architectural, 51 mechanical, and 43 electrical assets. The total cost associated with this combination is $9,994,640 ($4,509,670 + $3,415,870 + $2,069,100), which almost fully exhausts the available budget while maintaining an equilibrium state among the asset categories. The microeconomic EBCA approach can handle large-scale problems due to its formulation, and it is comparable to the mathematical model in terms of solution quality, yet with a structured strategy supported with economic justification.

5 CONCLUDING REMARKS

This paper discussed a comprehensive infrastructure rehabilitation framework that combines a strategic SD-based policy analysis model with tactical optimization to create detailed fund allocation plans. At the strategic level, the development of a holistic the SD model, including causal loop diagrams and stock-and-flow simulation model, have been discussed. The model was experimented on a policy analysis example with regard to rehabilitation budgeting. Using an appropriate budget level, three tactical optimization models have been discussed, each with a particular advantage, to effectively allocate the selected rehabilitation budget. The GA+Segmentation model can handle large-scale and nonlinear problems, but its processing time increased exponentially as problem size increased. The mathematical GAMS/CPLEX model had the highest solution quality and could optimize large-size problems within a very short processing time. The microeconomic-based enhanced benefit-cost analysis (EBCA) also results in high quality solution that can be economically interpreted, and can handle large-scale problems due to its formulation. The proposed framework of this paper can be applied to variety of asset types and can address the asset management needs at both strategic and tactical levels. This comprehensive model can be used to ultimately improve the economics of infrastructure rehabilitation by allowing asset owners to align all levels of decisions to maximize the impact on asset condition and backlog accumulation.

A FRAMEWORK OF ORGANIZATION PERFORMANCE ASSESSMENT IN THE CONSTRUCTION INDUSTRY USING FUZZY APPROACH

Zenith Rathore¹,² and Emad Elwakil¹
¹ Building Construction Management Department, Purdue University, West Lafayette, United States
² zrathore@purdue.edu

Abstract: Organizations have been trying to increase their efficiency and improve their performance in order to achieve their goals. The organizational success is determined by various factors that impact organization's performance. The ability to predict construction organization performance will enable practitioners to identify the weak points and in searching solutions to improve, thus leading to better efficiency and increase profit. Previous research works have focused on measuring project success and in the process the importance and evaluation of organization's performance in non-financial aspects has received little attention. Uncertainty and uniqueness of projects are inherent characteristics of this industry. Hence, developing an effective construction performance assessment model has been very difficult. Therefore, the objective of the present research is to identify and study the success factors and to propose a performance prediction model(s) for construction organizations. The potential success factors are collected from literature and shortlisted based on construction expert's opinion. A questionnaire is prepared and sent to evaluate the effect of these potential success factors on organizational performance. The collected data will be analyzed using Fuzzy modelling approach to build a prediction model, which will show robust results when verified and tested. The proposed research/model will benefit both researcher and practitioners to predict accurate company performance.

1 INTRODUCTION

Construction is a diverse, project based industry (Ozorhon, 2012). The project-based nature of construction industry makes every project unique (Veshosky, 1998). The unique nature of concerns and challenges often render the generalizable decision rules and frameworks for organizational phenomena unusable (Pinto & Covin, 1989). Financial and tangible assets gained are often translated to organization success. In a review of project success factors conducted by Müller et al. 2012, it is has been noted that project success was considered only as a subject of implementation in the 1980s. The approach towards the subject has evolved over the years. It is now gradually extending from inception to closing out of a project. Today, the literature in this field spans the entire product life cycle from product success to business success. This change has led to shift in emphasis from project success to organization success. The need to examine A/E/C organizations and the factors that impact the performance of organizations is now necessary to compete in an ever-changing marketplace (Liu et. al., 2014).

2 BACKGROUND

A company is a complex structure, comprising of various interconnected components that influence its performance (Tang & Ogunlana, 2003). The existing literature shows that numerous models were developed to measure performance by using critical success factors, performance measures, and
indicators. However, they mostly address metric requirements for the manufacturing industries rather than construction. Studies conducted in the construction industry have laid more emphasis on the measurement of project performance rather than company performance (Isik, Arditi, Dikmen, & Birgonul, 2010). Bontis et al. 1999 proposed Balanced Scorecard (BSC). The framework laid emphasis on qualitative measure at organizational level and advocated the balance between measure of financial and non-financial success. Another example of performance measurement and management framework is Performance Prism. The first part of this framework encourages to assess stakeholder satisfaction, and assess the needs of stakeholder. The second part is to understand the needs of organization (i.e. reciprocal relationships) as well as on how to align strategies, processes and capabilities (Neely et. al., 2001). The prism focuses on significant measures and connects the performance practices within the organization. These frameworks are more than a decade old. Hence, in order to keep up with the ever changing markets, many new studies are being carried out.

Performance prediction of construction organizations enables identification of the weak points in order to improvise processes and to increase profits (Zayed et al. 2012). The attention of organizations is usually focused on improving the efficiency of its tangible assets as they can be measured and evaluated (Hauser & Katz, 1998). In the process, the organizations often do not consider the invisible and intangible assets that impact the overall performance. A good metric systems empowers organization (Hauser & Katz, 1998). In a recent study and analysis of a case study by Gustavsson et al., 2012, a need for new collaborative project practice development and organizational change has been discussed. Company performance can be assessed by evaluation of measurable characteristics of performance indicators (Bititci & Muir, 1997).

2.1 Critical Success Factors in construction organization

Organizations that focus on satisfying the customers with greater efficiency and effectiveness have an edge over their competitors (Neely et. al., 2005). Studies have shown that practitioners have been able to settle that improving communication has a major impact on construction practice. It allows better customer engagement, leading to better performance of organizations. Neely et al. 2005 stresses on importance of metrics associated with quality, time, cost and flexibility, thus relating performance of organizations with project success. Pinto and Covin (1989), Müller et al, 2012 have discussed that project success is dependent on the interaction of individuals, project teams and organizational success. Chinowsky et al. 2000 proposed the concept of seven guiding principles of strategic management for construction industry. These comprise of Vision, Mission, Goals, Core Competencies, and Knowledge resources, Education, Finance, Markets and Competition (Chinowsky & Meredith, 2000). Knowledge and information are now considered as critical factors that influence a company's life. They are rated higher than land, capital or labor (Bontis & Dragonetti, 1999). A good knowledge data base will allow organizations to leverage against their competitors in future and thus giving organizations a competitive edge (Arthur, 1994). Unfortunately, Knowledge being an intangible asset is difficult to measure and hence often forgotten in the process (Bontis & Dragonetti, 1999).

Organizations are conceptualized as “the product of thought and action of [their] members” (Gioia & Sims, 1986) or as Weick 1987 stated “the body of thought by organizational thinkers” (Nicolini & Meznar, 1995). Human elements are the assets of organizations that are capable of learning, evolving, innovating and creatively propelling the growth of organization, which is essential for long-run survival of the organization. It has been noted that majority of Human Resource Accounting (HRA) techniques have been designed for industries like accounting firms, banks, insurance companies and financial service firms, where human resources represent a substantial share of the organization value (Bontis & Dragonetti, 1999). However, construction organization lacks such initiatives that are designed to evaluate employee performance, satisfaction and compensation. Factors such as organization's employee culture and engagement are important aspects for an organization. Other important factor is the feedback systems, as they are extremely crucial for implementation of metric system and evaluating performance of organization. Feedback evaluation is one of the critical success factors that aid in analyzing and improving organization performance (Hauser & Katz, 1998).
2.2 Previous studies

In a study conducted by Zayed et al. 2012 classified 18 Critical Success factors into four categories. i.e. (i) Administrative and legal factors, (ii) Technical factors, (iii) Management and (iv) Market and finance, as shown at Figure 1.

The research work is in continuation to the study carried out by Elwakil et al. 2009. The previously published paper was an overview for an outline or a framework for performance assessment of organizations in the construction industry. The procedure included a literature review and identification of 18 potential critical success factors. This was followed by preparation of questionnaire designed to assess the impact of these factors in the construction industry. The questionnaire had two parts where Part I asked the experts from construction organizations to answer the questions, reflecting their experience and corporation information. Part II asked the experts to use a specified 5 point subjective scale to rate the impact of identified success factors on organization performance. Additionally, the decision-makers were asked to evaluate the overall success of his/her construction organization using a value out of 100. One hundred and fifty questionnaires were sent out to top and middle management decision makers in construction organizations across different countries, i.e., Canada, Egypt, France, Greece, Germany, USA, Saudi Arabia and United Arab Emirates. A total of Sixty three responses were received i.e. A response rate of 42%, which is considered good. A sample response from data is provided in Table 1 (Zayed et al., 2012).

* Data is shared by co-author

Since the responses from questionnaire dealt with 18 factors, it is very difficult to analyse the impact of all the factors. Hence, these factors were evaluated and allotted ranks using ANN training i.e. ranking the factors to determine the relative importance of each variable and the highest impact on the model. Analysis of weights of the trained neural network are used to derive the contribution percentages. The higher the value implies that the variable contribution to classification/prediction is also high. Based on the ANN rankings, 9 factors with highest contribution factor were shortlisted from the pool of 18 factors as shown at Figure 2.

Figure 2: Factors shortlisted using ANN ranking method
2.3 Previous modelling techniques

The previously published paper guides the researchers to the starting point of a detailed research in the field. The previous paper discussed the overall impact of the factors. The selected nine CSFs were used to develop prediction models for performance of construction organization using Artificial Neural Network (ANN) model and regression. Neuroshell software package was used to develop and train the ANN model. Similarly, MINITAB software is used to build a regression model for construction organizations’ performance using the selected CSFs (Zayed et al., 2012).

One of the many advantages of theoretic properties of ANN is the ability to distinguish unspecified relations such as nonlinear effects and/or interactions. However, this advantage comes at the cost of minimized interpretability of the model output. The “black box” quality of an ANN model makes it next to impossible to gain insight into a problem based on an ANN model. Regression technique allows the user to sequentially remove possible explanatory variables that do not contribute to the fit of the model (Sargent, 2001). Regression techniques permit hypothesis testing concerning both the univariate and multivariate association amongst each explanatory variable and the outcome of interest. However, it fails to recognize or identify the highly nonlinear factors, or correlation among variables (Sargent, 2001). Human reasoning being more approximate than precise in nature often makes it difficult to measure and determine the measure of factors affecting a particular cause. Introduced by Zadeh (1965), Fuzzy logic can be used as a tool to understand imprecision and qualitative aspects of natural language and imprecise cognitive reasoning. Fuzzy logic-based systems are used to analyze and process linguistic inputs to derive outputs or decisions, refer Figure 1 (Senouchi et al 2014).

The background shows a lack of a model that considers the qualitative factors and the expert opinions. The objectives of this paper will be: identify and study the success factors and to develop performance prediction model(s) for construction organizations.

![Figure 3: Fuzzy expert system (FES) (Senouci et. al.2012)](image)

3 Research Methodology

The methodology of this research is presented in the schematic diagram (figure 4). The steps are summarized as following:

1. Conduct a literature review to identify the success factors that can impact performance of construction organization. Data collected from questionnaire in the previous study conducted by Zayed et al 2012 will be studied and analyzed.
2. Model the impact of individual factors and establish correlation between factors. It is proposed to develop a performance assessment model for construction organization using Fuzzy Expert System. The model will focus on analyzing the impact of preselected 9 CSFs on the performance assessment model.
3. The model will be tested and validated by results of ANN and regression analysis in order to determine their accuracy in assessing the performance of construction organization.

3.1 Development of Fuzzy Logic-based performance assessment model

Factors that have an impact on an organization's performance are the inputs for the fuzzy model. The selected CSFs have been identified and classified into 4 categories ie. 1. Administrative and Legal, 2. Technical, 3. Management and 4. Market and finance. The output will be the performance of construction organization. The methodology used to build the model using fuzzy expert system is shown in figure 5.
3.2 Values of Fuzzy Input and Output Linguistic Variables

The previous research paper included identification of potential success factors that impact an organization’s performance. These factors were compiled from various literature and expert professionals. A questionnaire was prepared to evaluate the impact of each factor on performance. (Zayed et al 2014). The values of linguistic input variables under the four categories (i.e. Administrative & legal, Technical, Management and Market & Finance) are allotted on a scale of one to five as they don’t have a tangible mean of measure. For example, an input value for a variable such as importance of factor of Clear vision, mission and goals cannot be given any crisp value. Such a factor can only be given rating on a subjective scale. The same concept applies to other variables as shown in Table 2. Miller et. 1956 suggested that maximum number of pieces of information should be seven, plus or minus two.

3.3 Fuzzy Member Function, Inference, Composition and Defuzzification

Inferencing is the process wherein specific values are applied to the input variables to calculate the values of the output variables. In FES, the inference process comprises of four subprocesses: fuzzification, inference, composition, and defuzzification. Inference is a step that involves computation of true value for the range of each fuzzy rule and then applying it to conclusion of each. The next step is called Composition where in fuzzy subsets are assigned to each output variable and then combined together to form a single fuzzy subset for each output variable; and followed by Defuzzification, where the fuzzy output set is assigned a crisp number. (Horstkotte, 2002)

3.3.1 Fuzzy Decision Rules

A FES computes the task formulated as a collection of fuzzy if/then rules. These are rules are formulated by combining certain scenarios and the corresponding output. These rules are represented in the form of linguistic if-then statement. They are describes as: IF precondition 1 exits AND precondition 2 exits AND precondition 3 exits AND THEN consequence 1 AND consequence 2 will be the output (Chao & Skibniewski, 1998). For instance,

\[
\text{IF } C \text{ is } c_n, \quad \text{AND } S \text{ is } s_n, \quad \text{AND } O \text{ is } o_n, \quad \text{AND } P \text{ is } p_n, \quad \text{AND } K \text{ is } k_n, \quad \text{AND } N \text{ is } n_n, \quad \text{AND } E \text{ is } e_n, \quad \text{AND } F \text{ is } f_n, \quad \text{AND } R \text{ is } r_n, \quad \text{THEN } OP \text{ is } op_n
\]
Where C= Clear Vision, Mission, and Goals; S= Competition Strategy; O= Organizational Structure, P= Political Conditions, K= Availability of Knowledge, N= Business Experience (no. of years), E= Employee Culture Environment, F= Feedback Evaluation, R= Research and Development and OP = Overall Performance. For example:

IF Clear Vision, Mission, and Goals is 4, 
AND Competition Strategy is 4, 
AND Organizational Structure is 4, 
AND Political Conditions is 4, 
AND Availability of Knowledge is 5, 
AND Business Experience (no. of years) is 5, 
AND Employee Culture Environment is 4, 
AND Feedback Evaluation is 4, 
AND Research and Development is 4, 
THEN Overall Performance is 70

3.4 Model Implementation

It is proposed to utilize the software Matlab R2014b Fuzzy Logic Tool Box to process fuzzy logic inference. The input of the linguistic variables are fuzzified using the membership functions. One by one the strength of variable is determined and its impact on the output value. The minimum operator is used to calculate the firing strength of each fuzzy rule. The firing strength is directly proportional to the impact on the output. Output membership function maps the height corresponding to the firing strength of rules (Chao & Skibniewski, 1998).

\[ F_i = \min(x_1, x_2, x_3, x_4, x_5, x_6, x_7, x_8, x_9) \]

where \( F_i \) is the firing strength of rule \( x_1, x_2, x_3, x_4, x_5, ... \) are the parameters representing membership of linguistic variables (Chao & Skibniewski, 1998).

After all the rules are evaluated, union member function is used to combine the consequences of all the rules to form an overall membership function. This function is then converted into crisp value using defuzzification method.
### 3.5 Model Validation

The purpose of this step is to check the accuracy of results provided by the model. It is proposed to set aside 20% i.e. 13 responses out of 63 responses from questionnaire for validation purposes. In order to predict error and validate the model, it is proposed to use average validity/invalidity percentages (AIP and AVP), followed by Root Mean Square error (RSME).

In addition to the mathematical validation, the results from previous study by Zayed et al., 2012 will also be used to determine the soundness of model. The models developed in previous study to assess the performance of organization used ANN modelling technique and Regression analysis.

### 4 CONCLUSION

The present study includes a literature survey to validate the importance of critical success factors identified in previous studies. This paper represents development of framework to assess the performance of construction organizations based on nine CSFs using fuzzy approach. These nine critical success factors (i.e. Clear Vision, Mission, and Goals, Competition Strategy, Organizational Structure, Political Conditions, Availability of Knowledge, Business Experience (no. of years), Employee Culture Environment, Feedback Evaluation, Research and Development) were selected in the previous study using ANN ranking system. In order to assess the impact of individual factors on the overall organization performance, they have been modelled using FES. Fuzzy input and outputs and the rules governing them are designed in order to cover maximum possible cases. The study will be a step towards understanding a detailed analysis of factors that may impact the overall performance. The study shows a need for further investigation on critical success factor to select the optimum number and nature for modeling the organization’s performance. The developed research/model benefits both researcher and practitioners to predict accurate company performance.

### References

Abstract: Public private partnerships (PPPs) are a method for the delivery of social and economic infrastructure services in over 80 countries worldwide. PPPs are a contractual arrangement between public and private entities through which the skills, assets and/or financial resources of both sectors are allocated in such a manner that provides optimal service delivery and good value to society. Central to the operation of public private partnerships is the systematic evaluation of the procurement options available to government, an output specification to encourage private design, risk transfer, construction and operational innovation, the detailed analysis of projects over their operational lifecycle, a rigorous and competitive bid process, and the selection of proposals that deliver value for money. Unlike traditional procurement, which is predominantly based on lowest cost to government, value for money (VFM) is a measure that takes into account both the quantitative and qualitative outcomes over the term of a contract. This paper is based on a larger study for the Asia Development Bank (ADB) which contained an international survey prepared by the authors. The ADB report reviewed PPP policy and using six case studies as a basis for comparison. Each study considered experience of policy and institutional frameworks, value for money evaluations and infrastructure projects delivered. The Australian case study is included in this paper as an example of good procurement practice.

1 INTRODUCTION

First introduced as part of the Private Finance Initiative (PFI) in the United Kingdom in the 1990s, public private partnerships (PPPs) have come into wider use around the world as an important method for government procurement of economic and social infrastructure services. In contemporary practice, the PPP is a specialised form of procurement that changes the role of government from owner and manager of infrastructure assets to a buyer of infrastructure services.

PPPs are a method of public procurement that employs a combination of private sector capital and management to deliver infrastructure services to, or on behalf of, government (Regan, 2010). To determine which procurement method is best for government, a comparison of the procurement options is undertaken in the early stages of the procurement process. The criteria used to select the optimal procurement method is known as value for money (VFM) although the criteria used to ascertain which method or which bid offers the best deal for government is determined under PPP policy and this varies significantly between nations. VFM was introduced to infrastructure procurement in the 1980s and has
long served as a measure of the impact of international aid and assistance programs, and spending programs of government agencies for audit purposes (Australian National Audit Office, 2012). In OECD countries, VFM generally includes the formal cost benchmarking of the PPP option against a traditional procurement option on a life cycle costed basis over the term proposed for the PPP contract (the public sector comparator or PSC). This occurs in the bidder selection or investment stage of the project. Further VFM analysis may be conducted following a competitive auction process (the procurement stage of the project) after bids have been received. Policy may also require a qualitative comparison of the best bid and the PSC to identify the best VFM for government.

VFM enables government to measure two key dimensions of infrastructure procurement. First, it requires government to undertake a detailed \textit{ex ante} quantitative evaluation of a project over its life cycle in order to compare and select the best procurement option. Second, with adjustment for risk and competitive neutrality, it provides a means of comparing the most efficient procurement mechanism available to government with proposals received from contractors in a competitive bid process.

1.1\hspace{1em}What is Infrastructure?

Infrastructure refers to the hard assets, networks and human capital that facilitate the functioning of both the economy and civil society. Economic infrastructure refers specifically to the services produced by airports, roads, ports, railway systems, electricity generation plants, water supplies, telecommunications, and waste management and recycling. Social infrastructure refers to services provided to develop human capital in areas such as primary, secondary and tertiary education, facilities for police services, court facilities and corrective services, the health sector, and public buildings. The cost of providing social infrastructure is mostly met from the government’s budget and services possess the characteristics of a public or merit good. However, economic infrastructure may also be fully or partly financed from user-charges, which enables services to be outsourced to private providers on a stand-alone basis.

Infrastructure is an important national asset class contributing to an economy’s output capacity, productivity, and its economic and social development. Infrastructure investment is also linked to employment (short and long-term), reduced private sector costs, productivity and growth (Weber and Alfen, 2010; Regan, 2004).

As an asset class, infrastructure assets and services possesses a number of distinguishing features:

- Investment is long-term, involves high sunk costs and is capital intensive
- Output quality standards and prices are generally regulated
- Long service intervals favour life cycle costing
- Assets generally form part of complex networks
- Output pricing of utilities such as electricity, gas and water have important impacts on the input cost structures of most sectors of the economy
- Assets are generally site and use specific
- Services are generally essential public goods
- Investment is subject to limited competition and economies of scale.

The investment economics of infrastructure assets are well matched to the PPP method of procurement and analysis based on VFM principles.

1.2\hspace{1em}What are the Infrastructure Procurement Options?

There are several procurement options available to government, which can be grouped into three distinct categories. The first is traditional procurement, which accounts for the majority of infrastructure provision throughout the world today. Traditional contracts have a number of distinguishing characteristics that generally include:

- The contract is based on an input specification
- Contractor selection methods is mainly determined on price
• An adversarial contractual framework in which the objectives and incentives adopted by the client, the contractor and other parties to the contract are non-aligned and therefore contributing to agency problems
• Mostly used with short-term complete contracts for construction-only services
• There is limited risk transfer beyond the typical time and cost provisions that apply under fixed price contracts.

The second group of contracts covers a variety of arrangements that adopt a less adversarial contractual framework and make greater use of the benefits of long-term contracts that incorporate both asset provision and service delivery, privately sourced capital and a greater sharing of project risks. The most common procurement forms include the build operate transfer (BOT) family of contracts, PPPs and outsourcing, franchises and concessions. These alternative procurement methods generally possess some or all of the following characteristics:
• An output specification
• A long-term incomplete contractual framework with a much greater alignment of the objectives and incentives of the parties compared with traditional contracts
• Transfer of decision-making to the contractor designed to encourage greater innovation in the construction and service delivery process
• Private finance
• The contractor carries a greater level of project risks than other procurement methods which may include construction time and cost, life cycle costs and operational risks
• Embedded regulatory arrangements including alternative dispute resolution mechanisms and a performance-based remuneration arrangement.

The third group of contracts are relationship-based arrangements for short-term or staged projects. These are an alternative to traditional and PPP procurement methods and are widely used for complex projects in which the specification may be incomplete or the contract price difficult to ascertain prior to commencement of works. The characteristics of relationship contracting include:
• Contractor selected on qualitative criteria including track record, expertise, previous experience with collaborative contracts and cultural match with client values
• A collaborative contractual framework with cost overruns and cost savings shared between the client and the contractor
• A contractual relationship based on high levels of trust and cooperation supported by a joint project management group, “open book” project accounting and an agreed contractor margin
• Agreed project scope and specification.

Procurement methods should be selected on a case-by-case basis and no single method is suitable for all projects. PPPs are a specialised form of procurement that may entail longer preparation times, complex documentation and higher transaction costs than other forms of procurement. Nevertheless, these disadvantages may be outweighed by better VFM outcomes for government determined on a risk-weighted comparative basis. PPP’s are not an appropriate procurement vehicle for delivery of all infrastructure projects or services. VFM is best achieved with projects or services involving complexity, economies of scale, where there is scope for significant risk transfer from government to private contractors, and when opportunities exist for innovation in design, construction and operations.

1.3 What is a Public Private Partnership?

A Public Private Partnership refers to a contractual arrangement between public (national, state, provincial or local) and private entities through which the skills, assets, and/or financial resources of each of the public and private sectors are allocated in a complementary manner, thereby sharing the risks and rewards, to seek to provide optimal service delivery and good value to society (Asia Development Bank, 2012). In contemporary practice, the term PPP has no precise
meaning and is used to describe a number of procurement forms including operations and maintenance contracts, management or service contracts (outsourcing contracts), the BOT family of contracts, franchises, concessions and partnering arrangements (World Bank 2007: 2; Hodge and Greve, 2005: 5-8). PPP is a generic description for long-term contracts between government and a private firm for the provision of economic and social services to, or on behalf of government. In a number of jurisdictions, PPPs are also called the PFI or Private Finance Initiative (United Kingdom and several Commonwealth member countries), PPF or Privately Financed Projects (New South Wales), PPI or Private Participation in Infrastructure (World Bank), BOT, concessions and franchises.

PPP policy may take the form of a special PPP law, the amendment of existing procurement laws and regulations, or a policy and guidance framework issued by a central agency of government such as Treasury and Finance. The characteristics of a typical PPP include the following:

1. An output specification that specifies the service to be delivered and not how it will be delivered (effectively transferring control rights and creating performance incentives for the contractor)
2. Scope for the exercise of private expertise, innovation and incentivised management
3. The transfer of significant service delivery and life cycle cost risk to the contractor
4. Contractor selection relies on qualitative and quantitative criteria (VFM) and not simply lowest price
5. Contracts are incomplete, long-term and generally self-regulating
6. The delivery process may be more complex than alternatives
7. Payment for performance: the government pays only for services that conform to specification.

In OECD member countries, a PPP is generally understood to mean a long-term contractual arrangement under which a private contractor is selected through a competitive bid process to finance and deliver goods or services to, or on behalf of the state (Burger and Hawkesworth 2011: 3; Hodge and Greve 2005, p. 4; Delmon 2009: 93-121; Regan et al., 2011: 364). Contractor selection is on the basis of best VFM, determined using quantitative and qualitative criteria and/or the application of a comprehensive and rigorous PPP policy framework (Regan et al., 2011).

Central to PPP procurement is the criteria used to select both the procurement method and the best proposal received from the contractors bidding for the project. Unlike traditional procurement that compares lowest-cost bids by contractors with an input specification, VFM is a life-cycle costed measure of the qualitative and quantitative aspects of a proposal. It describes the aggregate benefits from a particular procurement solution and measures the net positive gain or welfare benefits that a procurement strategy brings to government. VFM is a technique for selecting the best possible outcome for the money spent by government on a particular activity, program or undertaking (NAO 2009; HM Treasury, 2006: 7; Audit Commission 2010; Australian National Audit Office, 2012: 5, 8). It is widely used in project procurement and particularly for PPPs to determine whether a particular bid or proposal offers a lower cost and better service solution than an alternative procurement route (European Investment Bank, 2011). VFM is an objective that allows procuring agencies to ascertain whether service delivery is designed to appropriately meet the service specification while achieving a reasonable return on investment (Infrastructure Australia 2008a).

In contemporary PPP practice, VFM has assumed greater importance for measuring procurement solutions for infrastructure applications. In some jurisdictions, VFM is the critical determinant for determining whether the PPP is the optimal procurement method. This is done with a comparison of detailed models of a PPP with a traditional procurement alternative. In some jurisdictions, VFM is implied by creating a rigorous project implementation process and a competitive bid market (Delmon, 2009: 13-15). In other countries PPP policy requires the use of the PSC for both the procurement and contractor selection processes.

Value for money (VFM) in public–private partnership (PPP) projects is gained through the engagement of private sector efficiency, effectiveness, and economy and through the appropriate allocation of risks in the
project. The assessment of the potential to secure VFM is a key element of the PPP assessment process. The conclusions on VFM potential will inform governments in developing member countries (DMCs) on whether to proceed with a PPP procurement, and, if so, the form of PPP that could be used. (ADB 2012, Public–Private Partnership Operational Plan 2012–2020). Value for money allows procuring agencies to establish whether service delivery has been structured to appropriately meet the service output while continuing to ensure reasonable stewardship of financial resources. The assessment of value for money should encompass all aspects of the proposal including both quantitative and qualitative elements (Infrastructure Australia 2008). Value for money is the best deal that satisfies the government’s service objectives (National Audit Office 2009).

2 VFM ASSESSMENT IN PROCUREMENT

In some countries, PPP policy may endorse VFM principles without providing specific criteria to determine how VFM will be calculated. The reasons for this may be that government needs to fast-track projects or the government’s fiscal position limits public investment options. The informal assessment of VFM uses systematic approaches to the procurement process that embeds VFM principles in project evaluation and procurement methodologies.

In jurisdictions where a formal VFM process is not required, a comprehensive procurement process that embeds VFM principles may achieve a similar outcome. The elements of a VFM procurement process include a detailed feasibility or procurement options analysis, a pre-qualification procedure, competitive dialogue, technical and administrative requirements that incorporate quantitative and qualitative performance benchmarks, and adoption of a gateway system that prescribes the stages through which a project must pass before it is finally approved. Delmon (2009: 13) describes this approach as "... a holistic assessment of the project delivery and the marginal benefits provided by private investment and the competitive procurement process used".

A PPP policy that adopts one or more of these principles has a greater likelihood of achieving VFM outcomes for government than a PPP policy that does not. However, informal VFM methods do not provide government with sufficient data with which to improve the procurement process, document lessons learnt, raise the skill levels in line agencies and optimise risk transfer with future projects. These outcomes can only be achieved with adoption of a formal approach to VFM assessment.

A number of countries use a competitive bid market to enhance VFM outcomes. The competitive bid market approach is based on the assumption that private infrastructure procurement delivers projects at lower cost and in shorter periods of time than traditional public procurement methods and represent a better VFM option for government. Competition between private contractors in a well-managed bid market is considered the one of the drivers of VFM with PPPs (Ismail et al., 2011). VFM is more likely to be produced by a competitive procurement process over one that is not. However, competitive bidding alone does not ensure VFM outcomes.

When this option is chosen, the government will generally prepare an output specification, consult widely with the market ahead of the bid, make an allocation of project risks and proceed with a competitive bidding process. This is the practice adopted with many concessions and BOT contracts and it relies on a competitive bid market to deliver a better outcome for government than could be achieved with traditional procurement, which is widely accepted as the benchmark for measuring procurement performance. Unlike a PPP, a traditional contract based on an input specification is an adversarial contract and contractor selection employs criteria heavily weighted toward lowest cost. Policies that use competitive bid markets rely on bidder depth, transaction flow, risk transfer, and rigorous management of the bid process. Procurement method is also important and policies may require a minimum number of bidders, pre-qualification, open or closed bids, and competitive dialogue during negotiations. In some jurisdictions, a best and final offer may be requested from short-listed bidders although this may contribute to hold-up delays and rapid escalation of bid costs if not carefully managed. Experience in a number of OECD countries suggests that VFM outcomes are determined by the efficiency with which government manages the competitive bid process, an appropriate risk allocation strategy, and post-selection negotiations to

3 AUSTRALIAN CASE STUDY

3.1 Partnerships Victoria, State Government of Victoria, Australia

The PPP program of the State of Victoria was implemented in 2001 and is managed by Partnerships Victoria, a unit of the Commercial Division, Department of Treasury and Finance. All PPP projects in Victoria are implemented under the Partnerships Victoria policy that operates under the uniform national PPP policy implemented by the Australian Government in 2008. While national policy applies throughout the country, states and territories may modify the national guidelines to achieve a better interface with local institutions, practices and market conditions.

Victoria has a long tradition of outsourcing, concessions and BOT contracts although major projects initiated prior to 2001 are not technically PPP projects, they meet the general policy principles contained in Partnerships Victoria policy. The policy is contained in a comprehensive set of guidance materials without an enabling legislative framework. Victoria has commissioned 22 PPP projects and has two additional projects in the bidding stage. The project list spans a large number of different applications including corrective services, bioscience and medical research facilities, hospitals, waste water reclamation and processing services, court buildings, a convention centre, a rail and road transport interchange complex, toll roads, schools, desalination plants, telecommunications and data services. The Partnerships Victoria project list may be viewed at Partnerships Victoria web site (www.partnerships.vic.gov.au).

Projects that conform to Partnerships Victoria Policy are referred to as PPPs and projects delivered before the commencement of Partnerships Victoria or which involve alternative implementation procedures are described as BOT contracts, franchises or concessions. Victoria has undertaken a large number of non-conforming projects in the past 20 years including the franchising of operations and management for the Melbourne metropolitan public transport system and the construction and operation of the extensive Citylink toll road network. BOT projects are also undertaken by statutory authorities and institutions but no PPPs have been commissioned by local government.

3.2 Institutional Framework

The effectiveness of a government’s PPP policy and delivery schedule is influenced by the effectiveness of its institutions, both formal and informal. International indicators (The World Economic Forum 2013; Transparency International 2010; World Bank 2011) provide comparable data about the efficacy of institutions for most nations but not subnational governments. Victoria holds a similar credit rating to Australia and the national institutional survey data serves as an appropriate proxy for Victoria’s institutions.

3.3 Policy Framework

Partnerships Victoria is a policy-based framework that operates in parallel with conventional government procurement policy. The policy is issued by the Commercial Division of the Department of Treasury and Finance which operates a specialist PPP unit to assist line agencies with project selection, evaluation and implementation. Comprehensive guidance has been issued for the program and periodic updating takes place to meet changes in the operating environment and document the lessons learnt from both policy and project implementation over time. As a subnational government, Victoria’s PPP policy applies only within the state of Victoria although Partnerships Victoria policy has been adopted in other states and territories and serves as a best practice benchmark in many countries.

The foundations of Partnerships Victoria policy are the following guidelines:

- 2001 Policy Overview
- 2001 Practitioners Guide
The PPP framework for Partnerships Victoria involves a number of well-defined steps in the procurement process. The procurement evaluation process is initiated by the line agency responsible for service delivery and involves identification of the service need, an appraisal of procurement options, and the construction of a PSC. The project implementation stage refers to the bidding and contractor selection process, negotiation of the contract and contract close.

3.4 Value for Money (VFM)

Prior to the introduction of the national PPP policy in 2008, Partnerships Victoria required line agencies to approve PPP projects through a “gateway” system of eight well defined steps (Table 1). National PPP policy recognises the need for policy to be adapted for local conditions. In Victoria, the PSC is developed for a reference project that is constructed from the initial scoping exercise, the benefit cost analysis, the business case and procurement options analysis. It is finalised during the project development stage and before the distribution of expression of interest documentation to the bid market. When formal bids are received at the end of the request for proposal process, a comparison is made with the PSC and an assessment made of the qualitative attributes of each bid. Bidders are asked to submit bids that meet the output specification, scope and risk allocation nominated in the RFP. In reality, bids may not fully comply with the reference project: some may refuse to accept the risks nominated and others may offer alternatives ways to meet the service requirement. The assessment of VFM will need to consider these variations in bids and their impact in quantitative as well as qualitative terms. The PSC may be modified after bids are received if the agency believes that a significant component has been mispriced or omitted, and when there has been significant change in underlying assumptions between the commencement of the PSC and the receipt of formal bids (Partnerships Victoria 2013, pp. 15-16).

3.5 Value for Money Framework

Partnerships Victoria policy is based on VFM principles and employs the PSC to undertake the quantitative analysis in both the procurement and the bidder selection stages of the project. The policy provides comprehensive guidance to assist line agencies to undertake options analysis, identify and measure risk and construct a life cycle costed and risk-weighted PSC. For a PPP project to be approved, it is necessary for the line agency to establish that the PPP option represents a better VFM proposition than government delivery using a traditional model. This decision is not based solely on a quantitative comparison of a bid with the PSC but takes into account both the quantitative and qualitative dimensions of the bid. All things being equal, strong qualitative attributes may outweigh a more costly procurement option for government. The VFM assessment conducted for recent Partnerships Victoria projects is fully disclosed on the agency’s website www.dtf.vic.gov.au/Infrastructure-Delivery/Public-private-partnerships/

3.6 Projects Delivered

Few international PPP programs have delivered PPPs in as many industry applications as Partnerships Victoria which has delivered 22 PPP projects with a capital value of AUD11.5 billion since 2001 with a further AUD1.1 billion presently under tender (see Table 2). The industry sectors include:

1. Toll roads and non-tolled motorways (2)
2. Biosciences research facilities
3. Water reclamation works (2)
4. Hospitals (4)
5. Medical research facilities
6. Corrective services (3)
7. Waste water and bio-solids management (2)
8. Railway station and multi-modal transport node
9. Public facilities (showgrounds)
10. Convention centre
11. Schools
12. Judicial facilities
13. Desalination project
14. Emergency and security telecommunications and data storage (3).

Case studies for these projects and details about the PSC and VFM assessment are available at Partnership Victoria:

PPP contracts accounted for around 10% of Victoria’s capital spending between 2001 and 2013. The majority of Partnerships Victoria projects are delivered within 24 months of commencement, which reduces transaction costs and has assisted the development of a competitive bid market.
3.7 Role of Agencies

Partnerships Victoria policy is managed by the Commercial Division, Department of Treasury and Finance which operates as a PPP unit providing technical and other assistance to line agencies for project evaluation and delivery. The Department also applies considerable resources to the training of contract managers, conducting market briefings, preparing data and completion reports for commissioned projects, and assisting line agencies to build their own in-house capacity to deliver PPP projects under the Department’s oversight. Only one of the projects listed (Ararat Prison) has had construction problems.

4 CONCLUSION

There is a divergence in PPP policies between advanced countries and those at other levels of development. Advanced economies typically employ VFM principles in their policies both as an objective and as an assessment requirement, and explicitly include risk transfer, a PSC/quantitative measurement, or an output specification in their procurement decision-making. However, VFM can be achieved with a rigorous and well governed PPP process, a two-stage (pre-qualification and tender) bid process, competitive bidding and bid selection criteria that takes into account qualitative and quantitative factors. The evidence suggests explicit recognition of VFM as a PPP procurement objective and the adoption of
an output specification, risk allocation practices, and quantitative benchmarking will enable PPP policies to better harness the benefits offered by the PPP procurement method.

Abstract: When new delivery methods are introduced in public procurement, it is customary to analyze and compare their performance against traditional methods. Many early studies compared performance of different project delivery systems, and often developed decision support tools to help owners follow a structured path in measuring performance and, consequently, choose the most appropriate project delivery method. However, the measurement process adopted by these studies was mostly specific to the dataset to be analyzed. Only rarely, it took into account differences deriving from varying project characteristics, and, therefore was not generalizable. Building upon these studies, this study proposes a general framework for comparing performance of projects delivered through different delivery methods. A discussion of how the framework could also be adapted to every industry sector is included. This work can help owners choose a set of metrics to evaluate and compare the performance of project portfolios delivered with more than one delivery method and different industry sector.

Keywords: project delivery methods, construction project success evaluation, project performance metrics

1 INTRODUCTION

When in 1996 the U.S. Congress passed the “Clinger Cohen Act” authorizing public agencies to use the Design-Build (DB) project delivery method, the uncontested predominance of the traditional Design-Bid-Build (DBB) method was brought into question. Encouraged by results obtained on projects delivered through DB, a growing number of states passed legislation to allow other delivery methods including Construction Management at Risk (CMR), Design Build Operate (DBO), and Public-Private-Partnership (PPP). Early on, analyzing and comparing the performance of newly introduced delivery systems was required to allow public owners to assess and often justify their choice. Therefore, many early studies compared performance of different project delivery systems, and often developed decision support tools to help owners follow a structured path in measuring performance and consequently, choose the most appropriate project delivery method. However, the measurement process adopted by these early studies was mostly specific to the dataset to be analyzed, only rarely took into account differences deriving from varying project characteristics and size, and, therefore was not generalizable (Heisse et. Al. 2011).

Over the years, as the success of project management has become inextricably linked with cost, time and quality performance (Atkinson 1999), a number of relative, static and dynamic performance measurement metrics have been developed (Gransberg et al. 2003). Relative metrics are those independent from the size of the project, allowing for comparison among projects that consistently differ for size. Examples are time and cost growth metrics. Static metrics depend on project size, allowing comparison for those
projects that have roughly the same size only. Examples are cost per square foot of constructed area or charge days per lane-mile of highways. Dynamic metrics vary according to both time and size; construction placement expressed in dollar is an example. However, despite the increasing availability of various types of metrics to compare and analyze performance of delivery systems, a general understanding of the metrics that may be applicable to compare project portfolios delivered using different methods in various industries is still missing. As an attempt to overcome this gap and enhance the understanding on how to perform internal benchmarking for delivering diverse project portfolios, we propose a framework developed through a critical analysis of previous studies.

Following a meta-analytical approach, we combined results from previous studies to identify patterns and sources of disagreement among results, or other interesting relationships that may help us formulate a general framework for evaluating the performance of a diverse project portfolio. A small set of projects was also used to narrate the application of the framework. The framework is presented as follows. Firstly, we analyze previous studies. Secondly, we propose the methodology and develop our framework. Then, we give an interpretation of results. Finally, we draw conclusions with future research directions.

2 LITERATURE REVIEW

As previously highlighted, this paper relies significantly on the studies of the main authors who analyzed project performance according to the delivery method adopted.

Konchar and Sanvido (1998) were the first authors to introduce a model of performance comparison among DBB, DB and CMR delivery methods in terms of cost, schedule and quality performance. A sample consisting of 351 building projects in the U.S. was used in their analysis. The model consisted of two t-tests to verify if the difference in means among the delivery systems was significant, as well as a Mood's median test for sample medians (95% confidence interval). Two multivariate regression analyses were performed, aimed to develop three models explaining the variability of unit cost, construction speed, and delivery speed, and the second for cost growth and schedule growth. This first empirical study on the performance of project delivery methods strongly concluded that DB provided cost and schedule advantages over DBB and CMR without sacrificing quality. Allen (2001) performed a study on 110 MILCON projects of the Southwest Division, Naval Facilities Engineering Command (SWDIV), from fiscal year 1996 to 2000 to compare performance of DBB and DB projects. Performance of DBB and DB projects were classified and compared in subcategories as vertical and horizontal projects, homogeneous projects and Bachelor Enlisted Quarters (BEQs) projects. Again, this study found DB to outperform DBB in terms of cost and schedule, but quality performance of the two delivery methods varied depending on the quality target being measured. Gransberg et al. (2003) analyzed 88 federal building projects that were developed under DB and DBB delivery methods. The aim of their work was to establish a framework for making programmatic decisions about the expected results delivered by the two project delivery methods exploiting performance metrics. Project performance was compared using cost growth, time growth, completed unit costs, design placement, construction placement, DB placement. They found that DB projects were completed with much lower cost and time growth than DBB projects.

Ibbs et al. (2003) structured a model for performance comparison among DBB, DB and other available project delivery methods. A number of 67 projects from the Construction Industry Institute (CII)’s database were taken into account; and change cost, change schedule and productivity were the performance metric used in their study. This study confirmed previous studies when concluded that DB delivery results in time savings, but could not conclude that a method was better than the other in term of cost performance. Instead, the authors suggested that project management expertise and experience of the contractor impacted project performance more than project delivery strategy. Kuprenas et al. (2007) presented a comparison study of public sector municipal facilities projects delivered using DBB and In-House construction delivery method. Cost comparison was possible through 18 public sector municipal facilities projects completed for the Bureau of Engineering over two years. Project size, construction cost, change order value, design cost, construction management cost, total project cost, percentage breakdown by phase, and cost per square meter/square foot were the performance metrics utilized in this study. Results identified several benefits of the in-house delivery route over DBB, but also recognized that this approach was employed on smaller size projects.
In recent years, Hyun et al. (2008) set up a model for evaluating the level of design performance of DB and DBB multifamily housing projects begun in 2000, conducting a quantitative analysis on quality performance. Construction drawings and specifications of public multifamily housing projects were taken into account. Similarly to Allen (2001), Hale et al (2009) analyzed MILCON projects, but limited their analysis to BEQs projects. Thomas et al. (2009) used data from 617 projects from the CII, Benchmarking and Metrics (BM&M) database to compare performance of the DB and DBB delivery methods. This study relied on a set of performance metrics to evaluate performance in terms of cost, schedule, safety, changes, and rework. It also relied on a set of practice use metrics, including pre-project planning, constructability, project change management, design/information technology, team building, zero accident techniques, material management, planning for startup, quality management. Moreover, projects were compared by delivery system, sector, industry group, cost category and project nature, for both owners and contractors. Data were used to determine the relationship between practice use and performance. Practices that provided the greatest performance benefit for both owners and contractors of DB and DBB projects were identified. Moreover, Thomas et al. (2009) also analyzed the effects of fast tracking (i.e. difference between the actual construction phase start date and the actual detail design phase finish date) and schedule adherence (i.e. ahead/on time/behind) on safety performance for both owners and contractors of DB and DBB projects.

Shrestha et. al. (2007) performed an input-versus-output benchmarking approach to assess the performance of large DB highway projects, and found clear trends between project cost and schedule performance and 15 input factors, including location, pavement type, and nature of construction among others. Later, Shrestha et.al. (2012) compared and analyzed the relationship between DB and DBB project delivery methods and performance metrics of highway projects costing more than $50 million using a dataset of 130 projects, with the goal of developing a generic approach to compare performance of large highway construction projects. After normalizing the project for their size using per lane mile metrics, they found that DB projects were constructed and delivered significantly faster than DBB projects. Bogus et al. (2010) collected data from 100 water and wastewater projects with a total price of at least $3 Million to show the influence that project delivery method and contract payment provisions have on schedule and cost performance. As performance metrics, the authors utilized overall schedule growth, construction schedule growth, design and construction cost growth, and intensity. Three different statistical tests were performed during this study: a t-test to verify that the difference between the two population means exists, a Pearson goodness-of-fit to test for the difference between the two population medians, and a z-distribution test for the difference between two population proportions. The authors found that schedule or cost growth was more likely to appear when lump-sum contracts were used than when cost-plus-fee with a guaranteed maximum price (GMP) contract pricing provisions were used. Shane et al. (2013) collected data on 31 DB projects and 69 DBB projects through a survey from municipal water/wastewater facility owners. The aim was to compare performance of DBB over DB delivery method on cost (i.e. growth, unit, total) and schedule (i.e. growth, duration, construction speed, delivery speed). Finally a hypothesis testing to check for a difference between two population means was performed by treating the variable rating as a quantitative variable. These analyses led to quantify that schedule growth under DB was about fifty percent that under DBB. Similarly, DB led to better performance in terms of cost growth. Still, quality of projects delivered through the two delivery methods was comparable.

3 RESEARCH METHODOLOGY

3.1 Metric collection

The main objective of this research is to provide construction project owners and stakeholders with an unbiased and structured overview of the tools available for evaluating performance of project portfolios executed via different delivery methods and in different industry sectors. Starting from the broad concepts of project delivery and project performance, an articulated research was performed to identify previous studies that had compared the performance of project delivery methods or compared project performance in relation to the delivery method.
A thorough literature search process was carried out. This initially relied on the “snowballing” technique, but later moved toward a more systematic approach. In the first stage, the authors initially analyzed a sample of about 60 papers. Then, a more structured process was established that exploited standard searches in various research databases, including “Google Scholar”, “Engineering Village” and “JSTOR.” These searches relied on keyword strings, such as “project delivery method comparison”, “project delivery method performance comparison”, “project delivery method construction” and “project delivery method using performance metrics”. This search allowed analyzing work by the most influential authors, which led to identify a subset of 21 papers, named the project delivery method (PDM) sample that was further analyzed to retrieve the metrics that the authors utilized in their work. This subset included papers from authors who had analyzed the project performance in relation to the project delivery method. The set of metrics extracted from this subset was named PDM metrics sample. Table 1 provides examples of how the information was collected and organized.

Table 1: PDM metric collection format

While reviewing the 21 papers to extract the relative metrics, we underwent a classification into either measurable (i.e. metrics or variables) or abstract in nature (i.e. constructs) factors. Any factors that could not be measured because they were abstractions intended to conceptualize latent variables were excluded from the metric sample because they were not suited for this work. Following this approach, factors, such as administrative burden, conformity to expectations, operation and maintenance, system quality and satisfaction (Owner/Overall) were deleted from the metric list because they were intended as constructs. At the end of this operation, the PDM database consisted of 43 metrics.

3.2 Metric Validation

Since the PDM metrics sample relied on only 21 papers (i.e., PDM sample), we underwent a validation task to verify if any additional relevant metrics adopted in the construction industry to assess project performance were missing. A structured research was carried on the SCOPUS database with the following key-words: “Project Success” AND “Construction” AND “Cost”, “Project Success” AND “Construction” AND “Price”, “Project Success” AND “Construction” AND “Time”, “Project Success” AND “Construction” AND “Schedule”, “Project Success” AND “Construction” AND “Safety”, “Project Success” AND “Construction” AND “Quality.” Since construction literature on these topics mostly builds upon previous work, only the last three years were taken into account (i.e. 2012, 2013, 2014). This search resulted in the identification of about 80 papers that were analyzed to extract the metrics used by the authors in their project performance evaluation.

The validation process is based on the concept that the metrics found in our PDM sample are representative of the vast majority of the “metric population” in the construction industry. The objective of the database consultation was to highlight the fact that the PDM metric database is sufficiently reliable and no important metrics were excluded. A set of 28 factors was identified, of which, four (i.e. formality, phase schedule factor-design, profitability, and integration) were not present in the PDM databases, but with a frequency lower than 6%, and 6 that were considered constructs, so they were not included in this study.

After the filtering, the frequency of each of the 22 remaining metrics was computed in relation to the total occurrence in each paper (59), in relation to the number of papers containing the specific metric (15) and over the total number of metric appearance (71).

Once PDM metrics were separated from constructs and validated through the triangulation with the SCOPUS database, Table 3 below, was created with the relative metrics, occurrence of the latter with respect to all the papers in the sample and the relative frequency in relation to the total occurrence in each paper (21) and in relation to the number of papers containing the specific metric. An additional computation was made to obtain the frequency of appearance of each single metric, among all 21 papers, in the specific industry sector.

4 RESULT INTERPRETATION

Figure 1 shows the frequency distribution of PDM metrics. The mean value of the frequencies equals 2%; in particular, it can be observed that 21% of the metrics distribution is above the mean value, as follows: (a) Cost Growth (16%); (b) Schedule Growth (14%); (c) Unit Cost (6%); (d) Call Backs, Delivery speed, Intensity and Start-up costs (4%); (e) Change Order Cost, Phase Cost Growth-Construction (3%).

Figure 1: PDM metric frequency

Four main industry sectors have been identified though the analysis of the PDM metrics sample, as shown in Table 2. Figure 2 presents the Industry sectors distribution for each single PDM metric.

In particular, it can be observed how the maximum percentage value of the Residential building factor (25%) is at rework costs metric where the remaining factors cover the same percentages; the lower values of the same factor are recorded at schedule growth and cost growth metrics (9%). Nearly 79% of the total PDM metrics do not involve the residential building sector.

Some PDM metrics are representative for the building sector only; in particular, it has been observed how Phase Cost Factor-Design, Cost per Bed, Cost performance index, Fiscal year duration, Project duration per bed, LEED certification characterize only this industry factor. The lower values are recorded at Rework costs, Phase Cost Growth-Award, Change Cost Factor, Phase Schedule Growth-Construction, Phase Cost Growth-Design (9%). Nearly 7% of the total PDM metrics do not involve the building sector.
Some PDM metrics are representative for the infrastructure sector only; in particular, it can be observed how Phase Cost Growth-Design, Cost per lane, Phase Schedule Growth-Design are specific to this sector. The lower value is at unit cost (14%). Nearly 42% of the total PDM metrics do not involve the infrastructure sector.

As far as the Heavy Industrial sector is concerned, the maximum percent value (50%) is for the Phase Cost Growth-Startup, Phase Cost Factor-Startup, Phase Cost Factor-Rework, Change Schedule Factor, Phase Schedule Growth-Startup, Phase Schedule Factor-Rework, Phase schedule factor-Construction, Phase schedule factor-Startup, Recordable Incident Rate (RIR), Lost Workday Case Incident Rate (LWCIR). The lower value of this sector is at unit cost (14%). Nearly 14% of the total PDM metrics don’t involve heavy industrial sector.

When comparing the PDM metrics, filtered from the constructs, with the SCOPUS database, just 21 PDM overlapping metrics, appearing in both samples, have been studied over a total of 43 PDM metrics.

![Graph showing industry sector distribution by metric](image)

**Figure 2. Industry Sector Distribution by metric**

Figure 3 shows the frequency distribution of the overlapped metrics. It can be observed how the maximum and the minimum values in the two different datasets are found at the same metrics.
5 CONCLUSIONS AND FUTURE PERSPECTIVES

Recent advances in contracting approaches, delivery methods and technology have been making the construction industry more complex. Inefficient and biased evaluations about the project performance deriving from the involving technology, blurring geographical borders, green products or high quality
requirement, and vague identification of roles may lead to worsening management of construction projects. Apparently, owners tend to evaluate performance through personal preferences or previous experience rather than exploiting a systematic approach; these biases could result in misevaluation, subjective measurements or ultimate failure in generating the right motivations for the involved parties.

Based on a thorough research on previously used metrics, this paper is proposed as a support for selecting the appropriate metrics that optimize evaluations and help owners efficiently make better and more objective decisions. This work is intended to provide owners of construction projects with: (1) an objective and exhaustive overview on the metrics adopted by the most influential authors in the field; and (2) a structured selection approach for choosing the most suited set of metrics for the evaluation of their projects and project portfolios.

A set of definitions is proposed for all the identified metrics, which highlights what they measure and how they properly work as an instruction booklet. With this aided selection tool, the choice of the right metrics set requires only few simple steps. After the definition of the industry sectors involved in the project portfolio, a list of metrics, previously validated through the SCOPUS database, will be identified. The result is a subset of metrics, taken from the PDM database, that have been successfully exploited in the analysis of projects involving the same industry sectors.

As a practical example presented in Figure 5, a hypothetical project owner could aim to compare the effectiveness and efficiency of a project portfolio, ranging from residential buildings, infrastructure, to heavy industrial. Using the results of our work, this owner could timely access to the list, and develop his own subset of metrics, which includes nine available metrics to choose from. This guide not only saves time for owners, but also produces a more objective outcome for projects in cross-sector evaluations.

![Structured metric selection approach](image)

Figure 5: Structured metric selection approach

In this study, the small dimension of the PDM metric sample could be source of reduced results accuracy. Whereas the cross-validation against the SCOPUS database was designed to reduce this issue, it may be the risk that the literature on this topic may not be mature enough to encompass all possible metrics to evaluate project performance. These suggestions can be the basis for new studies in the project evaluation and delivery system field. Trying to consider in the analysis each project delivery method analyzed by the authors could lead to more accuracy.

**References**

Abstract: Retrofitting existing buildings has received significant attention due to the potential opportunities that it can offer for energy saving. This, in turn, has increased the demand for building a better workforce for advanced energy retrofit industry to successfully support planning, designing, and implementing energy improvement projects. Recently, the National Renewable Energy Laboratory, in conjunction with the National Institute of Building Sciences (NIBS) and the U.S. Department of Energy convened a study to identify the critical duties and tasks required for four of the advanced commercial energy job titles including Building Operations Professional, Energy Auditor, Building Commissioning Professional, and Energy Manager. In the present study, a competency model is developed for these four job titles, based on the job task analyses and best practices. In addition, focus groups and individual interviews were conducted to supplement and corroborate the findings. The goal of the competency model is to help articulate and classify the competencies required for engagement and advancement of talented individuals needed to complete energy retrofit projects. The model will also help to match job requirements with industry-recognized skills and reveal gaps in competencies in the industry to enhance the expansion of the energy retrofit market. It will also support the growth of the energy retrofit workforce by guiding the development of new education and training programs or modifying the existing programs to address the missing parts. The methodology followed through this research also informs future efforts to identify key competencies and associated work products in new and emerging fields in the building industry.

Keywords: Energy retrofits, commercial buildings, competency model, workforce demands

1 INTRODUCTION

Energy efficiency has a key role in achieving our nation’s goal of improving the use of resources. According to the preliminary results from the 2012 Commercial Building Energy Consumption Survey (CBECS), the United States has more than 5.6 million commercial buildings with approximately 87.4 billion square feet of floor space, representing a 14% increase in the number of buildings since 2003 (US Energy Information Administration 2014). This increase will greatly impact the energy consumption and expenditures. A 2011 survey conducted by Institute for Building Efficiency indicated a high interest in energy efficiency projects among building owners. This, in turn, is increasing the demand for building a
better workforce with advanced competencies in operations, maintenance, and energy-related technologies of buildings (Institute for Building Efficiency 2012).

To meet the needs of a high-growth sector such as the advanced commercial building workforce, business/industry leaders, educators, trainers, career counsellors, and job seekers must understand what competencies are necessary for workplace success. An industry competency model can serve as a resource to help articulate the workforce needs. Competency models also establish the basis on which instructional designer and curriculum developers ensure that workers are developing the right skills. Furthermore, an industry competency model can communicate the crucial competencies required for occupational licenses and certifications (Personnel Decisions Research Institutes, Inc. and JBS International, Inc., Aguirre Division 2012). Distinctive from the common articulation of knowledge, skills and traits associated with positions, competencies are typically aligned with the ability to create results.

In the early 1970s, McClelland indentified competencies as significant predictors of employee performance and employee success. A competency is an assortment of knowledge, skills, abilities (commonly called KSAs), behaviors, and personal characteristics, that encompasses mental, intellectual, cognitive, social, emotional, attitudinal, and physical aspects necessary for success in a given role, job, or position (Boyatzis 1982, McClelland 1976). McClelland regarded competency models as an assessment tool that can help to develop behaviorally-based interview protocols; clarify hiring requirements in terms of finding the right fit; equip the staff with complete information regarding succession into specific positions, inform employers about the necessary development strategies; and finally educate potential job seekers to be employable. Competency models are also regarded as an asset for human resources to assist employees, both at entry points into a position and moving up or over to other positions, in order to benefit the organization (Boyatzis 1982, McClelland 1994).

A competency model is a descriptive tool often represented through illustrations that map competencies in a hierarchical manner, which identifies the competencies needed to operate in a specific role within a(n) job, occupation, organization, or industry. Competency models can take a variety of forms (Campion, et al. 2011. Cao and Thomas 2013). Typically, they include the following elements:

- Competency names and detailed definitions;
- Descriptions of activities or behaviour associated with each competency; and/or
- A diagram of the model.

Thus, a competency model can benefit both supply and demand sides of employment. Learners, students, incumbent workers, or employment candidates applying for a position can all take advantage of it. Competency models are also equally useful for individuals seeking employment, advancing in their jobs, or transitioning between careers. Furthermore, educators, trainers, and human resource professionals can utilize the competency model to develop initiatives and programs that meet the needs of employees (Campion et al. 2011, Ennis, 2008). The Department of Labor’s Employment and Training Administration (DOLETA) provides job training and assistance with finding jobs and careers in government, and has started putting more emphasis on competency models as a means to build a better workforce (Ennis 2008).

2 DEVELOPING ADVANCED COMMERCIAL BUILDINGS WORKFORCE COMPETENCY MODEL

It is recognized by the Consortium for Building Energy Innovation (CBEI) and the DOE Office of Energy Efficiency and Renewable Energy (EERE) that there is a need to develop a support system to build a better workforce. Currently, there is an extraordinary amount of technical standards, training, and credentials related to the commercial building workforce. To help support these efforts, the CBEI began working on the competency model for the energy industry in 2012. The competency model was updated in 2014 to include updated job task analysis (JTA) information and align with the Better Buildings Workforce Guidelines.
2.1 Job Task Analysis

The JTA project was under the DOE Office of EERE by the National Renewable Energy Laboratory (NREL). Four job titles were selected as part of the Better Buildings Workforce Guidelines initiative and were the basis of the Advanced Commercial Buildings Workforce (ACBW) competency model. JTA is a procedure for analyzing the tasks performed by individuals in an occupation, as well as the knowledge, skills, and abilities required to perform those tasks. Specifically, a JTA can be defined as "any systematic procedure for collecting and analyzing job-related information to meet a particular purpose" (Raymond 2001). JTAs can be used to describe, classify, and evaluate jobs, ensure compliance with legal and quasi-legal requirements, develop training, promote worker mobility, plan workforces, increase efficiency and safety, and appraise performance (Brannick et al. 2007). The JTAs identified and cataloged all of the activities a worker performs for a given job, and determined the essential knowledge, skills, and abilities which define the minimum requirements necessary for an individual to adequately perform their job. The four job titles the JTAs were completed on include:

1. Building Operations Professional
2. Energy Auditor
3. Building Commissioning Professional
4. Energy Manager

2.2 Competency Model Framework

After analyzing JTAs and the background information, the building blocks model was utilized to depict the key competencies needed for the ACBW. The building block model is a visual representation of the competencies for an entire industry (Figure 1). Levels in the model correlate with the likely arenas in which competencies are cultivated from personal traits developed through life experiences to those learned in training, and onward and upward through increasingly focused work experiences. The model can be used to understand the competencies required to work in an industry and how they to match job requirements with industry recognized skills. The model can also illuminate gaps in competencies in the industries where short-term training programs can be developed to address them or where existing programs can be modified (Ennis 2008).

![Figure 1: The Competency Model framework](image-url)
The DOLETA Competency Model Clearinghouse describes the generic framework used for this study. Figure 1 represents the competencies that exist on three tiers. The first tier has a broader application to many industries or occupations and includes: workplace competencies, academic competencies, and personal effectiveness. The next tier is more specific to an industry and an occupation. These competencies are industry-related and include: industry-specific technical competencies and industry-wide technical competencies. The top tier is occupation-specific (Ennis, 2008).

2.2.1 Competency Modeling Process

The objective for creating a competency model for the ACBW is to provide resources that can keep pace with the changes in the industry and maintain a robust and diverse future talent pipeline. The following process describes how researchers in collaboration with the DOE and industry leaders used existing resources, collected and analyzed data to develop the framework of competencies. Figure 2 illustrates the steps that were followed to develop the ACBW competency model.

![Figure 2: Competency Modeling Process](image)

At first, general knowledge, duties, tasks, specialized knowledge, skills and abilities from JTA data were added to the competency database. Then, the database was reviewed to determine the tasks, duties, skills and knowledge that are consistent across all JTA's and to identify ones that are specific only to certain occupations. In addition, the critical competencies were highlighted. In the next step, we grouped the skills, abilities, and specialized knowledge into competencies associated with the tiers of the building blocks competency model. The model provides guidance but does not contain a strict definition of each competency level. Therefore, our team used their subject matter expertise when classifying the data into the competency groupings. A second review of the category groupings was performed after all of the JTA data has been analyzed. The intention is to determine if additional refinement was needed, such as further grouping of categories, if they were too similar or there were too many categories. Using this research process, the competency model was developed and aligned with the building blocks model.

The analysis identified the knowledge and skills that are common across the four jobs and highlighted those that are unique to each position. The researchers utilized the structure of the building blocks model as a basis for categorizing the knowledge and skills identified in the JTA. The knowledge and skills were categorized into competencies at the high level of the building blocks category (Industry Wide) and at the mid-level of the created competency categories (Fundamentals of Energy & Power, Measurement, Verification & Reporting, etc.). At the Occupation Specific Level, the competencies were grouped and categorized based on the knowledge and skills that were unique to each position. During the second refinement, the occupation-specific knowledge competencies were further analyzed to determine if those knowledge and skills were truly unique to each position. Additional sub-tiers were added to those categories that had a large amount of knowledge items associated with them. After the data was categorized, it was viewed through the lens of the original critical competencies to examine if each of these critical competencies were represented in the model.

3 COMPETENCY MODEL FOR ACBW

The final result is presented as a Competency Model for ACBW as illustrated in Figure 2. The pyramid graphic that illustrates the ACBW illustrates how most tiers consist of several building blocks, each of which represents a competency cluster. The tiers of the model are divided into blocks representing the skills, knowledge, and abilities essential for successful performance in the industry or occupation represented by the model. Each competency is described by key behaviors or by examples of the critical work functions or technical content common to an industry.
3.1 Foundational Competencies

Tier 1, titled as “Personal Effectiveness Competencies” are personal attributes, or also viewed as the soft skills that are needed for all four job categories. Tier 2 and Tier 3 are titled as “Academic Competencies” and “Workplace Competencies”, respectively, and include the cognitive functions and thinking skills one would typically learn in school or on the first couple of years working in the industry. Tiers 1, 2 and 3 are the foundational competencies and are the building blocks for this workforce group and can apply to many industries and occupations.

3.2 Industry Related Competencies

Tier 4 and Tier 5 identify the specific competencies for the advanced commercial building workforce industry and are the background knowledge, skills, and abilities for the specified work group. Tier 4 represents the building and construction industry including design, construction, and maintenance of buildings. The Tier 5 technical competencies are related to the more specific energy industry. Identifying this subset allows for cross-functional opportunities and promotes an agile workforce. The top tier isolates the specific competencies unique for each job category.

3.3 Occupation-Specific Competencies

Recall that the competencies become more targeted or specific as you move up the tiers of the model. Every occupation requires a different mix of knowledge, skills, and abilities, and is performed using a variety of activities and tasks. The top tier describes the occupation-specific knowledge, skills, and technical competencies for each of the job titles including Building Operations Professional, Energy Auditor, Building Commissioning Professional, and Energy Manager. Table 1 is a sampled list of Occupation Specific Competencies for Advanced Commercial Buildings Workforce.

4 CONCLUSION

Since the 1990s, competencies have been the key word used by human resources and talent management professionals relating to attracting, recruiting, assessing, selecting, placing, developing, training, evaluating, and rewarding employees. In addition, competency models are also being used in other areas of human resources management, such as aligning the organizational goals with the existing talents of its workers, organizing the business needs, directing strategic plans, and driving the mission of a company. However, the identification and application of the competencies required for effective job performance has become a complex and sophisticated approach. The most critical aspect of a competency model is that it must be robust, dynamic, fluid, and flexible, allowing it to change with technological advancements, economic volatilities, and uncertain conditions. Competency models are not an “end product,” but are developed as a resource for multiple uses including:

- Develop workforce planning;
- Conduct labor analysis;
- Communicate the needs of the industry;
- Guide career development;
- Establish career pathways;
- Inform curriculum and instructional developers; and
- Highlight requirements for certifications and licensure

The ACBW Competency Model aims to articulate and classify the competencies that employees must possess and use in appropriate ways on the job. However, ACBW Competency Model has many applications, such as retraining transitioning workers for new employment in the advanced commercial building sector. For example, there is a large number veterans transitioning out of the military. Many of these individuals have foundational skills and training that makes them an ideal candidate for a job in the ACBW. The ACBW Competency Model can help identify the skills and knowledge that employers are looking for. Another practical use of the model is creating a job-matching tool such as a career pathway or career map, which the research team is currently developing. The ACBW career map will be used to demonstrate what a possible career looks like in terms of sequential positions, roles, credentials, experience and education/training. A career map typically outlines common paths for moving within and across jobs in ways that facilitate growth and career advancement, which will ultimately support the development of a robust and diverse future pipeline for the advanced commercial building workforce (ACBW).

ASSESSMENT OF THE LEVEL OF SERVICE (LOS) OF PUBLIC RECREATIONAL CENTRE BUILDINGS: AN UNCERTAINTY BASED APPROACH

Rajeev Ruparathna¹,², Kasun Hewage¹ and Rehan Sadiq¹
¹ School of Engineering, University of British Columbia (Okanagan Campus), Canada.
² rajeev.ruparathna@ubc.ca

Abstract: The federal sustainable development strategy (FSDS) for Canada advocated that public sector operations should aim at shrinking the environmental footprint while enhancing social benefits. In this quest, improving the sustainability performance of public buildings becomes a key constituent since buildings are responsible for the highest portion of the corporate GHG emission and energy usage of public entities. Moreover, public buildings are an important constituent of the socio-economic environment of a local region. Hence, there is a need for improving the sustainability performance of the future and existing public buildings. Currently, various innovative methods are used by federal, provincial and municipal entities to improve the sustainability performance of public buildings. However, asset management of building has been overlooked from the above studies. There is a lack of comprehensive methods to assess the level of service (LOS) of a building that is crucial for life cycle asset management. To address this problem, this paper proposes an approach to calculate the LOS of a recreational centre building operated by municipal government. Firstly, a LOS framework is formulated for recreational centre building by taking into consideration the key aspects. Secondly, a fuzzy synthetic evaluation method is used to assess the building performance. Thirdly, a case study was conducted to validate the proposed methodology. Results from this approach provide detailed information about the performance of the building assets. This approach facilitates in identifying areas that require immediate attention for improvement. This study provides a novel approach to life cycle asset management of public sector buildings.

1 INTRODUCTION

Public buildings represent a key component of the socio-economic environment of any nation (Wright 2006). Despite the numerous benefits to the society, dramatic environmental and social concerns are associated with construction, renovations and operation of buildings (United States Environmental Protection Agency, 2009a; Industry Canada, 2013). There are over 28000 federal buildings and a large number of municipal buildings operating in Canada, that account for 15% of the Canadian infrastructure portfolio (Mirza, 2007; Environment Canada, 2013). Presently, Canadian building infrastructure stock is aging and have deteriorated considerably (Mirza, 2007). Moreover, there is a lack of financial resources to replace, repair or rehabilitate current infrastructure stock or to construct new infrastructure facilities, highlighting the importance of a systematic asset management approach for municipal buildings (Federation of Canadian Municipalities 2003).
A majority of public sector organizations of British Columbia (BC) had signed BC climate action charter and were committed to become carbon neutral by 2012 (Government of British Columbia 2013). In the quest of becoming carbon neutral, municipal governments are compelled to implement programs and policies to reduce the carbon footprint of both corporate and community operations. Federation of Canadian Municipalities, (2011) have stated that public buildings are one of the main contributors to GHG and smog-forming emissions in Canada. Statistics shows that, buildings account for over 80% of the public sector GHG emissions (Government of British Columbia 2013). Therefore, it is important for public sector organizations to improve the environmental performance of public buildings to comply with the ongoing climate action agenda.

Previous studies revealed that significant reductions in life cycle energy consumption and CO₂ emission can be achieved from the building operations phase (Wu et al., 2011; Airaksinen & Matilainen, 2011). However, currently, municipal facilities managers are faced with an onerous task of inspecting, repairing, maintaining, renewing and replacing a diverse portfolio of infrastructure facilities owned by the municipality in the most sustainable way (Vanier and Rahman 2004). Hence, there is an alarming need to focus on life cycle asset management (LCAM) of public buildings to prolong its life cycle as well as comply with contemporary legal and policy obligations. Consequently, many organizations around the world are turning to asset management to ensure optimized utilization of the asset (Félio 2006; Halfawy 2008). Asset management is the systematic process to maintain a desired service level of an asset at the lowest life cycle cost while complying with legal obligations and standards (Asset Management BC, 2011; USEPA, 2009b).

Assessment of the current level of service (LOS) is a main underlying process in the life-cycle management of infrastructure assets (Asset Management BC 2011). Félio & Lounis, (2009) and Federation of Canadian Municipalities, (2002) stated that the LOS is an assessment of the quality of the service provided with respect to the society and economy. Determination of LOS assists decision makers in prioritizing the infrastructure assets in investment planning related to the development, operation, maintenance, rehabilitation, planning, and replacement of municipal infrastructure (Ireland et al. 2008). Factors related to LOS includes customer relations, quality, consistency of service, capacity, reliability, responsiveness, environmental acceptability, cost, and availability (Federation of Canadian Municipalities, 2002 ; Félio & Lounis, 2009; Ireland et al., 2008). Asset Management BC, (2011) recommends that asset owners should regularly track service levels provided by the infrastructure assets. However, as per author’s knowledge, asset management of buildings has largely been disregarded in North America.

Recreational buildings represent an interesting component of the infrastructure portfolio of municipal governments. A recreational centre building can be classified as desire rather than a necessity for an area. However, recreational centre buildings have become an important element for the health and wellbeing of residents. Several GHG inventory reports indicate that recreational buildings account for a significant portion of the corporate energy consumption and the GHG footprint of small and medium municipal governments (Stantec Consulting Ltd. 2011). Recreational centre buildings are comprised of more building components and systems compared to conventional buildings. Moreover, such buildings also serve as service centres for the public. Hence, recreational centre buildings require more systematic management in maintaining its level of service and to prolong its life cycle. However, asset management of recreational building have been largely overlooked in the literature. Currently, lack of adequate operational knowledge and understanding among decision-makers is a key challenge in infrastructure management (Federation of Canadian Municipalities 2003). Therefore, better resources are required for LCAM of specialised buildings such as recreational centre buildings.

The objective of this paper is to develop a comprehensive LOS index for public recreational centre buildings. This index will assess the performance of the recreational centre building by considering the facility performance and the service level. Fuzzy logic would be used to characterize the imperfect information. This index would provide an objective basis for LCAM decision making for recreational centre buildings. As a proof of concept, the developed LOS index was used in a case study of a model recreational building identified from the literature. Findings of this research could be adopted in assessing the performance of other types of municipal buildings.
2 LITERATURE REVIEW

Published literature has largely overlooked performance assessment of public recreational centre buildings. Only a handful of studies related to this subject area were observed. Howat and Crilley (2007) developed a performance assessment model for aquatic centres integrating customer service quality, satisfaction, and operational performance. Another study by Howat et al. (2008) studied the relationships between service quality, overall satisfaction and loyalty measures in Australian aquatic buildings. This study revealed that main factors influencing the overall satisfaction are relaxation, staffing and facility presentation. Priyadarsini (2014) studied energy performance of aquatic centre buildings in Victoria and revealed that energy intensity of aquatic centres ranges from 632 to 2,247 kWh/m².

Sharma et al. (2008) mentioned that customer expectations, legislative requirements and community are important criteria for assessing the LOS of an infrastructure asset. The stakeholders of recreational centre building have different and conflicting expectations from the municipal infrastructure. Moreover, minimum service standards associated with an asset, financial constraints, and delivery mechanisms should be considered when setting up a target LOS.

Indicators based systems are a popular method of identifying the condition of an infrastructure. There is an overwhelming trend towards an indicator assisted planning and decision making within the Canadian municipalities (Federation of Canadian Municipalities 2003). An indicator provides information to identify the condition or status quo of an object or a service in consideration. Indicators associated with municipal infrastructure could be in a hierarchy reflecting the decision-making structure within the municipalities (i.e. operational indicators, functional indicators to strategic indicators) (Federation of Canadian Municipalities 2003). The Federation of Canadian Municipalities (2003) defines these indicators as defined below.

i. Operational indicators: Operational indicator includes data collected by operational crew while performing their duties or as a part of the inventory process. Operational indicators are expressed as survey results or score boards.

ii. Functional indicators: Functional indicators are identified by analyzing the operational indicators that provide an overview of the condition of the infrastructure asset. These indicators are applicable to managerial level decision makers of the municipality.

iii. Strategic indicators: Strategic indicators provide general and abstract information of the infrastructure asset. The top level decision-makers (i.e. city manager, the city board) require this information in the strategic decision-making. These indicators provide a measurement of the quality of life of a municipality or meeting the infrastructure budget.

The funding decision makers related to municipal infrastructure often does not have sound understanding of the condition of the municipal asset (Federation of Canadian Municipalities 2003). Sudden and unexpected problems create tension within the users, and expedited assessments can result in financial destitution for building owners (Condominium homeowners association, 2010). Therefore, it is important to identify meaningful indicators displaying the performance of infrastructure assets to support the decision-making process. Indicators are expected to assist in decision-making process but are not intended as substitute while exercising judgement related to infrastructure (Federation of Canadian Municipalities 2003). LOS indicators should display, strategic goals, stakeholder goals and organizational goals (Asset Management BC 2011).

3 METHODOLOGY AND FRAMEWORK DEVELOPMENT

LOS of a recreational centre building depends on the building performance associated with multiple criteria (i.e. technical, social, environmental, and economic attributes). Hence, LOS assessment is a multi-criteria decision analysis (MCDM) process that incorporates conflicting criteria into the asset management. This LOS framework is based on a fuzzy set MCDM technique that is presented in the next section. Approaches proposed by Félio & Lounis, (2009) and Khatri et al., (2011) were considered in developing the LOS assessment framework. Figure 1 presents an overview of the LOS framework.
The proposed LOS assessment framework, as outlines below, involves five steps in calculating the LOS of a recreational centre building:

i. Identification and classification of performance indicators.
ii. Fuzzification of the performance indicators.
iii. Weight calculation and weight assignment.
iv. Aggregation of performance indicators using MCDM.
v. Defuzzification of the aggregated indexes to calculate the overall systems performance.

3.1 Identification and classification of performance indicators

Two main paradigms associated with the LOS of a municipal facility includes asset LOS and the customer LOS (USEPA 2007). Hence, a hierarchical framework has been developed to assess the LOS of a recreational centre building. The framework consists of LOS indicators at level 1; LOS dimensions at level 2; LOS categories (level 3) and overall building performance (level 4). Dimensions for LOS categories and LOS indicators were obtained from building rating systems such as BOMA Bst, Living Building Challenge etc. (Building Owners and Managers Association of Canada., 2013; International Living Building Institute, 2014; Japan sustainable building Consortium, 2011). Published literature was referred to identify indicators and dimensions related to customer LOS (Howat and Crilley 2007, Howat et al. 2008, Priyadarsini 2014). The framework developed for assessment of LOS of recreational centre building is presented in Figure 2.
3.2 **Fuzzification of the Performance Indicators**

Fuzzy set theory is a powerful mathematical model to characterize uncertainty in reality (Zimmermann 2010). This theory has been used in a vast range of disciplines such as engineering, logistics, management, data processing. Moreover, fuzzy set theory is a powerful tool to be used in decision support due to imperfect information about the reality.

Equation 1 presents the basic definition of the fuzzy set theory. The fuzzy set \( \tilde{A} \) is denoted as a set of ordered pairs in a universe of \( X \), where \( x \) denotes the objects of \( X \). The membership function, \( \mu_A(x) \), maps \( x \) values to \( \tilde{A} \) in the interval 0 to 1.

\[
\tilde{A} = \{(x, \mu_A(x)) | x \in X\}
\]

Equation 1

This approach was used to convert a crisp number to a fuzzy set that is represented by the membership function. Four membership function levels (i.e. poor, satisfactory, good, and excellent) were described for LOS assessment using triangular and trapezoidal shaped membership functions. Excellent is the highest achievable performance level. Good level is the acceptable performance level while satisfactory level requires further performance improvement. Poor is the lowest performance level that requires immediate attention. Fuzzified value would be the places where the performance value intersects with the membership function. As an example for a hypothetical performance value of 55, the fuzzified value would be \((0, 0.22, 0.8, 0)\) (Figure 3).

![Figure 3: Membership functions and fuzzification](image)

3.3 **Weight calculation and weight assignment.**

Various subjective methods are used in MCDM to derive the weights (e.g. AHP, ANP). Analytic hierarchy process method (AHP) is a popular method of deriving the weights in MCDM (Khatri et al. 2011). In AHP method, expert opinion is sought to conduct pairwise comparisons. The opinions however, should be consistent to ensure the accuracy of the weights.

3.4 **Aggregation of performance indicators**

The aggregation operation consists of combining the lower-level performances to the upper levels. The hierarchical process is presented in Figure 1. For each level, the synthesised performance value is a four-tuple fuzzy number.
3.5 Defuzzification of the Aggregated Indexes to Produce the Overall Systems Performance

Four-tuple fuzzy number derived from LOS indicators would be made a crisp number through defuzzification operation. A commonly used defuzzification method, centroid method (Equation 2) would be used for defuzzification operation.

\[ C_A = \frac{\int_a^b x \mu_A(x) dx}{\int_a^b \mu_A(x) dx} \]  

Equation 2

Overall LOS index is calculated using Equation 3.

\[ LOSI = D^T C^T \]  

Equation 3

Where,

\( C^T = \) transpose of a vector of centroid values of the membership functions

\( D = \) performance of a dimension/category in the framework

4 A CASE STUDY FOR PROOF OF CONCEPT

The LOS index developed above was used to assess the LOS of a recreational centre building. Operational data were obtained from primary and secondary sources. Performance level data were obtained from published literature (e.g. Sydney Water, (2011)). Table 1 presents the performance values for indicator categories comprised in the index. Due to the time restrictions researchers could not obtain the required data to calculate weights for AHP method. Therefore, equal weights were assumed for all criteria.

LOS of the recreational centre building = **28.16**

Therefore the LOS of the recreational building is poor and needs immediate improvement.

5 DISCUSSION

This paper presented an approach for calculating the LOS of municipal recreational centre buildings. An MCDM based systematic framework has been used to calculate the LOS. Fuzzy synthetic method has been used to account for incomplete and qualitative information. The paper presented a case study using literature data to illustrate the underlying concept.

Currently, LOS of buildings is overlooked by asset managers. Even though performance assessment is common practise for regular buildings, there has not been any sound research focusing on specialized buildings such as recreational centre building. The concept of LOS in buildings has largely been disregarded in practise. Development of decision support tools would support facilities managers for the above purpose. Due to its convenience, indicator based assessment frameworks should be promoted among municipal decision makers and engineering departments. However, it is important to exercise cautious approach as indicator-based systems are not a silver bullet, and users should be reasonable in their expectations.

The proposed framework incorporated multiple criteria associated with the LOS of a recreational building. The LOS is evaluated primarily from the perspective of asset and customers. The LOS of a building is further, assessed considering various underlying dimensions. Therefore, a municipality could identify which aspect is affecting the building performance and take corrective action accordingly. This approach has the capability to customize the LOS index based on the priorities of the municipality. The fuzzy-based approach enables handling data that is incomplete, ambiguous, linguistic, and uncertain.

LOS indicators were identified from the published literature and building rating tools. The number of performance indicators could be improved using further analysis. When selecting indicators for rating systems, it is important to ensure indicators are manageable, meaningful, quantifiable, well defined and aligned with objectives. The fittingness of performance indicators could be further assessed considering relevance, measurability, etc. This approach would provide a more robust set of indicators. The results presented in this paper also illustrate a range of benchmark values for public aquatic centre managers.

The case study evaluated the LOS of a recreational centre building. Literature was used to obtain the indicator data to assess the LOS. This analysis identified that LOS of the recreational building considered is poor with a rating of 28.16. Therefore, this building requires immediate improvement. The water-energy performance of the building is satisfactory (49.9) while social equity is the extremely low (12.0). With this information, municipality could improve the LOS of the recreational centre by focusing on the areas that needs immediate attention. During the case study, equal weights were assumed for all the performance categories. The accuracy of LOS would heavily depend on the indicator types considered, the quality of data available and the weights assigned to the performance measures. Hence, the result observed could be different from the actual LOS of the recreational centre building.
There are several limitations associated with this study. Inclusion of limited number of performance measures for model is the main limitation of this paper. In addition, this framework considers equal weight for the criteria considered. However, it is important to realize that this approach should be tailored to meet the individual needs and priorities of the municipality. Data associated with LOS are uncertain and possesses considerable subjectivity. Several assumptions were used where ever data was not available. This concern could be resolved by using expert interviews and validating the interview responses using literature. Above issues would be corrected in the future publications with improved data collection and MCDM methods.

6 CONCLUSIONS

Assessing the LOS of public buildings is a challenge for municipal facilities managers. This paper presents a novel approach for analyzing and calculating the LOS of a recreational centre building. The LOS framework has been developed by integrating systems approach with fuzzy logic. This approach is reinforced by measures and data that is easily understood and can be used in diagnostic decision-making. This concept could be extended to assess the level of service of other municipal building classes.

The credibility of this framework depends on the types of indicators used and the precision of data and weights calculated. Further research is needed to identify more indicators and their interdependencies. Furthermore, it is important to identify sound data for LOS classifications (i.e. excellent, good, satisfactory, and poor). It is important to realize that when assigning weights, expert judgement could be subjective and be potentially biased. Hence, expert judgments from a diverse group of experts could be obtained to minimize the biases of the LOS index.

The outcomes of this research will inform LCAM of recreational centre buildings in Canada. The approach proposed in this study could be used to assess LOS of complex municipal infrastructure systems. Hence, an extension of the model would provide the Canadian municipalities with an integrated model to assess the LOS while developing holistic infrastructure system.

Abstract: Construction companies devote significant resources to front end planning (FEP). The potential substantial benefits of the strategic implementation of FEP practices across an entire portfolio have made FEP evaluation an important issue for both project leaders and scholars. The primary objective of this study is the use of multiple regression analysis for the identification of factors for use in predicting the gaps in project definition and for evaluating the FEP. FEP data from 59 North American capital construction projects from the same industry segment have been examined in order to establish such indicators and to enable the monitoring of project resources throughout the project lifecycle. When employed as a proactive approach during FEP, the results of this analysis have the potential to guide project managers in their search for important potential project definition gaps, and to prioritize there definition efforts. Its contribution to the body of knowledge is a methodology for understanding how to focus project definition efforts most effectively.

1 INTRODUCTION

Long-term strategies associated with a large capital project are established during front end planning (FEP), a process that is influenced by a number of risks and constraints, such as resource limitations, changes in government regulations, environmental restrictions, and financial and economic crises (Safa et al. 2013, Gibson 2005). A review of studies in this area reveals adequate FEP to be an essential component in the overall success of a project David Grau et al. 2012, George et al. 2008, Gibson et al. 1995, Hartman and Ashrafi 2004, Smith 2000, Webster 2004). The potential for acquiring substantial benefits from FEP and the opportunity to address problems encountered during the planning process have thus made the evaluation of the FEP phase of construction capital projects an important concern for both scholars and industry practitioners. With a focus on construction firms that have implemented a Project Definition Rating Index (PDRI) as a standardized tool across their capital project portfolios, the research presented in this paper has identified the most important influential factors for FEP assessment. Also included are the results of an investigation of key PDRI elements, including the statistical analysis method used, an evaluation of its effectiveness with respect to predicting gaps during the strategic phase of a project, details of potential uses of the indicators, and a synopsis of the benefits available for the construction industry.

Recent construction research has been directed at the establishment of a common set of construction phase metrics and their corresponding definitions (Park et al. 2005, Beatham et al. 2004, Rankin et al.
2008, Willis and Rankin 2012). Large capital construction projects are fraught with significant risk, with cost and schedule remaining key areas of scrutiny because failure to exploit opportunities for improving project value and decreasing risks could lead to the undervaluation of such projects (Ford 2002). Acquiring an in-depth understanding of this type of risk during the FEP phase is challenging because neither spending nor delivery has technically begun during this phase. A proven leading risk indicator employed during FEP is the PDRI. In current use as a widely adopted FEP standard, the PDRI stipulates key project elements suitable for representing the project team’s own assignment of scope definition ratings. The PDRI provides a framework for these ratings that allows project stakeholders to contribute important content and helps them acquire an understanding of the cross-functional impact of any risks identified.

Functioning as a multifaceted front end planning tool, a PDRI operates as a vehicle for the facilitation of strategic decision making through the evaluation of scope readiness as a means of measuring project risk. PDRIs are tailored to meet the specific needs of the building, industrial, and infrastructure sectors of the construction industry (Dumont et al. 1997, Weerasinghe et al. 2007, Gibson et al. 2010, Nasir et al. 2012). The correlation between a PDRI and risk factors related to project performance is based on published analyses of data from many hundreds of projects. The opportunity now exists to employ those historical project data sets at a portfolio level as a means of mining the powerful constituent elements of the index in order to develop methods that can support construction firms as they form proactive planning strategies for the execution of each new capital project. Such strategies encompass the use of influential factors, information technology systems, and common knowledge gaps that have been identified in the companies.

Since PDRIs are available in a variety of versions that vary according to the unique characteristics of each project, the authors have carefully considered each set of individual project features while developing the proposed analysis method for FEP risk assessment. The contribution of this study to the existing body of knowledge is to employ the data from 59 actual capital industrial projects from the same industry segment as a means of demonstrating the influential factors for analyzing and assessing the entire FEP process. The names of the projects and companies have been kept confidential. In accordance with the terms of the confidentiality agreement, because all materials related to these projects are also strictly confidential, including the designs, plans, specifications, models, reports, and other documents, their publication is not permitted. The results of this study have the potential to serve as a measureable process for aligning the owner and contractor with respect to complete scope definition for one or several projects as each is being defined.

2 PROJECT DEFINITION RATING INDEX

The primary deliverable of the FEP phase is an adequate level of design that enables the project team to prepare cost and schedule estimates, to make strategic decisions, and to identify risk (Dobler and Burt 1996, Safa et al. 2014). Once project funding has been approved, the FEP design deliverables become the primary input for the next phases in the project life cycle: procurement and detailed design. The FEP gates, four PDRI potential application points, and other life cycle project phases are illustrated in Figure 1. A gate is defined as the existence of the discrete information and definitions required for a decision to be made that determines whether to proceed.
The Construction Industry Institute (CII) offers a great positioning of PDRI and proven project risk review methodology based entirely on an assessment of the completeness of the scope definition of key project elements. The PDRI that the CII team created for construction projects includes a comprehensive checklist of about 70 scope definition elements spanning three sections – basis of project decision, basis of design and execution approach. The list elements were categorized through an extensive assessment of past and current industry best practices and were weighted in order of importance using input from more than 50 skilled project managers and proficient estimators (CII 2010). The process drills down to the essential details so that stakeholders can contribute critical content and understand the cross-functional impact of the risks identified. This tool enables an individual or a team to evaluate the status of a construction project during FEP and to determine a score that corresponds to its level of definition. Empirical evidence has shown that the PDRI can result in 6% to 25% savings in the overall cost of a project (CII 2010).

All PDRI's provide high-level project assessment following designated FEP phases. Figure 1 indicates the points where PDRI's are recommended. PDRI 1 follows the FEP feasibility phase and entails a high-level assessment of the project, which is usually held at an early project kickoff meeting with an architectural/engineering firm. The PDRI 2 review involves a high-level assessment of the project following the concept development phase, with the goals of evaluating the alignment of project objectives with stakeholder needs, identifying high-priority project deliverables, helping to anticipate late project surprises, and facilitating communication across the project team and stakeholders. PDRI 2i is an intermediate (i) assessment of the project, which is held at the midpoint of the detailed scope phase of the FEP. Its purpose is to provide further assurance of the alignment of project objectives with stakeholder needs, to confirm the efficient deployment of resources, to verify that the scope corresponds to the original project goals, and to identify and plan any remaining activities necessary for proceeding to the next FEP phase. PDRI 3 is the final assessment of the project during FEP, at which point risk issues have been identified and mitigation plans have been prepared. The overall maximum score to quantify the level of scope definition at any stage of the FEP is a 1000-Point Scale. Usual scores at the completion of this evaluation are between 150 and 250, with a preferred score being 200 or less. Acceptable PDRI score ranges for individual FEP phases are summarized in Table 1 (Gibson 1996, Wang and Gibson 2010). The suggested procedure is for all PDRI's to be conducted for all projects. However, if for any reason, the project management team is unable to implement all PDRI's, as a minimum, PDRI 3 should be completed in order to identify risk issues.

Project A is a Canadian project that was selected as an actual example. Its completion resulted in the conversion of a coal-burning process to one that burns wood pellets for the production of electricity and enabled the continued use of the majority of the plant equipment. The focus of Project A was on the unloading, storage, and handling of new materials; combustion; and control system upgrades. The project life cycle is assumed to be approximately 10 years, and the use of biomass fuel rather than coal will result in a reduction in net carbon emissions. The financial impact of the project will be moderate, with spending (approximately $200 million over 3 years) focused on the fuel-handling, combustion, and control systems. Table 2 shows the PDR12, PDR12i, and PDR13 scores for each FEP section as well as the total normalized scores for each PDR1.

<table>
<thead>

<td>321</td>
<td>191</td>
</tr>
</tbody>
</table>

As can be seen in Table 2, the PDR12 score of 575 is very close to the upper boundary of the acceptable CII industry range: 600. The graph presented in Figure 2 shows that this critical score was remedied by addressing the comments, recommendations, and suggestions provided by the project team, resulting in substantial improvement, as evidenced by the PDR12i score of 321, which is very close to the typical minimum industry range: 300. This trend was continued and enabled the achievement of a score of 191 for PDR13, which is a very good score for a final project assessment. The trend in the PDR1 evaluation of this project demonstrates that even if the project involves numerous and serious risks during the first FEP phase, the PDR1 evaluation can help the project team identify risk issues and then provide mitigation plans. In addition, knowledge of the gaps identified during the earlier FEP phases enables project managers to find solutions to deal with the deficiencies.

![Figure 2: Comparison of PDR12, PDR12i, and PDR13 scores for Project A with acceptable industry ranges as defined by CII](image)
3 IDENTIFYING INFLUENTIAL FACTORS

As mentioned, the primary thrust of this research has been to highlight the influential factors that have the greatest effect on final PDRI scores. For this study, the prediction of such potential indicators was based on the use of a multiple regression analysis technique that relies on a dependent variable and a number of independent variables. This type of analysis helps with the modeling of the relationship between a response variable (Y) and the dependent variables (X1, X2,...), as \( E(Y) = b0 + b1X1 + ... + bnXn \). While its successful application requires a balance of theoretical results, empirical rules, and subjective judgment (Chatterjee and Hadil 2013, 2004), it offers the following benefits:

1. Project managers can concentrate their efforts on the more difficult aspects of projects.
2. Consistent deficiency predictions are provided.
3. The nature of the relationships between variables can be quantified.
4. The time saved allows project managers to focus greater time and energy on the contingency aspects of projects.

The final PDRI score is the dependent variable, and the categories and elements are considered to be independent variables applied over two steps. Using the information about the categories and elements improves accuracy with respect to the prediction of the final PDRI scores. Figure 3 shows the PDRI hierarchy employed in this study.

![PDRI hierarchy diagram]

The regression analysis used for this study involves two steps. In the first step, the regression analysis is applied at the category level. The second step entails the evaluation of the elements of the categories selected. In an effort to develop a truly objective and quantitative analysis method, the authors decided to rely on data rather than only comments from experts, so they collected extensive data for 59 completed North American projects. The data was normalized used in Valency's Carve application, then exported to perform regression analysis using Excel 2010, which has a built-in regression analysis tool as a standard component that is available as an Excel add-in.

For the first step in the analysis, the dependent variable is the final PDRI score. The independent variables are designated as follows: (A) Manufacturing Objectives Criteria; (B) Business Objectives; (C) Basic Data Research & Development; (D) Project Scope; (E) Value Engineering; (F) Site Information; (G) Process/Mechanical; (H) Equipment Scope; (I) Civil, Structural, & Architectural; (J) Infrastructure; (K) Instrument & Electrical; (L) Procurement Strategy; (M) Deliverables; (N) Project Control; (P) Project Execution Plan.

Figure 4 shows the regression results. The top part of the output shown in the figure is the regression statistics table. The most important number in this table is R Square, which signifies how well the regression line approximates the real data. The closer the value is to 1, the better the regression line fits
the data. In this case, R Square equals 0.987, which indicates a very good fit and means that 98% of the variation in the PDRI final scores can be explained based on the independent variables: the categories.

Figure 4: Regression analysis output at the category level

The ANOVA table is shown in the center section of Figure 4. The F value indicated under the Significance F heading indicates the probability that the regression analysis output could have been achieved by chance. A small F value confirms the validity of the regression output. It should be noted that the Excel default is scientific notation, so 6.51958E-10 means 6.551958 * 10^-10 (0.000000000651958). To check whether the results are reliable (statistically significant), the significance F value (0.000000000651958) should be considered. If this value is less than 0.05, the model is statistically significant. If F is greater than 0.05, it suggests that the use of this set of independent variables should be discontinued.

The regression output of greatest interest is the bottom table in Figure 4: the regression coefficient table. The P-value column gives the p-value for testing H0: βj = 0 against Ha: βj ≠ 0. The p-value is the estimated probability that the null hypothesis (H0) of a research question will be rejected when that hypothesis is true. Variables with high p-values (greater than 0.05) have been omitted, and the regression is returned until Significance F drops below 0.05. In Figure 4, unacceptable p-values greater than 0.05 are highlighted.

Following a review of the results of the first analysis, an additional regression analysis was run using a different combination of variables in which those with p-values over 0.05 were eliminated. This process was performed five times. The results were as shown in Figure 5, and the categories A (Manufacturing Objectives Criteria) and P (Business Objectives) were selected.
In step 2, the elements of categories A and P were considered as the independent variables: (A1) Reliability Philosophy; (A2) Maintenance Philosophy; (A3) Operating Philosophy; (P1) Owner Approval Requirements; (P2) Engineering/Construction Plan & Approach; (P3) Shut Down/Turnaround Requirements; (P4) Pre-Commission Turnover Sequence Requirements; (P5) Startup Requirements; (P6) Training Requirements. The final PDRI score is considered to be the dependent variable. Three regressions produced the results displayed in Figure 6.

The analysis results reveal that two elements of category A, (A1) Reliability Philosophy and (A2) Maintenance Philosophy, as well as one element of category P, (P2) Engineering/Construction Plan & Approach, can be considered influential factors for evaluating the FEP phase of industrial construction projects.

4 ANALYSIS

As the results indicate, A1, A2, and P2 were identified as influential factors. However, the use of these results must be accompanied by the following provisos:
1. These elements can be used consistently only across an entire portfolio of projects for a specific construction industry sector (e.g. oil and gas).
2. These powerful influential factors cannot be used to replace the PDRI process.
3. The elements selected can vary from one construction industry sector to another (e.g. oil and gas and commercial buildings).

Regression analysis can indicate only how or to what extent variables are associated with one another. The results can therefore not be considered as establishing precise cause-and-effect relationships, which means that any conclusions about the relationships should be based on the judgment of project managers and experts. In fact, the use of expert intuition represents one method of model validation, and was the method performed by the authors in this case. In practice, a project management team embodies a combination of domain expertise and operational experience. Therefore, on September 18, 2014, the authors met with two experts who had been involved with some of the projects included in the study in order to gain insight and to benefit from the unique opportunity to influence the direction of this research. The experts validated and confirmed the accuracy of the results obtained from the statistical analysis. This type of analysis offers a number benefits for a company:

1. It enables a determination of whether PDRI scores are a reliable leading indicator of performance when a PDRI is implemented as a strategic tool and is used consistently across an entire portfolio of projects.
2. Given the positive correlation between PDRI scores and improved project performance across an entire portfolio, a construction company can use these results as a means of validating their process and their commitment to using best practices in project management in order to maximize the financial return on their capital investments.
3. PDRI data analysis will provide a formal framework for FEP evaluation, thereby enhancing the quality of project management, facilitating management succession, and forming the basis for the long-term educational value of the FEP process.
4. With respect to performance over both the short and long term, this analysis will add to the impressive body of studies related to the evaluation of FEP results.
5. These results can contribute to an analysis of trends or common gaps in FEP data to be used as indicators of the organizational effectiveness of a project because they provide a benchmark at the element level of baseline conditions that are related to project success.

The results of this study can also be employed at pre-meetings held by PDRI facilitators before they conduct PDRI sessions to analyze project documents with key project stakeholders. Critical powerful indicators are also useful for enhancing the speedy evaluation of FEP phases; the periodic evaluation and prediction of common gaps in projects, portfolios, and the organization; and the assessment of small projects, organizational strategic issues, and contingency planning.

5 CONCLUSION

More rigorously analyzed PDRI data can substantially improve the level of project managers’ understanding in this area. The primary contribution of this study is the identification of influential factors for FEP evaluation. The potential exists for construction companies to optimize their current use of such best practices and to integrate this new knowledge into their existing FEP. Data from 59 industrial projects have been evaluated and the results reported. It should be noted that the analysis and case projects all belong to the industry sector, which means that the results are not applicable for other sectors; however, the same methodology could be employed in additional construction industry sectors. Given the complexity of many construction capital projects, significant value accrues to the engineering and construction industry if the proposed method could be effectively utilized to enhance risk assessment for construction projects. Approaches to risk mitigation could then be more accurate and better focused, with fewer wasted resources. Other benefits include increased construction time and cost savings resulting from effective planning, which can further increase the success of risk avoidance procedures. PDRI users will have the opportunity to be at the forefront of the development, implementation, and exploitation of this crucial new method. The methodological limitations identified in these empirical studies (e.g. regression analysis constraints) suggest several avenues for future research in other construction industry sectors. As additional data become available, the results of this study will also be more broadly
applicable for use with further discoveries, such as operational excellence management, for which project risk management reporting represents a constant challenge for capital project teams and owners.

Abstract: Construction heavy equipment is a valuable asset for construction and equipment rental companies, which requires continuous monitoring and assessment for potential failures. Predictive maintenance has recently been proposed as an alternative to preventive maintenance strategy by scheduling maintenance tasks just before a predicted failure of the equipment. Such predictive approach is dependent on the existence of a data collection and analysis system that monitors the equipment performance, compares it to the previous history, and predicts the failure events before their occurrence. This paper presents the development and validation efforts of a data-driven prognostics system that utilizes timely collected telematics data to monitor the equipment health condition and predict its failure hazard. The system is designed to utilize equipment telematics data to develop regression-based Cox's proportional hazards functions. Regression analyses are performed for the historical telematics data to develop time-varying hazard functions for the successive life intervals of the equipment to generate dynamic predictions of its failure events. Accordingly, the outcome of the system would be the predicted probability of the equipment failure event considering the timely collected telematics data. The proposed prognostics system was validated by developing the hazard functions of two fleets of dozers and backhoes that provided high fit to the observed data and high prediction accuracy for the testing data. For both analyzed fleets, higher predictive and data fitting performance were achieved for later life intervals due the increased reliability of failure prediction for equipment with longer survival lives.

1 INTRODUCTION

Construction heavy equipment is a valuable asset for construction and equipment rental companies, which requires continuous monitoring and assessment for potential failures. The absence of a properly implemented maintenance program leads to premature equipment failure and increased construction crew idle time. Predictive maintenance (Gransberg et al. 2006) has recently been proposed as an alternative to corrective and preventive maintenance strategies by scheduling maintenance tasks just before a predicted failure of the equipment. Such predictive approach is dependent on the existence of a data collection and analysis system that monitors the equipment performance, compares it to previous history, and predicts the failure events before their occurrence. Despite the great promise of predictive maintenance, its wide implementation was not realized yet due to its need for large data collection process and supporting technology.
Telematics is a data collection technology that integrates wireless communications, vehicle monitoring systems, and location devices to provide real-time spatial and performance tracking of the fleet machines (Lovett et al. 2003). As a witness to its great benefits, the telematics industry has significantly grown to be installed in 5.8 million equipment units with revenue volume of $2 billion in 2009 (Fletcher and Lauron 2009). Telematics can be installed by either the original equipment manufacturer (OEM) or a third-party service provider (TSP). Telematics has been utilized as mainly a real-time monitoring system of equipment fleet for the purposes of theft protection, fuel consumption, and prevention of undesired behaviors of operators/drivers. Fleet managers are challenged to expand the utilization of telematics technology due to the difficulties in inking telematics data to business functions and performance metrics (Monnot and Williams 2011, Trimble and Bowman 2012, Jackson 2012, Sutton 2013).

2 RESEARCH OBJECTIVE AND METHODOLOGY

This paper presents the development and validation efforts of a data-driven prognostics system that utilizes timely collected telematics data to monitor the equipment health condition and predict its failure hazard. Prognostics is the field and methodologies of predicting the future health behavior, failure events, and remaining useful life (RUL) of equipment and machines by diagnosing the recorded temporal behavior (Mesgarpour et al. 2013). Current approaches of prognostics can be classified into three main classes (Lee et al. 2006): 1) model-based prognostics that depends on developing virtual models of the machine that mimic its behavior under healthy and faulty conditions; 2) data-driven prognostics that utilize collected sensor data of the machine’s previous behavior toward failure, and 3) hybrid prognostics that integrates models formulation with sensor data calibration. This paper proposes a data-driven prognostics model that utilizes equipment telematics data to estimate its failure probability.

To accomplish this objective, the research methodology encompassed four main tasks. First, a thorough literature review was performed to study the previous research in the areas of equipment health prognostics and telematics application in construction. Second, a brief description of telematics system architecture and data was presented. Third, the formulation of the proposed telematics-based prognostics system was developed and illustrated. Fourth, the performance of the developed system was validated by analyzing the telematics data of two types of heavy equipment fleets. The paper is concluded by summarizing the contribution of the proposed system to heavy construction and equipment rental companies, as well as recommendations for future research.

3 PREVIOUS RESEARCH

Relevant previous research related to this paper is summarized into two main categories: equipment health prognostics and application of equipment telematics in construction. First, previous research on equipment and machine prognostics focused on monitoring the condition of stationary mechanical machines or electrical micro-machines by majorly measuring their vibrations (Dutta and Giurgiutiu 2000; Yan R. and Gao 2007; Da et al. 2011, Thomson 2013). Equipment manufacturers have encouraged research and development efforts to develop health monitoring systems that integrate remote sensing and equipment oil sampling to diagnose its condition and estimate its life expectancy (Murakami et al. 2002). Little research was found to indicate the potential of utilizing telematics data in prognostics, with no development of proven models or systems (Mesgarpour et al. 2013). Second, little research was performed to investigate the use of the telematics technology in construction and heavy equipment fleet management. Monnot and Williams (2011) highlighted the possible use of telematics in various equipment fleet management tasks, like reporting of machines hours, locations, fuel consumption, and health. Aslan and Koo (2012) proposed an implementation plan for the use of telematics technology in the improving the productivity of roadway maintenance operations. The plan was to me completed in a future study with testing a telematics data collection system and developing productivity measurement metrics.

The careful study of previous studies identified the critical research gap and need for new prognostics systems that would enable the use of telematics data to assess equipment failure potential, as an essential part of effective predictive maintenance (Gransberg et al. 2006).
4 EQUIPMENT TELEMATICS: SYSTEM ARCHITECTURE AND DATA

The architecture of a typical telematics system integrates global position system, available communication infrastructure, and vehicle onboard sensors system. As shown in Figure 1, telematics transponders are installed in the different units of the equipment fleet, where each transponder is connected to the onboard sensors system of the equipment to collect temporal samples of different performance parameters (as discussed in next paragraph). The transponder also has a built-in GPS antenna that collects the location coordinates of every data entry collected. The equipment's performance data and location coordinates are then transmitted through standard wireless communication mediums, which include CDMA (Code division multiple access) and GSM (Global System for Mobile Communications) networks. On the other end, the data is received and stored in a central server that is managed by either the OEM or TSP companies. The data can be accessed by the equipment owners and fleet managers in both push or pull approaches. The system can push notifications to the mobile devices and email addresses of the fleet manager, especially in events when threshold have been activated, like fuel consumption rate, driving speed, or existing in unexpected locations. On the other hand, the data can be pulled from the servers by the fleet manager to view the data on the browser of the World Wide Web (www) or download the data timeline in different file formats.

![Figure 1: Telematics System Architecture](image)

The installed transponders have four types of cable connections that are used to collect three data elements and transmit them wirelessly to the system server. As shown in Figure 2, the transponder unit has four cables: the CAN-bus cable, main interface cable, the GPS receiver cable, and wireless antenna. 

*First*, the CAN-bus cable connects the transponder unit to the controller area network (CAN) of the equipment that connects between the microcontrollers of the equipment different components, such as the engine, transmission, and brakes. The CAN-bus cable enables the transponder to connect to these microcontrollers and their data. The transponders access the CAN-bus data by utilizing the same standard communication protocol used by most heavy equipment manufacturers, called J1939 (developed by the Society of Automotive Engineers). CAN-bus data provides rich and detailed reporting of the different performance aspects of the equipment, such as the engine oil pressure, oil temperature, coolant temperature, engine error codes. CAN-bus data is the main source of equipment health parameters that can be used in health diagnosis and prognosis, as discussed in section 5 of this paper. However, it should be noted that only heavy equipment of the third tier and later are equipped with CAN-bus network. This means that for older equipment, the transponder’s CAN-bus cable is left unconnected and all CAN-bus data cannot be collected or reported. 

*Second*, other basic data of the equipment are collected through the main interface cables, which connect to different points of the equipment to: 1) identify ignition events of the engine that can be used to calculated idle and working times; 2) obtain the odometer reading; and 3) provide a power supply to the transponder itself. Such basic data can be used for elementary utilization and fuel consumption analysis, not health diagnosis/prognosis. Third, the GPS receiver cable provides the location coordinates for every data entry (reading) collected by either the main interface or CAN-bus cables. Fourth, all collected data are communicated through the wireless antenna cable to the system servers. For this study, a commercial TSP telematics system is utilized to
study the telematics data and collect its samples for the development and validation of the proposed heavy equipment prognostics system.

Figure 2: Telematics Data Types

5  EQUIPMENT HEALTH PROGNOSTICS USING TELEMATICS-BASED SURVIVAL ANALYSIS

The development of the proposed equipment prognostics system is presented by listing the proposed telematics health data, providing an overview of survival analysis, and describing the modeling approach of the equipment failure hazard functions.

5.1  Proposed Telematics-Based Health Parameters

Telematics provides a rich data source that is utilized in this research to derive diagnosis and prognosis parameters of the equipment health. The proposed prognostics system is generic and can be applied to any set of telematics health parameters available in the collected data. However, the inputted telematics health parameters may affect the quality of the generated equipment health hazard functions. Accordingly, the following eight health parameters available in every telematics entry at time $t$, were proposed in this research based on available literature review (Murakami et al. 2002, Dekate 2013) and consultation with equipment telematics professionals:

1. Maximum coolant temperature ($MCT_t$) in degrees Fahrenheit, which is observed on the day when the telematics data entry is received.
2. Maximum engine oil pressure ($MOP_t$) in pounds per square inch (psi).
3. Maximum engine oil temperature ($MOT_t$) in degrees Fahrenheit.
4. Maximum engine speed ($MES_t$), in rounds per minute (rpm).
5. Maximum engine percent torque ($MPT_t$), which indicates the load on the engine as a percentage value.
6. Maximum fuel rate ($MFR_t$) in gallons/hour.
7. Engine working hours ($HW_t$), which reports the cumulative number of hours the engine run with a speed (rpm) above a specified threshold, set by the fleet manager.
8. Engine Idling hours ($HI_t$), which reports the cumulative number of hours the engine ran with a speed (rpm) less than the specified threshold.
5.2 Survival Analysis and Failure Hazard Functions

Survival analysis is a regression approach of reliability studies to assess the times and probabilities to failure events. Survival analysis has been applied before to analyze the lifetime of orgasms, survival times of cancer patients, occurrence of accidents, and failure times of machines (Gu et al. 2011). Survival analysis deals with the failure event time as a random variable $T$ using different representations (Allison 1995), such as 1) the cumulative distribution function of variable $T$, $P(t) = Pr(T \leq t)$; 2) the survival function $S(t)$ as the complement of the distribution function, $S(t) = Pr(T > t) = 1 – P(t)$; and 3) the hazard function $h(t)$ that assesses the instantaneous at time $t$. The goal of the survival analysis is to develop these representations of the failure event as a function of its determinant, i.e. its health parameters.

Survival analysis models can be classified as non-parametric, parametric, and semi-parametric models (Ma and Krings 2008). Cox’s proportional hazards model (Cox 1972), one of the fundamental semi-parametric survival models, is utilized for this study due to its ability to capture the failure covariates more effectively than non-parametric models with less modeling restriction like the parametric models (Bailey et al. 2006). As shown in Equation 1, a dynamic time-varying hazard function $h(t)$ of Cox’s model is utilized in the proposed equipment prognostics system to estimate the probability of equipment failure at time $t$, which is based on: 1) the telematics health parameters $X(t)$ (covariates) and their coefficients $\beta(t)$ that can be determined by performing a regression analysis to fit the observed health parameter values to the failure hazard probability $h(t)$; and 2) a baseline failure rate $h_0(t)$ represents the decay of the equipment health regardless of the values of its health parameters. The next section will explain in more details the methodology of developing the hazard functions and the calculation of the observed equipment hazard probability based on the available telematics data.

\[ h(t) = h_0(t) \times \exp \left[ \beta(t).X(t) \right] \]

5.3 Modeling and Development of Equipment Failure Hazard Functions

The proposed heavy equipment prognostics system follows a novel methodology to model and develop Cox’s proportional survival functions as a function of the available telematics data. As shown in Figure 3, the equipment hazard functions are developed in four main steps:

Step (a) – Telematics data are used to mark the failure events over the lifetime of the equipment and the engine hours. An equipment failure event is recognized if one of two engine lights is reported in the telematics data entry: 1) red stop light (RSL) that indicates a severe enough condition that it warrants stopping the vehicle; and 2) amber warning light (AWL) that reports a problem with the vehicle system but the vehicle does not need to be immediately stopped. Other engine lights, such as engine protection light (EPL) and malfunction indicator light (MIL), are not used to indicate a major equipment failure as they report less severe health conditions related to the vehicle electronic system and emissions-related issues. As shown in Figure 2, the existence of either RSL or AWL marks a failure event and the start/end of a survival life of the equipment. As shown in Figure 3, survival analysis permits the right and left censoring (Ma and Krings 2008) of the data to only consider the complete survival lives that start and end with a recorded failure/survival event.

Step (b) – The observed failure hazard value is quantified using another telematics data element, which is the engine total hours (HT) that reports the cumulative engine hours up to the time of the telematics data entry. As shown in Figure 2, the observed failure hazard is quantified over each of the identified survival lives as the ratio between: 1) the engine hours $E$, since the start of the survival life to time $t$; and 2) the total engine hours $L$ occurred during corresponding survival life. Accordingly, the failure hazard observed values range from 0 (at the beginning of the survival life) to 1.0 (at the end of the survival life).

Step (c) – All telematics entries are combined to form the analysis data population and divided into survival intervals, which each will have its own hazard function to represent the time-varying nature of equipment health performance. As shown in Figure 3, the analysis sample combines all telematics data entries of every unit survival life from the same-type equipment fleet (i.e. dozers, loaders, excavators). Each data entry include the following variables: 1) the observed failure hazard value
(dependent variable) that was quantified in step b; 2) the time t in days since the recovery from last failure; and 3) the proposed telematics-based covariates that are available from the collected data ($MCT_r$, $MOP_r$, $MOT_r$, $MES_r$, $MPT_r$, $MFR_r$, $HW_r$, and $HI_l$). The initial data sample is divided into subgroups of survival intervals to represent different hazard behaviors and rate of the equipment over its survival life.

Step (d) – The survival baseline rate $h_0(t)$ and coefficients vector $\beta(t)$ are estimated for every life interval hazard function using data linearization regression technique. First, the data sample of every life interval is divided into two groups (Lucko and Rojas 2010): a) the estimation data group that is used to estimate the baseline rate and coefficients vectors; and b) the validation data group that is used to assess the prediction accuracy of the hazard functions with the estimated coefficients. The coefficients can be estimated using traditional statistical analysis software packages to improve the fitting of the hazard function to the observed values. The fitting of the hazard function can be assessed using any or all of the following statistical metrics: 1) the p-value for the constant and each covariate coefficient as generated from by regression analysis, which is used to test the hypothesis of survival function dependency on each of the covariates; 2) coefficients of determination (R-square, Multiple R-square, and adjusted R-square) to test the fit of the resulting survival function to the observed data; and 3) analysis of variance (ANOVA) significance level F, which quantifies the probability that the proposed function does not explain the variation in the equipment hazard (Field 2005). Accordingly, the validation data group is used in assessing the prediction accuracy of the estimated hazard functions using the Pearson coefficient of correlation ($R_{corr}$), student t-test to examine and the root mean square error ($RMSE$) (Montgomery et al. 2001, Lucko et al. 2006).

![Diagram](image)

Figure 3: Telematics-based Survival Analysis to Develop Equipment Prognostics Hazard Functions

6 SYSTEM PERFORMANCE ILLUSTRATION AND VALIDATION

The performance of the proposed heavy equipment prognostics system was illustrated and validated using the telematics data of two fleets of an equipment rental company. The Cox’s failure hazard functions of the company’s dozer and backhoe fleets were developed by applying the proposed system methodology to the telematics data of 21 dozers and 29 backhoes. The total telematics data entries were
1836 for the dozers and 3315 for the backhoes that cover a one year observation period. Removal of the outliers resulted in reducing the data sample to 1767 and 3016 data entries for dozers and backhoes respectively. Five arbitrary life intervals were considered to develop the time varying hazard functions: less than 50 days; between 50 and 100 days, between 100 and 150 days; between 150 and 300 days, and more than 300 days. The data entries were split between these time intervals based on their survival lives, accordingly divided into estimation and validation data groups. Tables 1 and 2 list the data entries distribution over the life intervals, the estimated coefficients of the survival functions, and their prediction validation metrics. For example, 676 data entries of the dozers were located in the first life interval (0 – 50 days) and were split equally between the estimation and validation groups. Equation 2 depicts an example of how the estimated coefficients shown in Table 1 can be used to formulate the time-varying hazard function of the dozers fleet.

\[
\begin{align*}
    h(t) &= \begin{cases} 
    \exp[-0.0396 \cdot \text{MOP} + 0.0077 \cdot \text{MOT} + 0.0015 \cdot \text{HW}] & 0 \leq t < 50 \\
    \exp[-0.0165 \cdot \text{MOP} + 0.01835 \cdot \text{MPT} + 0.181 \cdot \text{MFR} + 0.00093 \cdot \text{HI}] & 50 \leq t < 100 \\
    \exp[-0.0145 \cdot \text{MOP} + 0.00047 \cdot \text{MES} - 0.00911 \cdot \text{MPT} + 0.00156 \cdot \text{HW} - 0.0013 \cdot \text{HI}] & 100 \leq t < 150 \\
    \exp[-0.0144 \cdot \text{MOP} + 0.00537 \cdot \text{MPT} + 0.00123 \cdot \text{HI}] & 150 \leq t < 300 \\
    \exp[-0.0132 \cdot \text{MOP} - 0.0009 \cdot \text{MOT} + 0.0079 \cdot \text{HW} - 0.00515 \cdot \text{HI}] & 300 \leq t
\end{cases}
\end{align*}
\]

The examination of the developed hazard functions provides useful insights on the dependency of equipment health prognosis on the telematics parameters over the successive life intervals. First, some telematics parameters have shown consistent correlation with the failure hazard probability for both analyzed equipment. The maximum oil pressure (MOP) and working hours (HW) variables were found to be a very significant health prognosis variables (p < 0.001) in the developed hazard function in most life interval. Also, it was consistently shown that higher MOP values result in lower failure hazard (all of its coefficients were negative) as it indicate a lower possibility of oil leakage. On the other hand, the positive coefficients of the working hours (HW) variable reinforce the concept that higher working hours increases the equipment’s failure hazard. Second, the fitting and prediction accuracy of the developed hazard functions were found to increase with the survival time of the equipment. This observation is illustrated by the high multiple R value, the high R<sub>corr</sub> value, and low RMSE value of the last life interval for both equipment types compared to earlier life intervals. This complies with the de facto that the failure of assets with longer survival time can be reliably anticipated compared to younger assets with shorter survival time that just recovered from a failure event.

7 CONCLUSION AND FUTURE RESEARCH

This paper presents the development of a telematics-based equipment prognostics system that can support heavy construction and rental companies to effectively manage their predictive maintenance programs. Telematics is an efficient data collection technology as it integrates equipment onboard...
sensing, global positioning, and telecommunication to provide a timely reporting of different equipment performance data. The telematics CAN-bus data provide a rich source of metrics that can be used to diagnose the equipment health. A new survival analysis methodology is proposed to develop the equipment hazard functions utilizing the available telematics data to: 1) identify equipment failure events and survival lives using the red and amber engine lights; 2) quantify the observed failure hazard probability using the reported engine hours; and 3) estimate the regression coefficients of the failure hazard covariates that are evaluated from a set of proposed telematics health parameters.

The proposed prognostics system was successful in developing the hazard functions of the analyzed equipment fleets that provided high fit to the observed data and high prediction accuracy for the testing data. For both analyzed fleets, higher predictive and data fitting performance were achieved for later life intervals due to the high tear and wear levels that results in increased failure probability.

The proposed telematics-based prognostics system should prove useful to equipment fleet managers to successfully implement predictive maintenance programs. The system would expand the current uses of telematics systems by transforming its timely data into useful decision making information. Future possible research venues of the developed system includes: 1) developing alternative telematics data-driven prognostics systems that utilize other statistical and probabilistic analysis approaches, such as logistic regression and fuzzy clustering; and 2) implementing the proposed prognostics system into an automated online or desktop prototype module that can be integrated into available telematics systems and fleet management operations.

Abstract: Schedule float is a fundamental concept in construction planning and control that refers to the flexibility of delaying project activities. However, traditional schedule floats offer limited help in congested construction sites and cannot answer a common field question of 'how much time is available to use this space to stage material?' This paper therefore presents the development of new theory and metrics of space float for construction activities based on a previously developed spatial scheduling model. It is structured into three main sections. First, it presents a review of a previously developed spatial scheduling model that utilizes singularity functions to represent and schedule activities as interdependent and overlapping workspaces. Second, it presents the different possible activity float types and the detailed calculation of activities shift float. Third, it describes the new space float algorithm to generate dynamic position float contours that change over the project time. The calculation of proposed activity and space floats are illustrated with an example of a small construction jobsite. The proposed concept has the potential to strengthen the relation between construction scheduling and other management functions, such as e.g. lean operations and material layout planning.

1 INTRODUCTION

All construction activities occur within their integrated environment of temporal and spatial constraints. While the time aspect has been thoroughly explored in construction scheduling, the linkage to the spatial dimensions has received less attention, potentially due to a lack of an integrated model that is able to jointly express these aspects mathematically, while adequately considering their very different nature: Time is a single dimension that can only move forward, inevitably passes whether progress is made on the jobsite or not, and is germane to all activities without being influenced by them. Space, on the other hand, has additional dimensions of the workspace wherein each productive activity occurs, which can move into either direction or remain stationary, and is typically occupied exclusively by a single activity and thus represents an important resource of limited availability. Previous research (Lucko et al. 2014a) has introduced how to mathematically describe both time and space with singularity functions - spatial scheduling, as is explained in the following section – but has not yet examined the float that is generated in such schedules, which will provide valuable information to the project manager about the criticality and flexibility of activities at different locations. The model assumes that spatial height can be simplified based on a safety rule that no two activities work underneath one another. Scheduling with explicit consideration of a spatial aspect thus has potential to improve efficiency while fulfilling constraints and ensuring safety.
Relevant previous studies can be clustered into four main areas, spatial float analysis, modeling activity workspaces, spatial scheduling, and space criticality. First, studies of spatial float were performed for one-dimensional linear schedules. The application of total float and rate float concepts in linear schedule were investigated by Awwad and Ioannou (2007), Ammar (2003), and Harmelink (2001). In addition, Kallantzis and Lambropoulos (2004) developed a methodology to determine the critical path and segments within a linear schedule. Lucko and Peña Orozco (2009) formulated diverse float types (total, free, interfering, independent, and safety) in linear schedules using singularity functions. Second, studies developed formulation and conflict analysis methodologies of construction activity workspaces using 4D topological metrics (Chua et al. 2010; Su and Cai 2014a/b), GIS (Bansal 2011), CAD (Gu 2002), and taxonomies (Akinci et al. 2002). Third, spatial scheduling systems were developed to generate and track construction schedules considering their spatial needs and behaviors. Thabet and Beliveau (1994) created a system that formulates and quantifies the workspaces of construction activity to be considered in sequencing of the work. Mallasi (2009) developed a 4D optimization model in search of an optimum execution strategy to minimize the conflicts between activity workspaces. Esfahan et al. (2013) described spatio-temporal schedule tracking and updating of resource movements through an enveloping prism of maximum and minimum expected progress rates. Fourth, Winch and North (2006) were explicit in acknowledging the job site space as a resource and developed a system that reports its overloading by activity workspaces.

Despite the contributions of these diverse previous studies, no methodologies or metrics were developed to quantify float of activities in two-dimensional (2D) spatial schedules (Lucko et al. 2014b). Absence of float in spatial schedules prevents project managers and schedulers from being able to properly evaluate the impact of potential delays and interruptions within its actual physical environment. Furthermore, the newly envisioned space float metric can be used as a link between the managerial tasks of construction scheduling and job site layout planning. Accordingly, this paper presents new methodologies to quantify activity and space floats by using singularity functions. The following sections will therefore sequentially explain the application of singularity functions in spatial scheduling, the new metrics of activity floats (shift, rate, and combined), space float quantification and contours for individual positions, and the illustration of the proposed methodology by calculating the new activity and space floats of an application example.

2 SPATIAL SCHEDULING USING SINGULARITY FUNCTIONS

Singularity functions are mathematically defined so that they can specifically express singularities, which are locations of discontinuities in the value or behaviour of a function. They employ an operator that is denoted with pointed brackets ⟨ ⟩ and a shape exponent \( n \) to indicate the type of behaviour — constant, linear, quadratic, etc. — that is being modeled. Within the brackets, the activation cutoff \( a \) is compared to the input \( x \) to determine whether the entire function \( f(x) \) remains zero or yields a non-zero value. Finally, the strength factor \( s \) determines the intensity of whatever behaviour \( n \) provides. Equation 1 provides the operator for a single term. As each term only captures exactly one behaviour (from its activation onward), multiple terms are added to compose any more complex singularity function. Multiple singularity functions can be added; multiple terms can be simplified if they have an identical activation \( a \) and exponent \( n \).

\[
\begin{align*}
t(x) &= s \cdot \langle x - a \rangle^n \\
&= \begin{cases} 
0 & \text{if } x < a \\
0 & \text{if } x \geq x
\end{cases}
\end{align*}
\]

To express one activity within a linear schedule, which measures quantity of work and durations across time, the former is selected as the independent variable \( x \) and the latter as the dependent variable \( t(x) \) (Lucko et al. 2014b) as Figure 1 shows. The reason is that time is typically supposed to be minimized on construction projects, while work is a given input. For an activity with start position \( a_s \) (often zero) and finish position \( a_f \), a start time of \( t_s \) and a productivity of \( \Delta x \) work units that are produced in \( \Delta t \) time units, the singularity function is \( t(x) = t_s \cdot (x - a_s)^0 + \Delta t/\Delta x \cdot [(x - a_s)^1 - (x - a_f)^1] - \Delta t^2/(x - a_f)^2 \cdot 0 \), where \( t_s \) is an upstep on the time axis (intercept), \( \Delta t/\Delta x \) is a slope (inverse of productivity, due to charting time over work). The singularity function models the activity: 1) Its first term adds the activity start \( t_s \) to the schedule only between the its start and finish positions, 2) the second term adds its rate of progress and removes it beyond its finish position \( a_f \), else this activity would continue to produce forever; and 3) the last term
removes the activity duration $\Delta t$ beyond its finish position $a_{xF}$, which is accumulated by the second term. By evaluating such equation for any work quantity, the time when it will be completed can be determined.

$$t(x) = s \cdot (x - a)^n$$

![Linear Singularity Function](image)

![Linear Activity as a Singularity Function](image)

**Figure 1: Singularity Functions and Their Use to Represent Linear Activities**

### 2.1 Activity Progress Representation

Previous work by the authors has broadened the definition of Equation 1 beyond its confines of a single independent variable (Lucko et al. 2014a). Since activities are located within the site, a two-dimensional plot of land, reflecting it in the planning and scheduling effort adds realism and value, because it enables that spatial interaction can be modeled and analyzed. Thus each activity can be located by its coordinates on two length axes $x$ and $y$. The third dimension – height – is beyond the scope of this research and will be addressed in future work. Activities are assumed to progress parallel to one or both axes as follows:

- Activity may be stationary and completely occupies an $x$-$y$-area for a specific period of time;
- Activity can only progress into positive, negative, or both positive and negative $x$-direction;
- Activity can only progress into positive, negative, or both positive and negative $y$-direction;
- Activity can progress into a combination of positive or negative $x$-direction and $y$-direction.

Equation 1 can only express progress in terms of the plane of time $t$ over a single length axis. Viewing a projection of the progress along both $x$ and $y$ provides a solution to the challenge of how to extend the model into the third dimension: Combining projections in the $x$-$t$-plane and $y$-$t$-plane via their common variable $t$. Each projection is a regular singularity function per Equation 1 of order $n = 0$ for a stationary activity or $n = 1$ for a directional one. Equation 2 models an activity with three dimensions, two of space and one of time. Its ranges are $[a_{xS}$ to $a_{xF}]$ on the $x$-axis and $[a_{yS}$ to $a_{yF}]$ on the $y$-axis, respectively. In this example, it grows into the positive $x$-direction as a multiplicative combination of linear behaviour in the $x$-$t$-plane and constant behaviour in the $y$-$t$-plane. All other such directions can be modeled analogously.

$$t(x,y) = t_s \cdot \left[ (x-a_{xS})^0 - (x-a_{xF})^0 \right] \cdot \left[ (y-a_{yS})^0 - (y-a_{xF})^0 \right]$$

$$+ \frac{\Delta t}{\Delta x} \cdot \left[ (y-a_{yS})^0 - (y-a_{yF})^0 \right] \cdot \left[ (x-a_{xS})^1 - (x-a_{xF})^1 \right]$$

The last terms in Equation 2 subtract slope and height at $a_{xF}$ to ensure that the activity does not continue to occupy space beyond its boundaries. If it is only evaluated for values within valid $x$- and $y$-ranges, it is not strictly necessary to subtract the duration (height on the $t$-axis) that the activity has consumed beyond $a_{xF}$ to yield correct results. Indeed, even the negative terms in the rectangular brackets could formally be omitted, and are merely used to convey the information about the upper boundary of the interval itself.
2.2 Activity Relation Types

Activities are modeled as entities with distinct boundaries on all axes. To create a complete and feasible schedule, one must define the types of relations that can exist between pairs of activities. For the model of a schedule that considers space, two main categories of relations will be distinguished in this study:

- Sequential activities are connected by finish-to-start relations due to resource or technical constraints;
- Concurrent activities can be dependent or independent and their ranges overlap along the time axis.

Figure 2 shows an example of two activities A and B in an x-y-plane (floor plan view) with their coordinate ranges between their respective start and finish and directions of progress. Three possible constellations are illustrated in their x-t-planes: (a) a sequential relation with an intermediate time buffer $\text{buff}_{AB}$ between any locations of A and B that prohibits overlap in time, (b) a relation that allows concurrency for A and B to occur partially overlapping in time, but maintain their dependency and buffer at any location, and (c) a relation that allows unlimited concurrency between independent A and B. Scheduling these activities into such constellations uses the spatial scheduling algorithm that is briefly explained in the following section.

![Diagram showing types of relations between activities in spatial scheduling]

Figure 2: Types of Relations between Activities in Spatial Scheduling

2.3 Spatial Scheduling Algorithm

The previously introduced spatial scheduling algorithm handles time and space constraints of activities to compose a feasible schedule (Lucko et al. 2014b) with heuristics to select among options in each step:

1. Activities are sorted by priority, which depends on the particular heuristic that is chosen by the user;
2. The next activity is selected and initialized by expressing it in form of a spatial singularity function;
3. One permissible progress direction of the activity is evaluated and its possible start time is calculated;
4. Repeating Step 3, the earliest (minimum) start time determines the selected actual progress direction;
5. Repeating Steps 2 through 4, successor activities are handled in the same manner until none remain;
6. Final singularity functions are written and starts, finishes, and directions of all activities are reported.

3 ACTIVITY FLOATS

Space float can take different forms, both due to the geometric constellations that activities can generate among themselves within a space schedule, subject to constraints, and due to the different ways in which it can be consumed by activities, as Figure 3 shows. In general, float is viewed as flexibility of an activity to mitigate a delay by postponing its start and/or finish. It is assumed that this occurs locally, i.e. between the current activity and its direct successor(s). This bears an analogy to the free float in CPM schedules, which is measured only between adjacent activities and is not shared along an entire path like total float. However, this is where the analogy between one-dimensional network schedules (time only) and three-dimensional space schedules ends, because CPM float are just single values of time without any spatial components, whereas space float takes a shape within the integrated temporal and spatial environment. Moreover, CPM float does not provide any information about its potential use, as opposed to space float.
3.1 Overview of Activity Float Types

Figure 3 shows an example with the predecessor A and successor B and their time buffer \( \text{buff}_{AB} \). They share an overlap zone in the \( x\)-\( y\)-plane. Assuming that they respective starts, finishes, and directions have been obtained in a previous analysis with the spatial scheduling algorithm, the questions remain if A has float and how much, of what type, and where. Therefore, the following definitions are established:

- **Shift float** (SF) is consumed by delaying both the start and finish of an activity, i.e. preserving its productivity and thus duration \( F_A - S_A \), but shifting its entire execution to a later interval on the \( t\)-axis;
- **Rate float** (RF) is consumed by delaying only the finish of an activity, i.e. modifying its productivity to a lower value and thus extending its duration by rotating its progress slope upward in the \( x\)-\( t\)-plane;
- **Combined float** (CF) can be consumed as shift or rate float, depending on need or user preference.

These float types can be determined for the previously discussed sequential or concurrent relation types. For brevity, only shift float will be discussed in detail and rate float is left to be studied in further research.

3.2 Activity Shift Float Calculation

Shift float, which has been defined in the previous section, is illustrated with an example of two activities per Figure 4. For illustration A and B progress into different directions. It is calculated in several steps:

1. Determining the overlap zone of both activities from the maximum of the activity start coordinates on both \( x\)-axis and \( y\)-axis to the minimum of the finish coordinates on both geometric axes. This example has a valid overlap zone with \( x\)-range = \{0 to 13\} and \( y\)-range = \{0 to 20\}. Activities in other examples may not overlap at all, which would end the shift float calculation for such activity pair at this step;
2. Establishing singularity functions for A and B per Equation 2, here \( f(x, y) = 6 \cdot [(x - 0)^0 - (x - 28)^0] \cdot [(y - 0)^1 - (y - 20)^1] + \frac{14}{28} \cdot [(x - 28)^0 - (x - 28)^1] \cdot [(y - 0)^0 - (y - 20)^0] \cdot [(x - 28)^0 - (y - 28)^1] \cdot [(y - 0)^0 - (y - 20)^0] \cdot [(y - 20)^1 - (y - 20)^0] \). Note that B is growing into the negative \( y\)-direction, which is mathematically expressed with a large upset followed by a negative slope into the positive \( y\)-direction. In other words, it is modeled from its finish to the start of the activity, which mathematically is equivalent to viewing it from its start to the finish, because singularity functions do not distinguish the meaning of start and finish, only cutoff points in a shape where any behaviour is activated or deactivated. Thus the successor activity is expressed as \( f(x, y) = 45 \cdot (x - 0)^0 \cdot (y - 0)^1 - 15/25 \cdot [(x - 0)^0 - (x - 13)^0] \cdot [(y - 0)^0 - (y - 25)^0] - (45 - 15) \cdot (y - 25)^0 \);
3. Modifying \( f(x, y) \) toward the equation for \( \text{buff}_{AB} \), which can be modeled with a singularity function in the same manner by setting its start to \( t_s + \text{buff}_{AB} \), which assumes that the time buffer has a constant value. A variable time buffer could be modeled in analogy to Equation 2, but is omitted for brevity;
4. Identifying the minimum of B as \( t_s + \text{buff}_{AB} = 30 \) and the maximum of \( f(x, y) \) at any location, not just corners of the overlap zone, which here is \( t_fA + \text{buff}_{AB} = 20 + 6 = 26 \). Their \( t\)-difference is \( 30 - 26 = 4 \), i.e. activity A has 4 hours for shift float (SF\(_{AB}\)) under the stricter sequential relation with activity B;
5. For the more efficient concurrent relation, while still maintaining dependency of A and B, shift float per Figure 3 is calculated as the minimum time distance between them in the overlap zone, less \( \text{buff}_{AB} \). The equation for \( \text{buff}_{AB} \) would be identical to \( f(x, y) \), except for its intercept \( S_{\text{buff}_{AB}} = 6 + 6 = 12 \). As the buffer here has a constant value, in the following calculation it will be simply subtracted from \( t_b - t_A \). The difference equation can be interpreted as expressing the volume between these two activities;
6. Evaluating this difference equation at all corner coordinates of the overlap zone and identifying shift float as their minimum (after deducting the required buffer). As listed in Table 1, the time difference between the singularity functions of A and B is calculated as \( t_{1} \) at \( \{0, 20\} \), \( t_{2} \) at \( \{13, 20\} \), \( t_{3} \) at \( \{13, 0\} \), and \( t_{4} \) at \( \{0, 0\} \). It is calculated by subtracting the required buffer (6 hours) from the minimum of the overlapping time differences (20.5 hours), which results in shift float \( SF_{AB} = 14.5 \) hours. Note that the shift float for the case of a concurrent relation is more than the float that can be realized for the more strict sequential relation. This fact should be considered in the field to encourage concurrent relations between activities to improve construction schedules in terms of increased opportunities from float;

7. Note that due to the right-continuous definition of Equation 1, finish coordinates are evaluated at an infinitesimal distance before the cutoff, at which the singularity function is already reset to zero. Note that in this example, A and B have perpendicular progress directions in their projection into the x-y-plane of Figure 4 (different from the example of Figure 3), so that at \( \{13, 20\} \) they are already in close proximity. For parallel progress directions, the concurrent shift float could potentially be even larger;

8. Shift float (shifting) is measured as duration, e.g. workdays, whereas rate float (rotating) – that future research will investigate – is measured as duration divided by length; a change in the progress rate.

4 POSITION SPACE FLOAT

Position space float \( PF(x, y, t) \) is a new schedule float metric that is calculated for any coordinates \( \{x, y\} \) of the project jobsite at time \( t \) of the project duration. It is the amount of time that is available to use the said location at time \( t \) before it will be occupied by the earliest successor activity whose workspace includes this point also. A new algorithm is developed to calculate \( PF(x, y, t) \), which is explained by continuing the example of Section 3 as shown in Figure 5. The new position float algorithm has five steps that are illustrated by calculating it at coordinates \( P = \{6, 10\} \) and \( Q = \{28, 25\} \) for the project start \( (t = 0) \):

1. The execution times \( t(6, 10)_{A} \) and \( t(6, 10)_{B} \) of activities A and B at position P are calculated from their singularity functions. Accordingly, \( t(6, 10)_{A} \) is calculated as 9 hours, and \( t(6, 10)_{B} \) is calculated as 39;
2. The earliest execution time (EET) is defined as the minimum value of any successor activities that are scheduled at position P, which here is calculated as the minimum of t(6, 10)\textsubscript{A} and t(6, 10)\textsubscript{B} as 9 hours;

3. The position space float PF(x, y, t) is calculated as the difference between EET and the current time t that must be known. Accordingly, at position P = (6, 10) at time t = 0, here its PF(6, 10, 0)\textsubscript{P} = 9 hours;

4. If no successor activities are executed at the position that is analyzed, its PF is simply the difference between project finish and current time. Thus at Q = (28, 25) at t = 0, the PF(28, 25, 0)\textsubscript{Q} = 45 hours;

5. The previous steps can be applied to all discrete positions within the jobsite to generate position float contours for any time of interest. Figure 5 shows the position float contours for this example at t = 0. Position float contours will dynamically vary across the jobsite as time passes until the project finish.

![Figure 5: Example of Position Float Calculations](image)

5 APPLICATION EXAMPLE

Calculating the new activity and position float metrics are illustrated in an application example that follows the approach that Lucko et al. (2014a) had originally analyzed. It comprises nine construction activities of a slab-on-grade (SOG) and underground utilities (electrical and drainage) as Figure 6 shows. Its activities are one-directional (B, C, D, E, G, and H); two-directional (A and I), or stationary (F). Resource-driven relations are considered between those of the same trade, e.g. electrical (B, C, D, E, and F) or drainage activities (G, and H). SOG concrete pouring activity (I) has a finish-to-start dependency with all activities, while rebar placement (A) has a concurrent relation with its predecessors (F, G, and H). The mentioned spatial scheduling model (Lucko et al. 2014a) generated the space schedule. Its optimized total project duration is 53 hours. The final scheduled direction, start, and finish of each activity are listed in Table 2.

Table 2: Spatial Scheduling Results and Activity Floats of the Application Example
Calculated floats of the activities indicate a high criticality of the generated schedule due to its assumption that activities are continuously executed without interruptions. Table 2 shows that all activities have zero shift and rate floats, except for F and H. Activity F has $S_F = 12$ hours but zero rate float, because it is a stationary activity that occupies its whole workspace during its duration (i.e. it does not have a progress rate). Its shift float is realized as the critical time difference with its concurrent successor A. On the other hand, H has both shift and rate floats, which are also determined based its concurrent successor A. Other activities have combined floats, but have zero shift and rate floats. This is due to the assumption in the new float metrics that activity interruptions are not allowed, which prevents utilizing the available spatio-temporal combined floats between the activities in the form of either shift or rate float unless it is explicitly permitted. It should be noted that activity I has zero floats because it is the finishing activity of the project.

![Figure 6: Application Example and its Spatial Schedule (after Lucko et al. 2014b)](image)

Position float contours provide a clear visual assessment of the space criticality and availability. Figures 7 and 8 depict the generated position space floats at two sampled times $t = 0$ and $t = 33$. At the project start $t = 0$, no float exists at the positions of G and F, because they are initial activities of the project (Figure 7). The entire workspace of F has zero float because of its stationary nature. On the other hand, G has zero float only at its start $x = 0$ between $y = \{10$ to 15$, \}$, because it is a one-directional activity that is scheduled to progress into the positive x-direction. At $t = 33$ (Figure 8), E has the least float, because it will start at the analyzed time ($S = 33$, as listed in Table 2). The longest position space float of 20 hours is at the edge of I ($y = 0$), because it is the final activity of the entire project, progressing into the negative y-direction.

![Figure 7: Position Float Contours of the Application Example ($t = 0$)](image)
6 CONCLUSIONS AND RECOMMENDATIONS

- This paper has provided an overview of a newly developed spatial scheduling model wherein singularity functions express the geometry and progress of each activity. However, previous research had not yet provided any metrics of space float (including criticality of activities without such flexibility). Therefore, shift, rate, and combined float have been discussed, and position float contours have been introduced. Together, they provide a detailed view of the spatio-temporal constraints and opportunities that exist within a project schedule from a spatial perspective. In summary, it is envisioned that spatial scheduling and floats can greatly support professionals in the construction industry in integrating space-aware project schedules, designing efficient site layouts, and facilitating lean execution of their construction activities.

- Future research should mathematically extend the new model with its two dimensions of space and one dimension of time to more dimensions, including height or even other aspects, such as e.g. cost, by generalizing the multiplicative approach (Lucko and Su 2014), even if it cannot be visualized completely.

PREDICTIVE MODELING OF PREFABRICATION FEASIBILITY FOR THE UNITED STATES ELECTRICAL CONTRACTING FIRMS

Hisham M. Said1,2,3
1 Department of Civil Engineering, Santa Clara University, USA.
2 Adjunct lecturer, Structural Engineering Department, Cairo University, Egypt
3 hsaid@scu.edu

Abstract: Electrical contractors have promoted offsite prefabrication after experiencing its potential in improving their operations. However, prefabrication is not a one solution that fits all. Accordingly, there is a need to develop better understanding of prefabrication feasibility for electrical contractors by analyzing its operational requirements and surrounding industry factors. The objective of this paper is to identify and model the determinants of electrical contractors’ prefabrication feasibility within the U.S. industry context, which can be used to predict the viability of prefabrication as a production approach for individual electrical contracting firms. The methodology of this study included four main phases. First, a qualitative analysis was performed to initially understand current prefabrication operations and practices of electrical contractors through a set of semi-structured interviews, site visits of prefabrication facilities, and prefabrication case studies. Second, a quantitative data collection task was performed by: 1) acquiring the internal business variables of a sample of electrical contractors using an online questionnaire; 2) complementing the questionnaire data with location-based economic data to represent external industry-related variables. Third, the collected data was used to develop and validate a binary logistic regression model that relates the prefabrication feasibility to its significant determinants. Fourth, a sensitivity analysis was performed for the developed model to provide a larger understanding of electrical construction prefabrication feasibility beyond the collected data. The developed predictive model provides useful insights about prefabrication feasibility dependency on union relations, labor conditions, market competition, supply chain relations, and building information modeling.

1 INTRODUCTION

Offsite prefabrication has been practiced in the construction industry for decades due to its clear benefits in reducing project duration and cost. Offsite prefabrication was identified as one of promising breakthroughs that can greatly improve the productivity of the construction industry (NRC 2009). Prefabrication can be applied with different extents for the typical systems and components of building projects. Building electrical systems provide great prefabrication opportunities due to their modular decomposition into standardized components and subsystems. For example, electrical systems are typically decomposed into panels, ducts, cables, receptacles, and rough-in supports. Due to their standardized modular structure, electrical and mechanical systems were reported to be as the most building components that can be constructed using offsite prefabrication operations (MHC 2012).
Electrical construction has been the subject of several previous research studies, but with little attention to prefabrication. Previous electrical construction research included: 1) schedule coordination between mechanical, electrical, and plumping (MEP) trades (Korman et al. 2003, Horman et al. 2006); 2) management of contract changes by electrical contracts (Hanna et al. 2004); 3) utilization of Building Information Modeling (BIM) in electrical construction (Khanzode et al. 2008, Hanna et al. 2014); 4) design-build considerations for electrical contractors (EC) (Rowings 2000); and 5) financial analysis of electrical contractors (Jaselskis et al. 2002). Few research studies were performed to analyze prefabrication practices of electrical contractors. First, Bogus et al. (2009) performed an industry study to identify the best practices of electrical construction prefabrication, through observing the prefabrication facilities of a sample of electrical contractors. Second, Mikhail (2014) performed a survey-based study of prefabrication practices of electrical contractors. The major findings of this study include: 1) the use of electrical prefabrication has increased by 9% over the period 2004 – 2014; 2) the majority of survey respondents still limit their prefab operations between 1% – 9% of their work volume (measured in labor hours); 3) electrical contractors experienced cost reductions in 97% of their projects; and 4) electrical prefabrication helped to achieve time savings in 94% of the projects.

The findings of the previous research studies documented the best practices and benefits of prefabrication, but did not analyze its determinants to be a feasible production approach for electrical contractors. Prefabrication is not a one solution that fits all electrical contractors, and its successful implementation is dependent on internal and external factors that influence its economic feasibility. A previous study (Mikhail 2014) investigated the internal and external drivers/impediments of electrical construction prefabrication. However, there is no quantitative tool that can predict for electrical contractors the feasibility of adopting prefabrication operations considering firm’s internal and external variables.

2 RESEARCH OBJECTIVE AND METHODOLOGY

The objective of this paper is to develop a data-driven predictive model of prefabrication feasibility of electrical contractors. To achieve this objective, the research methodology included four main phases. First, qualitative data of electrical construction was collected by interviewing industry professionals, visiting prefabrication facilities, and acquiring case studies of prefabrication work. Second, electrical construction prefabrication was qualitatively analyzed by interviewing a sample of electrical contractors, visiting their prefabrication facilities, and collecting case studies of prefabrication assemblies and projects. Third, the collected data is used to develop and validate a logistic regression predictive model of prefabrication feasibility that considers electrical contractor’s internal and external attributes. Fourth, the behavior of the proposed system is evaluated using multi-variable sensitivity analysis to better understand the impact of the model’s selected variables on the prediction of prefabrication feasibility.

3 QUALITATIVE ANALYSIS OF ELECTRICAL PREFABRICATION

Qualitative analysis of electrical construction prefabrication was performed using interviews, site visits, and case studies to obtain an in-depth understanding of prefabrication operations and drivers. The outcome of the qualitative analysis is the development of initial list of potential drivers/determinants of electrical prefabrication feasibility that will be considered in the next phase of collecting their quantitative values and developing the predictive model. The qualitative analysis was facilitated by a taskforce of electrical construction professional, which was formed by ELECTRI International Foundation to support this research study.

First, the taskforce members and other industry professionals were interviewed in a semi-structural setting to answer a set of open-ended questions (Patton 2002) about the impact of project supply chain stakeholders (designer, general contractor, vendor, manufacturer) on electrical construction prefabrication; as well as the impact of firm’s external environment on its prefabrication operations (i.e. union relations, labour hourly rates, etc.). The interviews were performed with 7 operation managers of different electrical construction companies, 1 vendor representative, 3 manufacturer sale managers and 1 executive director of a local chapter of the National Electrical Contractors Association (NECA). Second, the prefabrication facilities of a large and small electrical contractor were visited to observe on the ground their operations and document the interfaces between the facility, site work, and vendors. Third, case
studies were collected for electrical prefabrication coordination in construction projects, layout and equipment of prefabrication facilities, and samples of prefabricated electrical assemblies.

4 QUANTITATIVE DATA COLLECTION

Considering the observations and findings of the previous phase, prefabrication-related internal and external quantitative data of a sample of electrical contractors was collected using web-based questionnaire and available online governmental economic databases.

4.1 Web-based Questionnaire

A web-based questionnaire was designed and disseminated to NECA’s electrical contractors with the objective of identifying the level of their prefabrication operations, firm business attributes, and external industry parameters. The questionnaire included 26 questions, including the following that were utilized in this study:

1) Which of the following percentages represent the prefab facility contribution to the total work volume? (N/A, <5%, 5%-10%, 10%-20%, 20%-40%, >40%)

2) What is the annual volume of your work? (<$5M, $5M-$10M, $10M-$50M, $50M-$100M, $100M-$200M, >$200M)

3) What is the zip code of your FARTHEST project?

4) Which of the following services are provided by your company? (Engineering, BIM, Prefab, Maintenance)

5) Which of the following lean principles do you apply in your operations (either onsite or offsite)? (Last Planner System, Look-ahead schedules, Kanban, Value Stream Mapping, Kaizen, 5 S’s, none.)

6) Do you have a vendor partnership in place? (Yes, No.)

7) Which of the following value-added services have you obtained from your vendor(s)? (provided 11 possible services, like Managing material/tools inventory, Using vendor warehouse to store in-transit assemblies/material deliveries, material Packaging/kitting, and others)

8) How do you classify your vendor/distributor? (Local 1 state, Regional 4 states, National 10 states)

9) How frequent did you have your vendor involved early in an Integrated Project Delivery (IPD) setting? (>50%, 30%-50%, 10%-30%, <10%, Never)

10) Select from the following list the manufacturer’s services/programs that your firm used before, if any. (Training workshops, Products customization, Custom Packaging, Materials Logistics.)

11) What is the zip code of your main office?

12) In your opinion, how much flexibility do current electrical specification writers provide for electrical contractors to perform offsite work and achieve construction industrialization? (Very flexible, Flexible, No effect, Inflexible, Very inflexible)

13) How much resistance did/would your company experience with IBEW local for offsite work in your current/future prefab facility? (High resistance, Moderate resistance, Neutral, Encouraging, Very encouraging)

14) How much resistance did/would your company experience with IBEW local for outsourcing prefab work to either vendors or manufacturers? (same answer options of question 13)

The first question was used to identify the existence and size of the electrical contractor prefabrication operations. The second to the tenth questions were designed to collect firm-related business information related to the geographic spread of the company, type of services, adoption of lean principles, and supply chain relations with vendors and manufacturers. The last four questions (11 to 14) were included to collect relevant external industry-related attributes, such as the contractor location, union resistance to prefabrication, and flexibility of design and code requirements to prefabrication. The zip code is used to retrieve other industry economic data through available federal online databases, as explained later in section 4.2.

After a 5-month period of questionnaire online dissemination, 78 valid responses were received on a voluntary basis from a diverse sample of electrical contractors. The questionnaire was disseminated through NECA’s email list that included 2925 electrical contracting firms. 78 valid responses were
received with a response rate of 2.7%, which is similar to other previous study surveys that are based on voluntary participation (Galloway 2006, Rasdorf et al. 2010). There is no reliable source to identify the total population of electrical contractors and its ratio to the collected sample. As shown in Figure 1, the questionnaire sample is considered to be diverse and representative of the electrical construction industry. First, the sampled contractors are geographically dispersed as the responses were received from 32 states. Second, the sample included electrical contractors of diverse backgrounds in terms of company size (measured in work volume) and amount of prefabrication. For example, 54% of the respondents perform prefabrication with varying capacities (between 5% to 40% of the total work volume), which closely matches a recent industry survey (FMI 2013).

![States of Questionnaire Responses](image)

**Figure 1: Questionnaire Response Sample**

### 4.2 Industry Economic Data

The data of each questionnaire response was complementing by retrieving the values of its location-based industry economic attributes from available online federal databases. As shown in Figure 2, online databases of the U.S. Census Bureau (USCB) and Bureau of Labor Statistics (USBLS) were used to retrieve the local industry economic data of every response in two main steps. First, the zip code value of the response (provided in the eleventh question of the questionnaire) is used to identify the county of the electrical contractor and then its metropolitan area. It is proposed here that the economic metrics of the larger metropolitan areas are more accurate regional indicators of the industry-related determinants of electrical contractor prefabrication feasibility, compared to the localized metrics in the city or county levels. Second, the identified metropolitan area is used to retrieve the following data from the online databases: 1) the unemployment rate from the USBLS local area unemployment statistics (LAUS) database (USBL 2014-a); 2) the number, total annual payroll, and average employees of electrical construction firms in the metropolitan area, which are retrieved from the USCB's County and Metropolitan Areas Business Patterns database (USCB 2014-b); and 3) the number and average hourly wage of electricians in the metropolitan area, which are obtained from USBLS’s Occupational Employment Statistics (OES) database (USBLS 2014-b).

![Diagram of Economic Data](image)

**Figure 2: Complementing EC Survey Data with Local Economic Indicators**
The collected economic data was utilized as indicators of the demand for construction projects, industry competition, and supply of electrical workers. Unemployment rate was proposed as indicator of the economic growth and demand for construction services around electrical contractors. Economic data of electrical contracting firms (number, total payroll and average number of employees) was used to gauge the size and level of competition around the electrical contractor. Finally, electricians' occupational data (number and hourly wage) was used to indicate the supply and demand of electrical construction workforce. All these industry parameters (construction demand, competition, labor availability) were proposed based on the performed qualitative analysis of electrical construction prefabrication and suggestions of the study taskforce.

5 DEVELOPMENT AND VALIDATION OF PREFABRICATION FEASIBILITY BINARY LOGISTIC MODEL

Logistic binary regression analysis was utilized to model the dependency of electrical construction prefabrication feasibility on its firm-related and industry-related determinants. As shown in Equation 1, prefabrication feasibility \( PF \) is modeled as a binary dichotomous variable (Tung 1985, Kleinbaum 1994) that can be one of either values: 1 (true, meaning that prefabrication is a viable operations approach for the electrical contractor) or 0 (false, meaning that there are no enough drivers to justify the feasibility of performing prefabrication operations). The \( PF \) value is determined based on the prefabrication feasibility probability \( p \) that ranges between 0 and 1. As shown in Equation 1, prefabrication feasibility is declared \( PF = 1 \) if \( p \) is less than a threshold value of 0.5 (as suggested by previous studies, Cheung et al. 2010, Moon et al. 2011), and is declared infeasible \( PF = 0 \) if \( p \) is more than or equal to 0.5. As shown in Equation 2, prefabrication feasibility probability \( p \) has an exponential relation with its determinants \( X_1 \) to \( X_n \). A determinate \( X_i \) will be a driver of the prefabrication feasibility (i.e. increasing its probability \( p \)) if its coefficient \( C_i \) is found to be positive. Otherwise, a determinant will be impediment to prefabrication feasibility with a negative coefficient. In order to estimate these coefficients using linear regression techniques, the prefabrication feasibility probability is transformed into its logit value and with a linear relation with its determinants, as shown in Equation 3. The logit function facilitates transforming the prefabrication feasibility probability \( p \) (with exponential values between 0 and 1) into a linear variable that ranges between \(-\infty\) and \(+\infty\) (Kleinbaum 1994).

\[
PF = \begin{cases} 
0 & \text{if } p < 0.5 \\
1 & \text{if } p \geq 0.5 
\end{cases}
\]

\[
p = \frac{1}{1 + e^{-(C_0 + C_1X_1 + C_2X_2 + \ldots + C_nX_n)}}
\]

\[
\text{logit}(p) = \ln\left(\frac{p}{1-p}\right) = C_0 + C_1X_1 + C_2X_2 + \ldots + C_nX_n
\]

Twenty electrical prefabrication determinants were initially considered in the development of the logistic regression model, based on the performed qualitative analysis and collected data. The initially considered determinants included 11 firm-related variables and 9 industry related variables, which include:

1) Volume of Firm's Annual Work (workVolume, firm-related): this variable represents the EC size that may financially justify owning and running a prefabrication facility, which ranges between 1 (work volume is less than $5M) and 6 (more than $200M).

2) Business Territory Coverage Distance (coverDistance, firm-related): it is calculated as the driving distance between the firm’s main office and farthest project.

3) Engineering/Design Services (engDesign, firm-related): it is a binary variable that refers to the existence of electrical engineering/design capabilities within the company (i.e. 1) or otherwise (i.e. 0).

4) BIM Capabilities (BIM, firm-related): it is a binary variable that can take a value of 1 to refer to the existence of firm's BIM capability, or 0 for otherwise.

5) Level of Lean Operations (lean, firm-related): it represents the number of lean management principles used by the EC. The value of lean level ranges from 0 to 6.
6) **Vendor Partnership Existence** (vendorPartner, firm-related): it is a binary variable that can be 1 when a vendor partnership exists; or 0 otherwise.

7) **Strength of Vendor Relationship** (vendorRel, firm-related): it refers to the number of value-added services offered by the vendor to the electrical contractor, which can range between 0 and 11.

8) **Existence of Material Blanket Prices** (blanketPrice, firm-related): it is a binary variable to indicate the existence of material blanket prices (i.e., its value equals 1) or none (i.e., 0).

9) **Vendor Size** (vendorSize, firm-related), it is modeled to take three values: 1 for local vendors, 2 for regional, and 3 for national.

10) **Vendor Early Involvement** (vendorEarly, firm-related): it ranges from 0 to 4, where 0 refers to no involvement and 4 refers to vendor’s early involvement in more than 50% of the projects.

11) **Strength of Manufacturer Relation** (ManufRel, firm-related): it refers to the number of services and programs offered by the manufacturer to the electrical contractor, which can range between 0 and 4.

12) **Prefabrication Flexibility of Electrical Specifications** (specsFlex, industry-related): it ranges between -2 and +2, where the lowest value (-2) refers to the most inflexibility of electrical specification writers to prefabrication changes.

13) **Metropolitan Unemployment** (unemploy, industry-related): it is the ratio of unemployed workforce across all industries, which is utilized as an indicator of the overall economic progress of the metropolitan area where the electrical contractor is located.

14) **Annual Payroll of Electrical Contracting Firms** (payroll, industry-related): it is used to indicate the volume of the electrical contracting industry (in $1,000) in the local metropolitan area.

15) **Number of Electrical Contracting Firms** (nFirms, industry-related): it is utilized to indicate the volume and competition level of the local electrical contracting industry.

16) **Average Number of Employees per Firm** (nEmploy, industry-related): it is used to indicate the average size of electrical companies and competition in the local metropolitan area.

17) **Electricians Employment** (electEmploy, industry-related): it is proposed as an indicator of labor supply and availability in the metropolitan area.

18) **Electricians Average Hourly Wage** (electWage, industry-related): it is utilized to reflect the labor cost as a major driver for prefabrication, per the performed interviews.

19) **Union Acceptance of Prefabrication** (unionPrefab, industry-related): it refers to the electrician union (IBEW) position towards contractors performing offsite work in prefabrication facilities, which ranges between -2 (high resistance) to +2 (very encouraging).

20) **Union Acceptance of Outsourcing** (unionOutsource, industry-related): it refers to the electrician union position towards contractors outsourcing some of the project work to vendors and manufacturers in the form of prefabricated assemblies.

Before performing the logistic regression analysis, the proposed variables were tested for multicollinearity to remove any strongly-correlated variables that may affect the quality of developed predictive model. Multicollinearity in the collected data can be detected considering the following two tests (Pallant 2010): 1) variables are significantly correlated with a Pearson correlation factor (R) more than 0.7; and 2) variables with large Variance Inflation Factor (VIF) more than 5. As such, the Payroll and nFirms variables were found to be a source of multicollinearity in the collected data, as they were significantly correlated (R = 0.981) and they had very high VIF value, 64 for Payroll and 54 for nFirms. Accordingly, the number of variables considered for the regression analysis was reduced to be 18.

The 78 valid responses collected by the questionnaire were divided into two groups (Yiu et al. 2006, Cheung et al. 2010): 1) an estimation data group of 70 responses, which was used to estimate the logistic regression model coefficients; and 2) a validation data group of 8 responses, which was used to test the prediction accuracy of the developed model. IBM SPSS Statistics 22 package was used to apply a forward step-wise binary logistic regression analysis on the estimation data group. As shown in Table 1, only 6 variables were included in the SPSS results with their coefficient values, standard error (S.E.), Wald statistic, and its significance level p-value. The two variables with the strongest significance (i.e., smallest significance p-value) in the model were found to be BIM and unionOutsource. The other variables had a medium significance of p-values between 0.05 and 0.07. In general, the model fits the collected data with an acceptable quality that is illustrated by its very low P-value, high pseudo Nagelkerke R-squares, and high correct classification rate (CCR%). Figure 3 illustrates the histogram of the correct/incorrect classifications of prefabrication feasibility (showed as 1) and infeasibility (shown as 0), as
calculated by the developed model. Equations 4 and 5 illustrate the prefabrication feasibility probability \( p \) in its final form.

\[
[4] \quad p = \frac{1}{1 + e^{-\logit(p)}}
\]

\[
[5] \quad \logit(p) = -6.821 + 6.5916 \cdot (BIM) + 2.577 \cdot (vendorPartner) - 0.784 \cdot (unemploy) + 0.3914 \cdot (nEmploy) + 0.2407 \cdot (electWage) + 1.9687 \cdot (unionOutsouce) +
\]

The prediction accuracy of the developed modeled was validated by calculating the electrical prefabrication feasibility values of the validation group data and comparing them to the observed values. Table 2 lists the validation values of the model variables, observed prefabrication state, calculated prefabrication probability and resulting prefabrication feasibility for the 8 cases of the validation data group. The shown medium prediction accuracy (CCR\% = 75\%) is considered within the acceptable range of 50\% - 100\% correct classifications (Pampel 2000). The validity and prediction accuracy of the model can be improved by collecting a bigger sample of electrical contractors, which is planned in future research studies.

6 SENSITIVITY ANALYSIS

The behavior of the developed model was analyzed to obtain more insights about electrical construction prefabrication beyond the collected cases and data. As shown in Figure 4, two-way sensitivity analyses (Clemen and Reilly 2001, pp. 174) were performed to study the impact magnitude of the following example variables on the prefabrication feasibility prediction output of the proposed model: BIM, vendorPartner, nEmploy, and electWage. The other variables are assumed to take the value of a base case, which is modeled as the average value of the observed variables. The sensitivity analyses provided the following useful insights about electrical prefabrication feasibility:

1) Prefabrication feasibility increases with the escalation of the average local electrician wage (electWage) as indication of scarce labor supply and the need to deliver the projects with less labor hours using offsite prefabrication;

2) Prefabrication feasibility increases with the increase of local competition in the form of average employees per electrical construction companies (nEmploy), due the need to outperform the competitors in terms of project cost and time savings achieved by prefabrication; and

3) The contribution of BIM capabilities of increasing the feasibility of electrical prefabrication operation (i.e., the difference between cases A and C) is bigger than the contribution of having a vendor partnership (i.e., the difference between cases A and B).

Figure 4: Sensitivity Analyses of the Developed Model for four of its Variables
7 CONCLUSION AND FUTURE RESEARCH

This paper presents the development of a new predictive model of the prefabrication feasibility for electrical contractors. The development of the model was accomplished through four main phases. First, a qualitative analysis of electrical construction prefabrication is performed using interviews, site visit, and case studies to develop a better understanding of the drivers and impediments of electrical prefabrication. Second, quantitative data of the proposed prefabrication determinants were collected using a web-based questionnaire and online federal economic and occupation databases. Third, a binary logistic regression model was developed and validated using the data collected of a sample of electrical contractors. The logistic regression is designed to estimate the probability of prefabrication feasibility for electrical contractors, based on six identified significant determinants: BIM, existence of vendor partnership, local unemployment rate, average number of employees in local electrical construction companies (i.e. local competition), the local hourly pay rate of electricians, and the acceptance/resistance of electrical local union to outsourcing prefabrication services. Fourth, two-way sensitivity analyses were performed to analyze the impact of some of the identified determinants on the prediction outcome of the developed model.

The developed model should prove useful to both academic researchers and electrical construction professionals. The model supports the previous research on construction prefabrication in general and electrical prefabrication in specific by assessing the dependence of construction prefabrication feasibility on the contractor’s internal and external parameters. In addition, the developed model provides a data-driven tool to assess the feasibility of adopting prefabrication operations in comparison to their peers in the industry.

This research can be expanded in future studies to: 1) collected a larger data sample of electrical contractors to further validate and improve the prediction accuracy of the developed model; 2) apply the same methodology to other building construction trades (like mechanical, plumping, etc.) and analyze their differences and unique attributes; and 3) develop a web-based tool that facilitates the dissemination and use of the developed model by both academics and practitioners.

³ dsalem@purdue.edu

Abstract: The Sustainable buildings main objectives are to reduce, or avoid, depletion of resources like energy, water, and materials; prevent environmental degradation caused by facilities during the life cycle of the building. Lighting is one of the major energy consumption in institutional buildings. At 2012, the commercial sector, which includes commercial and institutional buildings, and Public Street and highway lighting, consumed about 274 billion kWh for lighting or about 7 % of the USA consumption. Most of the research works have focused predominantly on the environmental and physical factors and have neglected the daily activities of the occupants. This study examines the effects of environmental, physical, and daily activities on occupants’ performance in the institutional buildings as well as develops a model to predict the occupants’ performance using Regression analysis technique. The data was collected from the institutional buildings occupants and building facility experts using questionnaire. The model has been validated with 92 % Average Validity Percent (AVP) and R square of 0.83 which is a satisfactory result. The developed research /model benefits both architects and practitioners to choose the appropriate workplace design due to the occupants’ preferences to enhance performance, and energy efficiency.

1 INTRODUCTION

Buildings are one of the major energy consumers in the U.S. as shown in Fig 1. Both commercial and residential buildings account for 42% of the national U.S. energy consumption. The majority of commercial buildings energy consumption is attributed to lighting (25%), space heating and cooling (25%), and ventilation (7%) (Azar and Menassa 2011a).

Lighting and HVAC energy used in buildings are considered the main consumers of the total buildings energy consumption. Nearly lighting energy used is responsible for 23%, Heating, ventilation and cooling accounting for 38% (Guo et al. 2010). In a recent study, in US commercial building, 25-40% of the total electricity energy consumption is from electrical lighting (Ihm et. al., 2009).
Building professionals’ significant role is how to reduce energy consumption as well as considerably maintain comfort to the occupants. Artificial lighting systems are considered as a major consumer of energy in buildings and contribute significantly to building cooling load. Daylighting has two fold; contributing in determine the overall environmental quality in buildings as well as saving energy (Alashwal and Budaiwi 2011). Before 1940s, daylighting was considered the main light source in buildings design. Recently, in sustainable buildings, daylighting is considered as energy and environmental aspect (Edwards and Torcellini 2002). In case of office lighting, the switching patterns along with the outside conditions are at the core of investigation from the occupants’ behavior point of view. One of the studies has culminated into the fact that as much as 40% energy conservation can be realized if natural light is relied upon compared to the artificial one (Bourgeois, Reinhart, and Macdonald 2006).

Therefore, the scope of the present study is to investigate the lighting preferences in commercial buildings with focus on the institutional buildings and develop a framework for predicting occupant’s performance.

2 RESEARCH OBJECTIVES

The objectives of the present study is to build a sustainable occupant’s performance based model for institutional buildings which can be summarized as follows:

i. Investigate and identify the factors affect occupants usage of lighting.

ii. Data collection from a real workplace

iii. Determine the significant factors that mostly contribute to the Lighting intensity in the workplace.

iv. Determine the factors that affect the occupants’ performance

v. Develop a model / framework based on these factors.

vi. Validate the developed model / framework

3 BACKGROUND

The most significant factors that influence the energy and indoor environmental performances of buildings are outdoor/indoor climate, building characteristics, and occupant behavior. The most important factor is human behavior, followed by building design. Indeed, there is often an obvious discrepancy between real
total energy use in buildings and what is predicted. The reasons for this gap are a general need to understand the role of human behavior within the buildings (Fabi et al. 2011).

Several studies (Carrico and Riemer 2011, Dietz et al. 2009, Henryson, Håkansson, and Pyrko 2000) have taken two different approaches can typically be used to reduce buildings’ energy use: First, the technological approach deals with more energy efficient building systems and equipment. Second, the behavioral approach focuses on understanding building occupant presence and behavior to measure actual energy consumption and develop best practices to encourage conservation (Azar and Menassa 2011b).

3.1 Occupants behavior

Occupants behavior definition is; “the result of a continuous combination of several factors crossing different disciplines.” The factors effecting occupant interactions with building control systems are classified into external and internal. The external factors which related to the building science area (e.g. outdoor and indoor temperature) can be categorized in two categories: the physical environment and the context. The internal drivers concern the social science area can be defined into three categories: physiological, social and psychological.

These External and Internal factors influence occupant behavior, defined as “Drivers.” Drivers can be defined as: “the reasons leading to a reaction in the building occupant and suggesting him or her to act.

3.2 Occupants interactions with indoor environmental controls

Several studies have investigated occupants’ preferences of the windows in their workplace; window size, position in the walls, and its degree of transparency (Galasiu and Veitch 2006). Many studies investigate the occupants interact with the lighting system without providing the occupants satisfaction or performance in the workplace.

These models predict how occupants interact to the lighting system depending on the lighting intensity, the occupant’s schedules and the surrounded factors to predict the occupant’s use of lighting, and therefore predict the lighting energy consumption as a result (Reinhart 2004; Bourgeois et. al. 2006).

It can be deduced here that the previous studies investigated the occupants’ behavior inside the workplace and the interactions with the environment; otherwise, the impact of the interactions on the consumption. These studies however seem to have overlooked the effect on lighting preferences in the workplace due to the difference in environmental, physical, occupants activities and the policies on the occupant performance.

To that effect, this study proposes the occupants’ preferences in the commercial building regarding to the lighting in the workplace has a significant effect on the occupants’ performance.

4 ACTORS AFFECT OCCUPANTS USAGE OF LIGHTING INCORPORATED IN THE CURRENT RESEARCH

Based on the above review of literature and focusing on the institutional buildings, the lighting preferences in institutional buildings that affect the lighting intensity in the workplaces are identified and selected as shown in Table 1. These factors are considered in the present study. Fourteen factors are incorporated in this research, which represents the environmental, physical, activities, and policies factors. The factors that influence occupants’ usage of lighting are hard to quantify and thus a qualitative approach is followed.
The factors selected to be incorporated in Regression analysis model are clustered into four main categories and their factors, as shown in Figure 3. The four main categories include environmental, physical, users and Tasks lighting required. Each category includes several factors.

5 RESEARCH METHODOLOGY

To achieve the objectives of the present research, several steps are accomplished as shown in the schematic diagram Figure 4. The proposed framework for this project consists of 5 main steps. It starts with a comprehensive literature followed by data collection, which in itself consists of two parts studying the lighting factors that affecting the occupants usage and a semi structured questionnaire and open ended interviews is adopted in order to identify the occupants’ artificial lighting preferences due to environmental, physical and activities. A Regression Analysis model is developed using model information data which is then underwent a verification process. The next part of the research methodology is to develop a daylighting usage scale which will guide the architects to best design their office buildings. The model is used to assess daylighting efficiency in private and two-person offices.
Then develop lighting behavioral modeling using Regression Analysis. The last step is the conclusion and future research.

![Research methodology]
6 DATA COLLECTION

After identifying the lighting preferences factors that may affect the occupants performance, a questionnaire was prepared to assess the effect of these factors on occupants performance. The data is collected via a questionnaire collected form 87 occupants in the institutional buildings at Purdue University. The questionnaire was designed to identify factors that affect lighting intensity in the workplace and then to predict the occupants performance in an abstract approach. It had two parts where the first part (1) was asking the occupants how strongly the factors contributes to the daylighting intensity as shown in Figure 5. Part (2) was asking the occupants using a specified 5 point subjective scale to represent their performance. The data collected is the weights of various factors to be incorporated in the model and the performance of each factor.

This paper presents findings from a web-based survey on the current use of in building design. The survey was administered from October 2014 to December 2014. Two hundred and thirty four individuals from 5 institutional buildings at Purdue University completed the survey. The respondents are Faculty, staff and students have an office at Purdue University. They worked in offices with or without windows in the workplace.

Among those participants 134 about 59% who have windows in their workplace. The rest of them 92 respondents has no window and skipped from the questionnaire. The total respondents who complete the questionnaire are 87 respondents about 37% of the total respondents. See Fig 5 as sample of the questionnaire and Fig 6 the Questionnaire statistics.

7 DEVELOPMENT OF LIGHTING PREFERENCES MODELS

Regression analysis is used to develop the prediction model for the occupants' performance in the workplace regarding to the lighting preferences. The model is developed based on the previously specified/selected lighting preferences. It is developed in order to represent the collected data.

7.1 Regression-Based Occupants Performance Model

For the implementation of the model MINITAB is utilized to develop a regression model. MINITAB is a general statistical technique that has capabilities of basic and advanced data analysis in a wide range, such as analysis of variance, basic statistics, correlation and regression, and multivariate analysis (Minitab 2006). To select the best number of variables, we used step-wise regression analysis in the model.

MINITAB is utilized to develop a regression model for occupants' performance as a function of the previously selected lighting factors in the commercial buildings. Four selection criteria are used to distinguish between different proposed models. These criteria are R-square, adjusted R-square, mean square error (S or MSE), and Mallow's Cp. The best model that can represent the collected data set is selected according to the largest R-square and adjusted R-square, the minimum mean square error (MSE), and the closest Cp to the number of independent variables. Therefore, the selected model has the highest R2 of 0.85 and adjust R2 of 0.83, the Cp value of 8.2 close to 9 (i.e. number of variables), and the minimum MSE value of 2.2524. The best obtained formula describing the organization performance as a function of CSFs is given by Equation 1.

\[ Y = 5.7 + 0.326 x_1 + 0.083 x_2 - 0.056 x_3 - 0.179 x_4 - 0.023 x_5 - 0.124 x_6 - 0.034 x_7 + 0.507 x_8 + 0.510 x_9 + 0.394 x_{10} - 0.125 x_{11} - 0.090 x_{12} - 0.120 x_{13} + 0.347 x_{14} + 0.173 x_{15} + 0.350 x_{16} \]

The dependent variable (Y) denotes the occupants' performance expressed as a percentage and Xs denote the lighting factors that shown in Table 2 and the subscript refers to their numbers in the table. For example, X5 denotes number 5 which is “Window size to Wall Ratio.” The built model is checked for its statistical validity. The main diagnostics in this regard are R square (coefficient of multiple determination), F-test, and t-test for model coefficients.

7.2 Validation of Developed Occupants Performance Model

The validation process is to guarantee that the developed models best fit the available data. In order to determine the efficiency of the developed model to derive real world results, the model is tested statistically, logically, and practically. The collected data are divided into two data sets, model building (80%) and validation (20%). The validation data set, that is 20%, selected randomly and kept away while modeling the regression analysis. After developing the regression analysis model, the validation data set is used to test the capability of the developed lighting factors model to predict the occupant’s performance. The developed model is validated by comparing the predicted results with the actual values of the validation data set.

\[ AIP = \frac{1}{n} \sum_{i=1}^{n} 1 - I \left( \frac{E_i}{C_i} \right) \]

\[ AVP = 100 - AIP \]

Where AIP is the Average Invalidity Percent, AVP is the Average Validity Percent, \(E_i\) is the \(i^{th}\) predicted value, \(C_i\) is the \(i^{th}\) actual value, and \(n\) is the number of observations.

Equation 2 expresses the average invalidity, which indicates the prediction error, while Equation 3 presents the average validity percent. The AVP values for the developed performance prediction models regression is 92.55%. These values indicate that the obtained results are satisfactory.

8 CONCLUSIONS AND FUTURE RESEARCH

Lighting energy consumption is considered a highly energy consumer in commercial buildings. Achieving higher energy efficiency at commercial buildings demands considering the lighting preferences to the users and their performance in their workplace. It is difficult to measure the occupant’s performance due to their diversity and complexity. The proposed framework is an effective methodology for developing an institutional building sustainable occupant’s performance based model. This model will help the decision
makers and the designers at different levels to design the work places that accomplish the required levels of visual comfort for the users, while saving energy used in lighting. A multi-dimensional study on performance of the occupants in the commercial buildings has been conducted using 87 surveys obtained from intuitional buildings. The obtained data are analyzed using regression-based performance model and predict the performance of occupants. The developed model benefit both architects and practitioners to choose the appropriate workplace design due to the occupants’ preferences to enhance performance, and energy efficiency. It also provide energy modeling professionals with the various essential factors that affect occupants performance and how it can be assessed/predicted, i.e. performance assessment/prediction tool. The model has been validated with 92 % Average Validity Percent (AVP) and R square of 0.83 that is a satisfactory result. The research study shows a room for improvement for future study like modeling and simulate the occupant’s interaction.

PRINCIPLES, CHARACTERISTICS, AND METHODOLOGY TO DEVELOP A PROJECT MANAGEMENT ASSESSMENT TOOL AT THE CONSTRUCTION PROJECT LEVEL

Antonio G. Sanjuan\textsuperscript{1,3}, Thomas Froese\textsuperscript{2}
\textsuperscript{1} British Columbia Institute of Technology, Canada
\textsuperscript{2} University of British Columbia, Canada
\textsuperscript{3} antonio_sanjuan@bcit.ca

Abstract: This paper describes the principles, characteristics, and methodology to develop a conceptual approach and a preliminary project management assessment tool based on an integrated framework of international project management (PM) standards and construction projects success factors. Previous PM assessment tools have been designed to measure organizations’ PM practices, and individuals' knowledge of PM. After completing these assessment tools, individuals or organizations would identify their strengths, weaknesses and training needs. These tools, though powerful, do not assess what is actually implemented on a specific project. The intention is to develop an assessment tool that diagnoses an organization and an individual project manager by what was actually implemented in a specific project. By assessing what was actually implemented in a project and comparing this with the project results, it could be possible determine the strengths, weaknesses, and value of PM in a construction organization, as well as to benchmark PM best practices. Three types of questions will be used: context questions, PM implementation questions, and project results questions. Each question will have a reference to one or more of the international PM standards. Each question will evaluate the quality or the frequency of the PM implementation, which could be a competence, knowledge, tool, technique, process, or practice. This paper discusses the question design methodology for developing the tool using the resource management knowledge area as an example. Finally, the assessment tool is tested with 18 construction projects executed by different organizations.

INTRODUCTION

Over several decades, project management (PM) communities of practice have put substantial effort into defining good project practice, and these practices are codified in a number of PM standards. The ability to assess the PM practices of a project organization with respect to these best practices would provide a valuable tool for improving PM performance and benchmarking PM best practices. Furthermore, a comparison of the assessed PM levels with assessed project success can provide insight into the quantitative value that PM brings to construction projects.

The goal of this research is to develop a PM assessment tool that can benchmark PM best practices, as well as to diagnose the strengths and weaknesses of an organization's PM implementation, assess levels of project success, and explore the relationship between PM practices and project success in order to evaluate the PM value. A feature that differentiates this research from previous work is the focus on assessing PM practices at the level of individual projects, rather than assessing practices at the level of a company or of an individual manager. This paper will focus on the principles, characteristics, and methodology to develop the PM assessment tool using the resource management area as an example. In
order to design the questions of the assessment tool, it is important to determine the methodological process, which includes a planning, preparation, and testing phase.

The planning phase consists of developing an integrated framework of global standards and a ranking of critical construction success factors. The preparation phase consists of structuring and elaborating each question of the assessment tool. The questions will be based on specific PM standards and/or project success factors. The questions are intended to determine the strengths, weaknesses, and value of PM implementation. Each of the PM implementations defined in the PM standards does not contribute equally to project success. Therefore, some weighting technique should be applied to aggregate the PM assessment results into higher-level, overall PM scores. The weighting scale will be based on an average of the number of citations of the success factors in management journals and the number of projects involved in the empirical data collected either from surveys or case studies in the literature review.

Finally, this paper will test the questions included in the resource management area with 18 construction projects from different organizations and determine the correlation coefficients between the resource management implementation and project results.

1 EXISTING PROJECT MANAGEMENT ASSESSMENT TOOLS

Previous PM assessment tools have been designed to measure organizations’ PM practices, and individuals’ knowledge of PM. The Boston University Corporate Education Center (BUCEC, bucec.com), the Atlantic Management Center Inc. (AMCI, amciweb.com), the Business Improvement Architects (BIA, bia.ca), the Enterprise Information (EII, eiicorp.com), Harold Kerzner’s PM maturity model, and the PM/ROI Assessment by Ibbs Consulting are assessment tools designed to measure PM technical competencies, personal competencies, leadership and business competencies, or PM maturity levels. After completing these assessment tools, individuals or organizations would identify their strengths, weaknesses and training needs. These tools, although very powerful and reputable sources of organizational PM and individual knowledge assessment, do not assess what is actually implemented on a specific project.

The intention is to develop an assessment tool that diagnoses an organization and an individual project manager by what was actually implemented in a specific project. By assessing what was actually implemented on a specific project and comparing this with the project results, it may be possible to determine the strengths and weaknesses of the PM in a construction organization, as well as to explore the value of PM.

2 PROJECT MANAGEMENT STANDARDS

There are many standards for PM practices: A Guide to the Project Management Body of Knowledge by the Project Management Institute, the Capability Maturity Model, Prince2, ISO 9000, the standards by the International Project Management Association (ICB), the Project and Program Management (P2M) by the Engineering Advancement Association of Japan, and the C-PMBOK by the Chinese project management conference among others. This study will use an integrated framework from four international PM standards: A Guide to the Project Management Body of Knowledge (PMBOK) from the Project Management Institute, the International Project Management Association Competence Baseline Version 3.0 (ICB), PRINCE2 by the Government of UK, and the ISO 9000 family of standards. It is important to note that PRINCE2 is a methodology but it has all the components of a standard. Mapping these four global standards gives validity to the process of developing the PM assessment tool.
3 PROJECT SUCCESS FACTORS

Project success factors were identified to provide a source for the weighting scale of the questions of the assessment tool. Project success factors from previous research also give validity to the initial PM assessment tool questions.

Projects are considered successful when they meet stakeholders’ needs and expectations. Most of the time, the stakeholder’s needs and expectations are met when the project is on time, on budget and within the scope and quality planned. However, project success criteria are subjective, and most of the time, are determined by the stakeholders. There is a clear difference between project success and PM success (Wit, 1998).

In a recent study, a set of metrics were used to try to determine the link between PM practices and project success. The outcome of this study was that the better the PM practices, the better the project results, “the results suggest that the PM practices that make a difference may not be the most frequently used” (Papke-Shields, Beise, & Quan, 2010).

For the purpose of this study, critical success factors has been selected from construction projects only. So far, there has been identified 60 research papers from different scientific journals stating the number of construction projects and the critical success factors identified. Table 1 provides an example of these success factors, listing just the top ten ranked factors, based on the number of reference that identified the factor and the total number of project cases studied in identifying the factor. Each of these success factors, as well as the PM standards, will be related to one or more of the questions of the initial PM assessment tool.

4 ASSESSMENT TOOL METHODOLOGY

In order to design the questions of the PM assessment tool, it is important to determine the methodological process, as well as some principles and assessment tool characteristics. The process of developing the PM assessment tool includes a planning phase, a preparation phase, and a testing phase.

The planning phase consists of developing an integrated framework of global standards and the project success factors literature. The preparation phase consists of structuring and elaborating each question of the assessment tool. The questions will be based on specific PM standards and/or project success factors. This link between the questions of the assessment tool and the PM standards and success factors will give face validity to the PM assessment tool. The questions are intended to determine
strengths, weaknesses, and the value of PM, as well as to benchmark PM best practices. Thus, the questions are divided in three categories; one set of questions related to the project context, another set of questions related to the actual PM implementation in reference to one finished project, and a third set of questions related to the project results.

The testing phase consists of using a preliminary PM assessment tool to test the reliability and validity of the PM assessment tool on several pilot cases. After pilot testing and refinement, the PM assessment tool will be ready for a full scale survey.

5 DEVELOPING AN INTEGRATED FRAMEWORK OF INTERNATIONAL PROJECT MANAGEMENT STANDARDS

This study developed an integrated framework from four international PM standards: A Guide to the Project Management Body of Knowledge (PMBOK) by the Project Management Institute (PMI), the International Project Management Association Competence Baseline Version 3.0 (ICB3), PRINCE2 by the Government of UK, and the ISO 9001:2008 standard.

This framework is organized around the same structure of the PMBOK, but it consists of 11 management areas and 5 process groups. All four international standards include the following PM knowledge areas in different forms or wording: integration, scope, time, cost, quality, human resources, communication and information, risk, and procurement. For the purpose of this study and to adapt the framework to construction projects, the following two PM areas have been added: context, and safety and environmental management. Project context, and safety and environmental management are missing in the PMBOK, or included in a different set of standards. However, these management areas are specifically included in the ICB3 as contextual competences. The five process groups are clearly identified in the PMBOK and PRINCE2: initiating, planning, executing, monitoring and controlling, and closing.

The most comprehensive and elaborated standard is the PMBOK by the PMI, so some knowledge management areas such as cost, risk and procurement contain processes that are taken from the PMBOK as is. The other international standards mention these and other knowledge management areas and process groups in general term and definitions, so mappings to these standards have been made. For instance, project human resource management is also called Resources in ICB3 and Organization in PRINCE2, Table 2.

6 DESIGN OF QUESTIONS USING THE RESOURCE MANAGEMENT KNOWLEDGE AREA

The four global standards emphasize the process of planning, selecting, training, and managing the project team. Table 2 shows a mapping of the four global standards for the resource management area.

Project human resource management for the PMBOK standard is the process of organizing, managing, and leading the project team to achieve a goal. This process includes planning human resources, acquiring the project team, developing the project team, and managing the project team. The human resource plan includes the identification of roles and responsibilities, the required skills, reporting relationships and the creation of the staffing management plan. It is the most elaborated standard in the matter of human resource management, but also it misses other project resources, behavioural competences, the work environment, and the organization executing the project.

The PRINCE2 methodology defines roles and responsibilities as one of its principles, which relates directly to one of the PRINCE2 themes, the organization. The organization is defined in different levels, from project level to corporate level. The definition of roles and responsibilities in item 5.4 of this standard are very broad and more toward the internal corporate organization, as well as the definitions on the PM team, PRINCE2, item 5.3.2. However, this standard states clearly the importance of training the project team if needed. In this standard or methodology, the team plans (section 7.2.6) is the closest parallel to the human resource plan and is also vaguely defined.
Table 1. Mapping of the Four PM Standards for the Management Area of “Project Human Resource Management” (or “Resources” in ICB and “Organization” in Prince2). Each column represents one of the five PM process groups. Items marked “*” are from the ICB3 standard, those marked with a “+” are from PRINCE2, “#” from ISO9001, and the rest are from PMBOK.

The international standard ICB-3 states and defines resource management, resource competence (section 1.12), as the planning, allocation, optimization, and monitoring and controlling of humans, materials, and equipment resources. In addition, project organization competence, teamwork, and project structures competence are considered part of this management area since they are related to the project environment. In terms of the latent variables of this study, project organization, teamwork, and project structures are part of the project context. Behavioural competences are considered in this area because they are relevant to PM and the project manager. However, the PM assessment tool will not include a question for each behavioral competence element, since the tool will be more focused on technical competences. It will include leadership, creativity, consultation, and ethics as part of the leadership score.

The global standard ISO 9001:2008 mentions the need to ensure the availability of resources and defining responsibilities and authority as part of the management commitment and responsibility. However, it is item 6 of the standard that states clearly resource management, not only to continually improve the management system in place, but also to achieve the satisfaction of the stakeholders by reaching their project requirements. It is a general statement of the resource management process. It does not state or mention a plan, but it includes important elements such as definitions of competence for people executing the work, the training needs, the infrastructure and equipment required, and the work environment.

The questions in the assessment tool and in the resource management knowledge area in particular are designed to address the PM implementation in one project, the context in which the project and the
organization performed during the project life cycle, and the project results. These are called the latent variables.

In addition, there are different types of PM implementation: competence, knowledge, skills, tool, technique, process, and practice. Each question fits one or more than one of these PM implementation according to their definitions (see table 3). Each question has been elaborated based on the best PM practices according to four global PM standards and construction success factors. Each question has a reference to one or more standard (see table 3), or one or more construction success factors (see ranking of construction success factors in table 1).

Finally, each question is designed to evaluate the quality of the PM implementation or the frequency of the PM implementation during the project life cycle, or both of them.

One of the key questions to assess the quality of the resource management process is the presence of the human resource plan. If the plan exists, there may be different levels of implementations from informal to a very formal process. Thus, the question of the assessment tool would be formulated towards how well the human resource plan was implemented in terms of its component elements or processes.

</table>

The next four questions on the resource management area are related to construction experience (owner/developer manager, construction organization, and construction manager). The PMBOK and ICB standard do not mention specifically this element within their standards. PRINCE2 states it in the standard 5.3.2.1 which is referring more towards the PM team structure than to the experience itself. ISO 9001-2008 6.2.1 states the importance of experience in the general definition of human resources, table 3. However, experience is what makes a competent project manager, which is ranked at the top five on critical construction success factors by the number of citation in journal articles. Seven citations with a total of 565 project cases concluded that the project manager competence is key to project success. Table 1 shows the ranking of the construction success factors. The type of answer for these questions are open ended.

The next question of the assessment tool in the resource management area is the level of education of the project manager of the construction organization. This question is related to the project manager knowledge. It is referred in the PMBOK standard on item 1.7.1 and 9.1.3.1 as knowledge and competence. ICB3 refers to the knowledge and the professional PM in item 1.2. The only standard that refers to the competence on the basis of the appropriate education is ISO 9001:2008, 6.2.1, see Table 3. In addition, the top construction success factor according to number of citations from journals and 661 case studies within those citations is multidisciplinary, competent project team, table 1.
The next nine questions in the resource management area are related to the leadership skills and personality types. It is difficult to fully assess the leadership and personality type of a project manager. These two interpersonal skills could easily be two separate assessment tools themselves. The leadership skills is assessed based on five questions. One is a self-assessment of the leadership by the tool user, how would you rate your leadership skills from excellent to poor. The other ones are based on the very definition of the leadership skills by the PMBOK “Leadership is the ability to get things done through others by establishing and maintaining the vision, strategy, and communication; fostering trust and team building; influencing, mentoring, and monitoring; and evaluating the performance of the team and the project.” Table 3 shows the references to their specific standards on questions 61 to 65.

The personality type is based on the Myers and Briggs type indicator assessment. It is a summary of the Myers and Briggs assessment. The first question is related to the individual preference for energy (introvert or extrovert), the second is related to the individual preference for information gathering (sensing or intuitive), the third one is about the individual preference for decision making (thinking or feeling), and the last one is related to the individual preference for lifestyle (judging or perceiving). The PMBOK standard mentions personality types on the required skills as part of the human resource plan, 9.1.3.1 and appendix X3 (interpersonal skills). PRINCE2 methodology states personality types in 5.3.3.1. Research suggest that a large majority of all managers have personality either Introvert-Sensing-Thinking-Judging or Extrovert-Sensing-Thinking-Judging, Noe et al.2003. Table 3 shows the references to their specific standards on questions 66a to 66d.

The last six questions in the resource management area are related to acquiring and developing the project team. The questions are intended to triangulate or corroborate the existence of the necessary project team, question 71. So, if there is an adequate project team then the hours of work should be around the normal working hours (question 67), working in one project most of the time (question 68), with a performance, recognition and reward system (questions 69 and 72) that allows the organization to reduce the employees’ turnovers. See table 3 for the questions with reference to their specific standards, their PM implementation types, and their quality of frequency characteristics. Acquiring the project team could also be extended to the proper selection of the subcontractors, which is ranked as the fourth construction success factor; formal and structured selection of subcontractors, table 1.

7 SCORING CRITERIA

After elaborating the questions, the next step is the scoring criteria for each question. There were several calibration processes in order to weight the score of each question; from assigning 1 point for each question to separating the questions according to the latent variables in the following groups: context questions, PM implementation questions, and project results questions. Finally, a scoring criteria based on the construction success factors was chosen. Questions within the top ranking of construction success factors were given more weight. For instance, resource management questions related to roles and responsibilities, the staffing management plan, experience, leadership, knowledge related to construction, acquiring the necessary project team, performance assessment plan are being scored with 10 points, as these questions are closely related to the following construction success factors: multidisciplinary project team(1), formal structured selection of subcontractors (4), competent project manager (5), project team commitment (7), client competencies (9), leadership (26), employee enhancement (38), and availability of resources (52).

The total scoring for resource management area on the planning group is 132 points in PM implementation, for the executing process group is 13 points for PM implementation and 14 for project results, and finally the monitoring and controlling process group has a maximum score of 4 points for PM implementation. In total, the resource management area account for 149 points out of 591 (25.2%) of the total possible PM implementation, as well as 14 points out of 220 (6.3%) of the total possible project results. The low percentage in project results in this area can be explained in the sense that this management area can be considered more of an input than a project result, and also because the project results are measured and located more in other management areas such as the project time, cost, scope, and quality.
8 TESTING PHASE AND ANALYSIS

The assessment tool has been tested with 18 construction projects from different organizations, with different types of projects, sizes, and context. In order to test and analyze the results in the resource management area, the projects are separated according to these differences. At the end, the results are compared among all projects to draw some general conclusions.

8.1 Residential Projects from the Same Organization

The first selection are high-rise residential projects from the same organization. The projects range from $19 million to $70 million, with an average of $44 million Canadian dollars. All these project are located and built in lower mainland BC. The project managers taking the assessment tool rated these project with complexity level 3 or 4, where 5 is very complex (e.g. demanding stakeholders, complex design, etc.) and 1 is very simple project (e.g. similar to previous type of project). Table 4 shows the resource management implementation for the specific project in HR column, the total PM implementation in all management areas, and the total project results.

<table>
<thead>
<tr>
<th>Project ID</th>
<th>Human Resource Management Score</th>
<th>Overall PM Score</th>
<th>Project Result Score</th>
</tr>
</thead>
<tbody>
<tr>
<td>CR1</td>

<td>297</td>
<td>136</td>
</tr>
<tr>
<td>CR4</td>
<td>99</td>
<td>442</td>
<td>149</td>
</tr>
</tbody>
</table>

The correlation coefficient is 0.878 between human resource management implementation and project results. The correlation coefficient is 0.812 between human resource management implementation and total PM implementation. Finally, the correlation coefficient is 0.704 between PM implementation and total project results. Although these coefficients are lower than the critical values of the Pearson correlation coefficient for n=4, r = 0.95, the results show that there is a strong association between the three data sets. The better the resource management implementation, the better the project results in terms of time, cost, quality, and customer satisfaction. In addition, the better the resource management area implementation, the better the overall project PM implementation.

8.2 Institutional Projects from the Same Organization

The second selection consists of 11 institutional projects from the same organization. The projects range from $3 million to $20 million, with an average of $7 million. All project are located in different islands of British Columbia. Most projects are new schools or additions to existing schools for different First Nation communities. The project level complexity range from 3 to 5. For these projects, the correlation coefficient is 0.012 between resource management implementation and project results. The correlation coefficient is -0.013 between resource management implementation and total PM implementation. These two correlation coefficients show that there is no correlation between the two data sets. Interestingly, there is a statistical correlation between PM implementation and total project results for n= 11 and the Pearson correlation coefficient r = 0.602. The correlation coefficient is 0.739 between PM implementation and total project results.

8.3 All Projects Combined

The remaining three project are a $1.6 billion highway, a $32.5-million high-rise residential, and a $4.4-million institutional, all of them from different organizations. In this particular situation, n=18, the Pearson correlation coefficient is r = 0.468. There is a coefficient correlation of 0.280 between resource management and total project results, so there is no statistical correlation. There is a coefficient correlation of 0.167 between resource management area and the total PM implementation including all
management areas, so there is no statistical correlation between these two data set as well. Figure 1 shows the trend line, the equation that relates the two variables, and the R-squared value.

![Resource Management Implementation vs. Project Results](image.png)

Figure 1. Resource Management Implementation vs. Project Results

9 CONCLUSIONS

This paper explains the process, principles, and methodology to build the assessment tool using the resource management area as a demonstration. The questions are divided in three groups: context, implementation, and results, which are the latent variables. The questions are based on a finished project and are oriented to test the quality or frequency of the PM implementation, which could be a competence, knowledge, skill, tool, technique, process or practice. Some of these PM implementation may involve more than one of these elements.

The PM assessment tool was tested with 18 construction projects. For analysis purpose, the cases were separated based on the type of project and the organization. At the end the cases are combined to analyze the overall statistical correlation between the variables and data set in question.

The results and analysis show that there is a strong association between resource management implementation and project results for the four high-rise residential projects. The better the resource management implementation, the better the overall PM implementation and project results. Furthermore, the results for the eleven institutional projects shows that although there is no correlation between resource management and project results, there is a strong statistical correlation between the overall PM implementation and project results. Finally, when all eighteen cases are combined, there is no statistical correlation between resource management implementation and project results.

In conjunction with the other management knowledge areas and process groups as well as using an integrated framework among four global PM standards, a PM assessment tool may be used to determine the strengths, weaknesses, and the value of PM. It can also be used to benchmark PM best practices.

ULTIMATE AND FATIGUE STRENGTH OF GFRP-REINFORCED, FULL-DEPTH, PRECAST BRIDGE DECK PANELS WITH ZIGZAG-SHAPE TRANSVERSE JOINTS FILLED WITH UHPFRC

Mahmoud Sayed-Ahmed¹,² and Khaled Sennah¹
¹ Department of Civil Engineering, Ryerson University, Toronto, Ontario, Canada
² m.sayedahmed@ryerson.ca

Abstract: One of the prefabricated bridge system used to accelerate bridge construction is the precast full-depth deck panel (FDDP) with transverse joint placed over steel or concrete girders. In this system, grouted pockets are provided to accommodate clusters of shear connectors connected to steel or concrete girders. In this research, ultra-high performance fibre-reinforced concrete (UHPFRC) and high-modulus glass fibre reinforced polymer (GFRP) bars are utilized in the closure strip between the adjacent precast FDDPs for enhanced strength and durability. Two actual-size, GFRP-reinforced, precast FDDPs were erected to perform fatigue tests using the footprint of the truck wheel loading specified in the Canadian Highway Bridge Design Code (CHBDC). Each FDDP had 200-mm thickness, 2500-mm width and 3700-mm length in the direction of traffic and rest over braced twin-steel girder system. The transverse closure strip between connected precast FDDPs has a width of 100-mm with zigzag-shape from each side of the joint to increase moment capacity along the interface between the UHPFRC and the precast FDDP along the joint. GFRP bars in the precast FDDPs project into the closure strip with a development length of 175-mm. Two types of fatigue tests were performed, namely: (i) high-cyclic constant amplitude fatigue loading followed by monotonically loading to-collapse; and (ii) low-cyclic accelerated variable amplitude fatigue loading. Overall, the test results demonstrated the excellent fatigue performance of the developed closure strip details. In addition, the ultimate load carrying capacity of the FDDP was far greater than the factored design wheel load specified in CHBDC.

1 INTRODUCTION

Precast full depth deck panels (FDDPs) have recently used in new accelerated bridge construction (ABC) or for the rapid bridge replacement (RBR) of existing deteriorated bridge decks. FDDPs are produced off-site, quickly assembled on-site, reduce construction time, minimize lane closure and are considered to a good solution to minimize traffic disruption (Clumo, 2011). FDDPs are placed side by side as shown in Fig. 1, then the closure strips between them are filled with bonding material. FDDP closure strips should take the advantage of high quality concrete and non-corrosive reinforcement as glass fiber reinforced polymer (GFRP) bars for enhanced strength and durability. GFRP reinforcement is a composite material made of polymer matrix reinforced with fibers. It has high strength-to-weight ratio, is free of corrosion and lasts longer. Although the Canadian Highway Bridge Design Code, CHBDC (CSA, 2006) allows the use of GFRP-reinforced FDDPs in bridge construction, there is no code provisions on the joint details between such precast system. The behaviour of the FDDP monolithic concrete joint (MCJ), also known as moment resisting connection (MRC), accounts for the state of bond of the projected longitudinal bars anchored through the cast-field joints. The Ultra-High Performance Fiber Reinforced Concrete (UHPFRC)
is a relatively new class of cementitious matrix with steel fiber content that has high compressive strength (in order of 140 MPa) and relatively large tensile strength (in order of 8 MPa), with strain hardening behavior in tension that ensure crack opening remain very small (Russell and Graybeal, 2013). The use of UHPFRC as a filling material of the closure strip between connected FDDPs have numerous benefits, including reduction of joint size, improving durability, speed of construction and prolonging usage life.

Fig. 1. Isometric view of a precast full-depth, full width, deck panels placed transversally over girders

Deflection and vibration play an important role on the serviceability of bridges. The current AASHTO-LRFD Bridge Design Specification (AASHTO, 2012) specifies the bridge deflection limits at L/800 for vehicular bridges and L/1000 for pedestrian bridges as optional criteria where L is the span of the structural element. Traditionally bridges are designed using static loads that include the dynamic load allowance (DLA) due to passing trucks at the ultimate, serviceability and fatigue limit states. It is important to examine the structural behaviour of the jointed precast FDDPs under different fatigue loading conditions which lead to progressive, internal and permanent structural changes in the materials. After the crack initiation and propagation, failure is caused by the deterioration of the bond between coarse aggregate, reinforced bars and the binding matrix. Two types of fatigue loading are considered in testing, namely: constant amplitude fatigue loading (CAF) and variable amplitude fatigue loading (VAF). Fatigue loading is known to reduce the life span for the bridge deck (Karunananda et al., 2010). The constant amplitude fatigue (CAF) is the classical method for fatigue analysis of the materials to obtain the three fatigue resistance components and structures, namely: stress-life (S-N) known as Wöhler curve, strain-life (ԑ-N) and fatigue crack growth (FCG). CAF limit is the safe stress level under elastic deformation for design that can take a very large number of cycles, longer than one-million cycles. The variable amplitude fatigue (VAF) limit is based on the same concepts with addition of cycle counting and damage summation due to increasing step loading. However, the resulting stresses are high enough for plastic deformation to occur within the number of cycles very much less than one-million cycles.

The use of the precast FDDPs in bridge construction started in United States in early 1960s, with the purpose to shorten the deck construction in areas with high traffic volumes. The deck-girder system was primarily non-composite, and the panel-to-panel connections exhibit partial failures. By 1974, FDDPs were made composite with the superstructure by extending the steel shear stud into the deck. The spacing of the shear pockets ranged from 457 mm to 610 mm and the number of studs per pocket ranged from 4 to 12. Two sizes of steel studs are typically used, namely: 19 mm and 22 mm. FDDP were supported on girders and secured to it using the shear studs embedded in the shear pockets that are normally filled with non-shrink grout to eliminate stress concentrations in the panels (Badie and Tadros, 2008). The transverse panel-to-panel connection is provided with shear keys to protect adjacent panels from relative vertical movement due to traffic load. This type of joint has two types of forces, namely: (i) vertical shear force between the panel and the field-casted joint; and (ii) bending moment that puts the top half of the joint in compression and the bottom half in tension. The panel-to-panel connection has several
shapes available in the literature including male-female (tongue/groove) shear key. However cracking, spalling and leakage were observed in such joints in practise. Other panel-to-panel connections included female-to-female shear key which comes into bulb shape, and diamond shape. Splicing longitudinal reinforcement was introduced into overlapping U-bars or using HS spirals, or using open or closed steel tubes (PCI, 2011a and 2011b). Grouting materials to fill the shear pockets and transverse joints have common properties as: (i) high strength at young age, (ii) small shrinkage deformation, (iii) superior bonding and (iv) low permeability (Badie et al., 2006). The steel reinforcement lap-splice joints exploit bonding performance with the joint-field materials made of UHPFRC (Hwang and Park, 2014). The direct tension of GFRP bars were pulled out from UHPFRC blocks to determine the development length (Sayed-Ahmed and Sennah, 2014c). This led to developing few precast panel connection details that were considered for qualifying tests. Three developed female-to-female connections for the GFRP-reinforced precast FDDPs with lap-spliced bars were constructed in full scale in the laboratory to examine their strength and serviceability under increasing static loading with the use of normal strength concrete (Sayed-Ahmed and Sennah, 2014a) and high-performance concrete (Sayed-Ahmed and Sennah, 2014b) in the precast deck slabs. This paper reports the experimental program to test one of these developed joints in real-world situation. Two precast FDDPs were constructed over twin-steel girder system, with one of them tested under CAF loading followed by loading it monotonically to-collapse, and the other one was tested under VAF loading directly to-collapse. Test results are analyzed to examine the fatigue performance and the ultimate load carrying capacity of the developed jointed precast slabs.

2 NEW CONNECTION DETAILS

Figure 2 depicts the trapezoidal zigzag-shape panel-to-panel connection with vertical female-to-female shear key. The slab thickness of 200 mm is divided vertically into equally four layers. The clear joint width between the ends of the jointed panels is 100 mm, while the zigzag-shape (i.e. trapezoidal tooth-shape) allows for an extension of the joint width of other 100 mm into the precast panel. So a projecting GFRP bar from the end of one panel at its wide width of the trapezoidal shape will project into the joint with a length of 175 mm in 200 mm joint width in the same bar direction (i.e. 100 into the closure strip and 75 mm into the grooved trapezoidal shape in the adjacent panel). The pullout strength of the embedded GFRP in the joint will be resisted by the bond between its surface and the surrounding UHPFRC filling in addition to the bearing pressure between the UHPFRC filling and the precast concrete at the included surface of the trapezoidal shape at the interface between the two concretes. Such bearing pressure expects to be resisted by the concrete surface normal to the joint at the narrow end of the trapezoidal shape and the GFRP bar projecting through it from the adjacent panel. A vertical shear key is introduced along the side of the precast panel as depicted in Fig. 2(a). The slope of the inner side of the shear key has a slope of 1vertical to 5 horizontal.

3 EXPERIMENTAL PROGRAM

The experimental program included testing two laterally restrained precast FDDPs supported over /twin-steel girder bridge system, using the available force-control hydraulic actuator system. The width of the cast slab is 2500 mm so that it can be supported over the twin girders to produce slab span of 2000 mm as depicted in Fig. 3(a). The precast slabs were of 200 mm thickness and were made of 35 MPa normal strength concrete (NSC) with 10 mm nominal size aggregate, 150 mm slump with added super plasticizer, and no air-entrant. Straight-ended, 16M ribbed-surface, high-modulus GFRP bars was used to reinforce the precast slab per CHBDC requirements. The bottom and top transverse reinforcement of the slab was taken 16M@140 mm and 16M@200 mm respectively. While the slab was reinforced with 16M@200 mm GFRP bars in the bottom and top longitudinal direction (i.e. parallel to the girder). The specified modulus of elasticity and ultimate tensile strength of the GFRP bars were 64 GPa and 1188 MPa, respectively (Schoeck, 2012). To form the joint between the precast FDDPs, two precast FDDPs were formed first. The first FDDP was of 200 mm thickness, 2400 mm length in girder direction and 2500 mm, while the second FDDP was of 200 mm thickness, 1000 mm length in girder direction and 2500 width. This made the final dimensions of the jointed slab of 3700 mm in the direction of traffic as depicted in Fig. 3(a). It should be noted that the short precast slab of 1000 mm was introduced beside the large precast slab to ensure deck slab continuity beyond the joint. Figures 3(b) and 3(c) show views of the formwork, GFRP
bar arrangement and Styrofoam used to form the joints and the shear pockets before casting concrete. The panel-to-girder connection was made using shear pockets to achieve the full composite action. Shear studs were used to establish such full composite action between the girder and the precast panel every 1200 mm. High tensile headed shear studs (structural bolts) of 25 mm diameter were used. The UHPFRC (Ductal Joint Fill JS1000) was used for the cast-in-place of the panel-to-panel connection. The ultimate strengths of the UHPFRC were 140 MPa, 30 MPa and 8 MPa in compression, flexural and direct tension, respectively, while its modulus of elasticity was 50 GPa. More details about the experimental program can be found elsewhere (Sayed-Ahmed, 2014).

The panel-to-girder connection was made using shear pockets to achieve the full composite action. Shear studs were used to establish such full composite action between the girder and the precast panel every 1200 mm. High tensile headed shear studs (structural bolts) of 25 mm diameter were used. The UHPFRC (Ductal Joint Fill JS1000) was used for the cast-in-place of the panel-to-panel connection. The ultimate strengths of the UHPFRC were 140 MPa, 30 MPa and 8 MPa in compression, flexural and direct tension, respectively, while its modulus of elasticity was 50 GPa. More details about the experimental program can be found elsewhere (Sayed-Ahmed, 2014).

The experimental program included testing two precast FDDPs supported over twin-steel girder bridge system, using the available force-control hydraulic actuator system. The steel I-girders were 7500 mm in length and made of W610x241. They were placed over 330x330x25 mm elastomeric pads that were supported over steel pedestals, making the clear spacing of the girder equal 7000 mm. Transverse cross-type bracings were installed at the two ends of the steel girders to provide lateral restraints to the deck slab as specified into the CHBDC empirical design method. The spacing of the twin girders was 2000 mm measured center-to-center of the girders. The first slab system was tested under high-cycle constant-amplitude fatigue (CAF) loading followed by increasing monotonic loading to-collapse, while the second slab system was tested under low-cycle incremental step fatigue loading of variable amplitude (VAF) to collapse. The actuator system generates sinusoidal harmonic force,

\[ p_t = p_{avg} + p_a \sin(2\pi f t) \geq 15 \]

where \( p_{avg} \) is the average between the maximum and minimum loads, \( p_a \) is the amplitude of applied load, \( f \) is the frequency and \( t \) is the time. Before performing fatigue tests, a crack was initiated in the tested slab by applying monotonic loading equal to 3 times the applied wheel load for fatigue limit state design per CHBDC. This applied wheel load equals the heaviest wheel load in the specified CHBDC truck, multiplied with the 1.4 to include the dynamic load allowance (DLA) and 0.9 as the load factor.(i.e. \( 87.5 \times 1.4 \times 0.9 \times 3 = 330.75 \text{kN} \)). The footprint of the applied wheel load on top of the tested slab measures 600 mm wide by 250 mm long as depicted in Fig. 3(a). It was decided to locate it just beside the joint as depicted in Fig. 3(a).

The constant amplitude fatigue (CAF) loading was applied under force control with sinusoidal shape to represent the FLS load specified into the CHBDC as \( 87.5 \times 1.4 \times 1.0 = 122.5 \text{kN} \) at the frequency of 4 Hz for 4 million cycles. To prevent rattling of the test setup under cyclic loading, the loading cycle started with 15 kN applied load that increased by 122.5 kN. Thus, the sinusoidal cyclic CAF ended up with loading range of upper and lower absolute values of 137.5 kN and 15 kN, respectively with sample rate of 20.013 Hz. Monotonic test at 1.5 time the applied FLS load (i.e. \( 122.5 \text{kN} \times 1.5 = 183.75 \text{kN} \)) was conducted.
after each 250,000 cycles to assess the degradation of the FDDP system due to fatigue loading. The force-control monotonic test had a ramp segment shape at loading and unloading rate of 5 kN/min. and 10 kN/min., respectively, with collecting data points every 0.049967 sec. After the end of the 4 million cycles, the FDDP system was monotonically loaded to-collapse using a hydraulic jack with 1,300 kN capacity. The incremental step variable amplitude fatigue (VAF) loading was applied under force control with sinusoidal shape to different 7 absolute peak levels of 1.0, 1.5, 2.0, 2.5, 3.0, 3.5, and 4.0 times the FLS load of 122.5 kN plus 15 kN as the absolute load lower level. The corresponding peak loads of the 7 incremental step VAF loadings were 137.5, 198.75, 260, 321.25, 382.5, 443.75 and 505 kN. Each load level was applied for 100,000 cycles at the range of 2 Hz to 0.5 Hz depending on the stiffness of the FDDP system, and the steel loading frame system, with lowest frequency when approaching failure of the slab. Data was collected at a sample rate of 20.013 Hz. Monotonic test was performed after each 100,000 cycles with the same setting of the CAF monotonic test. After finishing with 7 absolute peak levels mentioned earlier, the VAF loading testing continued with the highest peak value up to the failure of the specimen. Figure 4 shows view of the test setup during fatigue testing, while Fig. 5 shows view of the test setup during the monotonic testing.

4 TEST RESULTS

This section discusses the structural behavior of the tested specimens in the form of slab vertical deflection, and crack pattern. As mentioned earlier, fatigue precracking was conducted under force control. The first hair flexural crack was observed at 2.5 times the FLS loading (275.625 kN) underneath the wheel footprint area at the mid-span in the longitudinal direction (parallel to the supporting girders). Load was increased to 3 times the FLS load (330.75 kN) to increase the crack propagation beyond the wheel footprint area. The flexural crack width was found to be 80 µm at that monotonic load. CHBDC specifies that design factored load of the deck slab is the multiplication of CHBDC truck wheel load of 87.5 kN, load factor of 1.7 and DLA of 0.40. This makes the factored design applied load 87.5 x 1.4 x 1.7 = 208.25 kN. It is interesting to mention that at the precracking monotonic load of 330.75 kN, at which a minor flexural crack propagated, is about 59% greater that the CHBDC factored design load.
4.1 Constant Amplitude Fatigue Loading

For the tested specimen under CAF loading, the compressive strength of the concrete cylinders taken from the concrete mix were 41.16, 35.32 and 35.028 MPa, with an average value of 37 MPa. The tested cylinders for the UHPFRC, that were cast 10 days before the start of the fatigue testing, resulted in compressive strengths of 130.90, 136.43, 114.96 MPa, with an average value of 127 MPa. The splitting tensile tests for the NSC resulted in tensile strength of concrete of 3.37, 2.72, and 3.61 MPa, with an average value of 3.23 MPa. During the initiation of fatigue precracking procedure, at a static load of 220.5 kN, flexural crack propagated from underneath the mid-point of wheel footprint about 100 mm towards the middle shear pockets shown at the middle of the precast slab segment shown in Fig. 3(a). When the applied load increased to 275.625 kN, the flexural crack propagated further another 300 mm. However, when the applied load reached 330.75 kN, the flexural crack propagated diagonally from the mid-point of the wheel footprint to the closest corner of the middle shear pocket. The maximum recorded flexural crack width at that point measured 80 µm. No more flexural cracks were observed during the CAF test that last over 16 days. After each 500,000 cycles, the slab was subjected to monotonic loading to observe the change in slab flexural stiffness through deflection measurements. Figure 6(a) depicts the load-deflection
relationship for the slab at the centre of the footprint of the wheel load. It can be observed that the slope of the curves after each group of fatigue cycles appeared unchanged and maintained linear. After the 4-million fatigue cycles, the slab was subjected to monotonic load to-collapse. The precast FDDP failed due to punching shear at a jacking load of 931 kN. It is interesting to mention that such failure load is about 4.47 times the CHBDC factored design wheel load. Figure 7(a) shows top view of the slab showing punching shear failure at the footprint of the wheel load. While Fig. 7(b) shows bottom view of the slab showing crack pattern after failure. One may observe the radial cracks starting from the location of the footprint of the wheel load and propagating towards the support line in a fan shape. At failure, concrete spalling appeared in some parts of the bottom side of the slabs as signs for punching shear failure. Figure 6(b) depicts the load-deflection relationship for the tested slab under static loading to-collapse. Deflections values were recorded at the mid-length of the free edge of the short slab shown in Fig. 3(a), noted as “Free Eng” curve in Fig. 6(b). Such deflection reached 1.78 mm at failure. On the other hand, the deflections under the wheel footprint, denoted as “Under Load 1 and Under Load 2” in Fig. 6(b) were recorded as 30.29 and 28.94 mm at failure. The deflection at the centre of the long precast slab, denoted as “Mid-span” in Fig. 6(b) was recorded as 19.30 mm. The maximum deflection of the long precast slab at the mid length of the edge joint, denoted as “Fixed End” in Fig. 6(b) was recorded as 2.65 mm at failure.

**Figure 7.** Crack pattern after failure of the first slab tested under CAF loading
4.2 Variable Amplitude Fatigue

The second precast FDDP specimen underwent sinusoidal waveform fatigue load cycles with incremental step low cycle fatigue loading. The compressive strengths of concrete cylinders for the NSC used to cast this slab were 43.26, 68.16, 64.99, 65.74 MPa, with an average value of 60 MPa. The compressive strengths of the concrete cylinder for the UHPFRC used to fill the joints were 163.35, 183.31, 153.28 MPa, with an average value of 167 MPa. The splitting tensile test for the UHPFRC resulted in tensile strength of 18.30, 20.47 and 21.69 MPa, with an average value of 20 MPa. The first 895,000 fatigue load cycles were performed at a frequency of 2 Hz, then followed by 21,736 cycles at 1 Hz, and finally followed by 44,804 cycles at 0.5 Hz leading to punching shear failure at a total number of cycles of 961,540. Figure 8 depicts the punching shear failure at wheel footprint on top of the slab. While Fig. 9(a) depicts the crack pattern at the bottom surface of the slab at failure. A fan-shape crack pattern was observed at the bottom surface similar to those developed for the slab tested to collapse after passing the CAF loading. However, Fig. 9(a) shows greater concrete spalling along the perimeter on the punching shear plane at the bottom of the slab but only from one side of the closure strip. This precast FDDP failed at a jacking load of 488.43 kN and a maximum slab deflection of 37.03 mm. It is interesting to mention that such failure load is about 2.35 times the CHBDC factored design wheel load. Figure 9(b) depicts the monotonic load-deflection relationship of the slab after each 100,000 fatigue load cycles. It can be observed the slope of the curve decreased, leading to a reduction in slab flexural stiffness, with increase in number of VAF load cycles.

Figure 8. Views of punching shear failure of the slab tested under VAF loading

Figure 9. Crack pattern and monotonic load-deflection history for the slab tested under VAF loading
4.3 Stiffness degradation

The stiffness degradation of slabs under flexural loading was calculated in the form of spring stiffness \( k \). \( k \) is considered as the ratio between the applied monotonic load, \( F \), in kN and corresponding slab deflection, \( d \), in mm. Table 1 summarizes the results for the CAF loading (high cycle fatigue, HCF) and for the VAF loading (low cycle fatigue, LCF). Figures 10(a) and 10(b) depict the relationship between the spring stiffness and the number of fatigue cycles and slab deflection, respectively. One may observe that the first specimen’s stiffness degraded by about 21.9% after 4 million cycles of constant amplitude fatigue (CAF) loading. On the other hand, the second specimen’s stiffness degraded by 71.32% when subjected to variable amplitude fatigue (VAF) loading before complete collapse.

5 CONCLUSIONS

This paper investigates the fatigue behavior and ultimate load carrying capacity for laterally restrained precast FDDP reinforced with high-modulus GFRP bars with developed trapezoidal-zigzag transverse joint combined with vertical shear key filled with UHPFRC and subjected to CHBDC wheel loading. Based on the experimental results, it can be concluded that the developed transverse panel-to-panel connection with projecting straight-ended high-modulus GFRP bars can provide a continuous force transfer in the transverse joints for the FDDPs. Experimental results also indicated that precast FDDP reinforced with high-modulus GFRP ribbed-surface bars showed high fatigue performance and there was no fatigue
damage when subjected to 4,000,000 cycles under high-cyclic CAF loading of 122.5 kN specified in CHDBC. The tested precast FDDP under high-cyclic CAF loading sustained a failure load about 4.47 times the CHBDCC factored design wheel load of 208.25 kN. While the tested precast FDDP under low-cyclic incremental step VAF loading sustained a failure load about 2.35 times the CHBDCC factored design wheel load. The two laterally restrained precast FDDPs failed in punching shear mode. Finally, the first precast FDDP specimen’s stiffness degraded by about 21.9% after 4 million cycles of constant amplitude fatigue (CAF) loading. On the other hand, the second precast FDDP specimen’s stiffness degraded by 71.32% when subjected to low-cyclic variable amplitude fatigue (VAF) loading before complete collapse.

6 ACKNOWLEDGEMENTS

This study was sponsored by Ontario Ministry of Transportation’s Highway Infrastructure Innovation Funding Program, Lafarge North America through supplying UHPFRC premix materials and Schoeck Canada Inc. through supplying GFRP bars. Such support is greatly appreciated. Opinions expressed in this paper are those of the authors and do not necessarily reflect the views and policies of the Ministry.

Abstract: Construction projects are complex systems and their behaviors are extremely dynamic throughout their life cycles. This complexity and dynamism makes them perfect candidates for system dynamics modeling for management purposes. However, ill-known variables, a lack of historical data, uncertainties, subjectivity, and the use of linguistic terms in defining construction variables all complicate the application of system dynamics in construction. Fuzzy logic is an artificial intelligence technique that has the ability to model vague, incomplete, linguistically-expressed, and subjective data in a precise way. Since the quality of system dynamics modeling relies significantly on the accuracy of the data, integrating system dynamics with fuzzy logic makes for a powerful construction project simulation tool. Integrated fuzzy system dynamics models can effectively capture the dynamic characteristics of construction projects and simulate them more precisely by using fuzzy logic to capture subjective and linguistically-expressed information. In this paper, we illustrate how fuzzy logic and system dynamics can be integrated for use in construction project simulation. Moreover, we present a review of potential applications of integrated fuzzy system dynamics models in construction. Finally, we compare the performance of system dynamics with integrated fuzzy system dynamics for a construction-related problem adopted from the literature, and discuss how integrating fuzzy logic can enhance system dynamics capabilities for construction modeling.

1 INTRODUCTION

Construction projects always involve uncertainties and complexity, which makes construction management a critical task in the industry. During the last century, several managerial tools and approaches have been developed in construction or adopted to this area from other industries to help managers plan and control their projects effectively. Simulation models—such a managerial tool—help managers to observe the conditions and performance of their projects prior to the execution phase. Simulation models are powerful planning tools that can help managers to identify the key factors affecting their projects in order to proactively manage problems before they arise. Among simulation models, the system dynamics (SD) approach, developed by Forrester (1961) for the analysis of complex industrial systems, has unique characteristics that make it well-suited to construction planning purposes. SD
models can effectively capture the dynamism of the systems where the state of the system can continuously change. This characteristic of SD models suits construction modeling, since construction projects are always changing under the effects of various factors. Moreover, SD models describe interrelationships between the elements of the systems with cause and effect loops (Ford 1995), which also makes these models an ideal choice for the construction context, where there are often numerous interactions between elements in a project.

Previous research by Lyneis and Ford (2007) shows SD models have been successfully applied in project management. Sterman (1992) asserts that project management is one of the most poorly performing areas of management and SD modeling can help the managers of large scale engineering projects. There are several applications of SD models in construction project management by researchers as well. Mowdesley and Al-Jibouri (2009) developed a SD model for construction productivity at the project level, Park (2005) used SD models for resource management, and Lee et al. (2006) used SD modeling for dynamic planning in construction. However, despite the extensive use of SD models in construction project management, SD models are limited in their ability to capture qualitative and linguistic variables in simulation (Levary 1990). In order to address this deficiency, Levary (1990) introduced the use of fuzzy logic in SD modeling.

Fuzzy logic, developed by Zadeh (1965), gives the human cognitive process mathematical precision. Fuzzy logic is a tool for modeling subjective and imprecise variables or variables that are expressed in linguistic terms. Fuzzy logic is a powerful modeling technique well suited to construction, since construction projects are unique in terms of their characteristics, and lack of historical data is one of the biggest challenges that researchers and practitioners face when modeling construction problems. Fuzzy logic has been implemented to solve construction-related problems successfully many times before (see Chan et al. 2009 for a review).

In this paper, we illustrate how fuzzy logic and SD can be integrated for use in construction project simulation. Moreover, we present a review of potential applications of integrated fuzzy SD models in construction. Finally, we compare the performance of SD with integrated fuzzy SD for a construction-related problem adopted from the literature, and discuss how integrating fuzzy logic can enhance SD capabilities for construction modeling. For the remainder of this paper, system dynamics (SD) integrated with fuzzy logic will be referred to as fuzzy system dynamics (FSD).

This paper is organized as follows; first a brief literature review of FSD is presented, followed by applications of SD and FSD models in construction. Secondly, different methods of integrating SD and fuzzy logic are discussed. Then, a comparison is made between SD and FSD models in a construction-related problem, followed by a discussion of how the integration of SD with fuzzy logic can enhance the capabilities of SD in construction modeling. Finally, future extension to the current research is discussed.

2 LITERATURE REVIEW

2.1 Fuzzy System Dynamics

Levary (1990) introduced the idea of integrating SD with fuzzy logic in order to enhance the capability of SD models for simulation of real-life systems. Common approaches of SD modeling use crisp numbers to define the variables, and the relationships between the variables are defined by either mathematical or table functions. However, there are subjective variables in real-life systems which are better expressed in linguistic terms than crisp numeric values (e.g., good weather). Therefore, as Levary (1990) discussed, integrating SD and fuzzy logic solves a major problem associated with quantitative variables modeling. Integration of these two methods has two requirements: (1) defining subjective variables by fuzzy membership functions and (2) defining the interrelationships between the fuzzy variables either by using fuzzy arithmetic in mathematical equations or fuzzy rule-based systems.

Ghazanfari et al. (2003) presented a review of the literature of different approaches for integrating fuzzy logic and SD modeling. Polat and Bozdag (2001), Nasirzadeh et al. (2008), and Khanzadi et al. (2012) provide some examples of applications of FSD models in different disciplines. Tessem and Davidsen
(1994) developed a simple FSD model with three fuzzy variables for population estimation using fuzzy arithmetic in mathematical equations. They pointed out that the use of fuzzy arithmetic in their system caused fast growth of the support of the fuzzy output (i.e., population) and the output of the system contained too much uncertainty. Sabounchi et al. (2011) developed a FSD model for product diffusion based on customer-based propagation of product (i.e., word of mouth) using two fuzzy variables in a SD molecule. They replaced the equation that contained fuzzy variables with a fuzzy rule-based system to avoid the growth of the support of fuzzy outputs. In the FSD model proposed by Sabounchi et al. (2011), in each time step the output of the fuzzy rule-based system is defuzzified and used as a crisp input in other equations.

2.2 System Dynamics in Construction

Lyneis and Ford (2007) conducted an extensive review of applications of SD models in all disciplines of project management (software development projects, manufacturing, etc.). There have also been some recent applications of SD models for project management specifically in construction. Mowdesley and Al-Jibouri (2009) developed a SD model for simulation of construction productivity at the project level. Mowdesley and Al-Jibouri (2009) refer to the large number of the factors that affect productivity in construction projects and the complex relationships between the variables and conclude that SD models are good candidates for modeling productivity. Nasirzadeh and Nojedehi (2013) developed a SD model for the simulation of labour productivity in construction projects. Their model was composed of four sub-models, each with different levels of the factors affecting labour productivity. Nasirzadeh and Nojedehi (2013) assert that the factors that affect labour productivity are rarely independent from each other and that therefore, SD models are the best options for the simulation of labour productivity. Park (2005) referred to the dynamism of construction projects and proposed a SD model for resource management. The dynamic simulation of construction projects Park (2005) proposed minimizes the idle time of resources and decreases project costs. Despite the widespread use of SD models in construction contexts, some recent studies (e.g., Khanzadi et al. 2012) refer to some deficits of this modeling tool for construction modeling. Khanzadi et al. (2012) assert that because of the subjectivity of some variables in construction, integrating SD models with fuzzy logic can improve this modeling tool for the construction domain.

2.3 Fuzzy System Dynamics in Construction

Most applications of FSD models have been developed in business and the social sciences until recently. The FSD model for construction risk assessment proposed by Nasirzadeh et al. (2008) is one of the first applications of FSD models in construction. Nasirzadeh et al. (2008) adapted the SD model for risk management developed by Ford and Sterman (1998) for production projects to suit the construction context. They proposed the use of fuzzy numbers to represent the risks’ magnitudes and possibilities due to subjectivity and lack of historical data for probabilistic representation of construction risks. Fuzzy arithmetic, based on alpha-cuts (α-cuts) and interval analysis, was used to calculate the risk consequences. In the application presented by Nasirzadeh et al. (2008) there are only five major risks affecting the project, and the model has not been tested for more risk factors.

Khanzadi et al. (2012) proposed a FSD model to estimate the concession period of BOT projects. In their model, the concession period is estimated based on the magnitude of the project’s risks. The relationships between the fuzzy variables are defined using fuzzy rule-based systems and the results are defuzzified for further calculations. Nasirzadeh et al. (2013) developed a FSD model for quality management in construction projects. In their model, the variables affecting the quality management process are estimated as fuzzy numbers and entered as fuzzy inputs to a FSD model which uses mathematical equations and fuzzy arithmetic. Nasirzadeh et al. (2013) use fuzzy arithmetic based on α-cuts and interval calculations; however, they do not discuss their system’s problem of growing support in fuzzy results as previously pointed out by Tessem and Davidsen (1994).
3 METHODS OF INTEGRATION OF FUZZY LOGIC WITH SYSTEM DYNAMICS

As previously discussed in Section 2.1, integration of the SD modeling approach with fuzzy logic enhances the performance of SD for modeling real-life systems. Fuzzy logic can contribute SD modeling by defining linguistic and subjective variables and relationships for simulation of real-life systems. Moreover, fuzzy logic can model uncertain variables when sufficient historical data are not available for probabilistic distribution fitting. Integration of fuzzy logic with SD should be implemented in two steps: fuzzy variable definition and fuzzy relationship definition. The process of integrating the two methods is explained below:

1. Variable definition: The subjective variables that need to be defined with fuzzy membership functions should be selected first. Then, membership functions for defining the variables should be developed. Membership functions can be defined with one of several different approaches proposed by the literature, using expert judgment or historical data. Fuzzy c-means (FCM) clustering, for use when historical data is available, is one example (Bezdek 1981; Pedrycz and Reformat 2006).

2. Relationships definition: Once the subjective variables of the system have been defined with fuzzy membership functions, the relationships between these variables must be modeled using fuzzy logic techniques. For defining the relationships between the system fuzzy variables, there two alternatives:

   - Fuzzy arithmetic and mathematical equations: In this method, as in SD models, the relationships between the system’s variables are defined by mathematical equations. However, here the classical arithmetic is substituted with fuzzy arithmetic where some variables of the equations are fuzzy numbers. This method provides a quick approach for developing FSD models, as it is mostly based on pre-developed SD models but with the slight modification that some of the crisp variables are changed to fuzzy variables. However, the main deficiency of this method is the fast growth of the support of the fuzzy results of the system (Tessem and Davidsen 1994).

   - Fuzzy rule-based systems: In this method, the relationships between the fuzzy variables of the systems are defined by fuzzy rule-based systems. Fuzzy rule-based systems can be defined using a few different approaches. FCM clustering (Bezdek 1981) is an alternative for defining fuzzy rule-based systems where historical data is available. Khanzadi et al. (2012) used expert judgments for developing a fuzzy rule-based system in their FSD model where historical data was unavailable. Usually, the outputs of a fuzzy rule-based system have irregularly shaped membership functions. Therefore, the results must be either defuzzified or approximated by a regular membership function for further calculations. Defuzzification is the process of converting the fuzzy memberships to a single crisp value. The most common defuzzification method is the center of area (CoA) method.

The flowchart presented in Figure 1 summarizes the steps for developing a FSD model as discussed in this section.
4 APPLICATION OF FSD MODELS IN CONSTRUCTION

4.1 FSD Model for Crew-Related Factors Influencing Construction Productivity

In this section, we develop a construction-related SD model to illustrate how fuzzy logic can contribute to SD modeling for construction applications. In this model the effect of crew and labour characteristics on construction labour productivity at the crew level. Tsehaye and Fayek (2014) conducted extensive research on identification of the key parameters that influence construction labour productivity in different levels. They categorize the factors influencing construction labour productivity into 18 groups based on their sources. For the model developed in this study uses only one of these categories: crew and labour characteristics. Next, the factors that change on a daily basis and affect labour productivity at the crew level are extracted for modeling and are modified to some extent to fit the SD modeling approach. For developing the model, we studied three concrete construction projects and collected a total of 32 data points for the selected factors for analysis purposes.

For qualitative model development, each factor is analyzed to find which factors affect it (i.e., feature selection is performed). For this purpose, the correlation-based feature selection (CFS) method is used for its simplicity. Hall (1999) introduces CFS as a simple filter algorithm which ranks the features through a heuristic evaluation function. The CFS algorithm uses historical data and identifies the features that have the greatest effect on each variable. Table 1 shows the variables of the system and the attributes selected for each factor that are used for developing causal loops. Then, based on the results of CFS, the
causal loops for each variable of the system can be identified. Finally, the qualitative model is developed as presented in Figure 2.

Figure 2: Qualitative FSD model for crew-related factors influencing construction labour productivity

Like the SD model, the FSD model is based on the qualitative model presented in Figure 2. However, the difference between the two approaches lies in their method of quantification (i.e. definition of the variables and their relationships). For quantification purposes, the SD model considers all the variables as crisp variables and the relationships are defined by mathematical equations using statistical extrapolation. To define the relationships between the variables in this model using statistical extrapolation, this model uses
the linear regression method. Two of the model's equations are presented in Table 2: (1) labour productivity, the measurement of which is the main objective of the model, and (2) production rate, which is used to compare the results of the SD model with those of the FSD model. The equation for calculating the production rate is selected for further comparison with the FSD to show that FSD models can also accept crisp values in their equations. Based on the equations presented in Table 2, the accuracy of the two models in defining the relationships between their variables is discussed. Once the relationships between the system variables are defined by mathematical equations, quantification of the SD model is complete.

For quantification in the FSD model, first, the subjective variables (i.e., cooperation among craftspeople, fairness of work assignment, motivation valence, motivation expectancy, and motivation instrumentality) of the system are defined by fuzzy membership functions. Since labour productivity is a function of both these fuzzy variables and other crisp variables (i.e., crew composition and crew size), it is also defined by membership functions. As discussed in Section 3, the resulting membership function for labour productivity can be defuzzified to find the crisp value for labour productivity. FCM clustering is an approach for defining of the fuzzy membership functions when historical data are available. In this model, triangular membership functions are selected while they are simple and widely used. Therefore, all variables of the system are defined by triangular membership functions using FCM clustering method. The membership functions which define labour productivity are presented in Figure 3 as an example. The next step for quantification of the FSD model is defining the relationships between the fuzzy variables as mentioned in Section 3. For defining the relationships between the fuzzy variables, fuzzy rule-based systems are selected. Where the historical data is available, FCM clustering is used for development of the fuzzy rule-based systems. The fuzzy rule-based system developed for estimating labour productivity is presented in Table 2.

![Figure 3: Labour productivity membership functions developed by FCM clustering](image)

The results of the fuzzy rule-based system can be defuzzified and used in further calculations of the system. In the example shown in Figure 2 and Table 2, labour productivity is defuzzified using the center of area (CoA) method and used to calculate the production rate.

Once quantification is complete, the accuracy of the two models is tested for predicting labour productivity using the historical data. While the performance of the models strictly depends on how well the variables and their relationships have been defined, the model with the more precise estimate for the variables potentially performs better for simulation. Results of the analysis show that in this case, the FSD model with the fuzzy variables and fuzzy rule-based system predicts a labour productivity value with a root mean square error (RMSE) of 0.19. However, the SD model with the mathematical equation as presented in Table 2 predicts a labour productivity value with a RMSE of 0.24.

</table>

The results of analysis of the SD and FSD models shows that the integration of fuzzy logic with system dynamics can increase the accuracy of the resultant model when there are subjective variables in the system. In this study, historical data were available and used for the definition of the fuzzy variables' membership functions and the fuzzy rule-based system for the FSD model. In cases where historical data are unavailable, other methods of defining the fuzzy variables and fuzzy rule-based system—such as expert judgment and consensus methods—can be used.

### 5 CONCLUSION

Integration of the system dynamics (SD) modeling approach with fuzzy logic develops a powerful tool for construction modeling which captures the subjectivity and complexity of construction projects at once. In this study, integration of SD modeling with fuzzy logic is illustrated and some applications of these models in construction are presented. Moreover, an application of SD and fuzzy SD (FSD) approaches for modeling the effect of crew characteristics on construction labour productivity at the crew level is presented. The comparisons between the two models (i.e., the SD model and the FSD model) verified that the FSD model is more accurate in predicting construction labour productivity at the crew level based on the sample model. However, this study only develops sub-models for the purpose of testing and comparing their performances in a construction context. To extend this research, a comprehensive model for simulating construction labour productivity can be developed. Moreover, in this study, a fuzzy rule-based system is used to define the relationship between the system variables, which results in a better performance than when linear regression is used for this purpose. The relationships between the system variables are usually defined by extrapolation methods. However, the mathematical equations that are used in SD models can also be substituted with artificial intelligence tools (e.g., neural networks). Investigating which options for defining the system variable relationships in SD models might serve as the best substitutes for statistical extrapolation is another area of extension to this study.

Abstract: Annually there are many small-scale industry projects implemented in Iran, most of which are financed by local financial institutes. The financing agreements between project owners and financial institutes are usually formed and finalized during the initiation phase and are based on feasibility studies done at the early stages; before project design and construction begin. However, in many cases actual costs of projects exceed the costs estimated in feasibility studies which have been approved by financial institutes. Limited financial resources in the country, from one side, and the lengthy process of increasing the project financing limit, from another side, cause delays in the project completion. In many cases the cost increase and the delay make the entire project unfeasible; projects stop forever; a big waste of money is the result. To respond to this issue and improve accuracy of cost estimation prior to the design and construction phases, in this research we have developed a new cost estimation model based on neural network method. At this stage of the research the model is implemented and tested for the main industrial building, which usually has a portal frame structure. Results indicate a reasonable improvement in accuracy for the estimated costs.

1 INTRODUCTION

Small-scale industry projects constitute a considerable part of industrial construction projects in Iran. Statistics for 2014 show that small industries account for 92% of the industries in the country, and that 40% of the total industrial employment is in small industries. (Fars News Agency 2015). Owners of small-scale industry projects generally own smaller industries and workshops and they are completely familiar with their target market. They feel the need to expand and develop their industries and want to increase their production power. So, they take steps to introduce industry projects, but generally they lack suitable project management knowledge. Funds needed to meet the costs of these projects in the country are provided jointly through project owner investments and financing banks. The initial capital required for carrying out projects is one of main factors contributing to the economic justification of building them. However, in many small-scale industry projects in Iran it is observed that the actual costs exceed the estimated capital. This causes many projects to face problems in providing funds during the construction phase. Moreover, many owners of such projects have limited assets and cannot meet the increased costs. On the other hand, increasing bank loan ceilings requires complicated processes and is time consuming; and, in many cases, banks no longer agree to raise their loan ceilings for the projects since elevated costs pull the projects out of their profitability margins.
Compared to large industries, small-scale industry projects generally include limited production lines; a greater part of construction costs in these industries are related to buildings and civil works required. Studies conducted on 30 industrial projects showed that construction expenditure in industrial projects with costs of less than 20 million dollars (small-scale industry projects) constituted 20% of the total costs, while in industrial projects with costs of over 20 million dollars this figure declined to 12%. Moreover, studies have shown the main industrial building accounts for the main part (58%) of the total buildings and civil works in the projects. Furthermore, most owners of these projects need to make sure banks will finance their projects before they start the design and building phases. Therefore, signing a contract with the bank for financing the project usually takes place before the detailed design and based on the initial feasibility studies. Moreover, it is difficult to estimate accurately the costs of constructing civil engineering facilities just by knowing specifications regarding their initial dimensions, and this will reduce estimation accuracy and lead to errors in cost estimation of these facilities. Study of 30 industry projects mentioned above suggested the mean deviation from the allocated budgets for industrial projects was 16% while this figure rose to 30% for the building and civil work parts. Higher variations in cost estimation of civil works compared to production line in small-scale industries originate from the fact that manufacturers of these production lines are usually specialized and have many past experiences in making specific types of machineries required; they already have design of production line machineries and can provide accurate estimations in the early stages. Therefore, what actually causes costs of small-scale industry projects to deviate from the predicted values is inaccurate cost estimation in buildings construction and civil works which need to be custom designed and built. This is also the case for main industrial buildings in which the costs deviate 28% from the allocated budgets.

Inaccurate cost estimation is accompanied by the possibility of increased construction costs because it will cause delays in paying construction contractors, and it will increase the possibility of contractual disputes. The time-consuming process of bank approval in raising loan ceilings, and the loss of economic feasibility of the projects due to increased costs, cause work stoppages in industrial projects or lead to their annulment and termination, as confirmed by the fact that there are 2900 unfinished small-scale industry projects in the country (ISNA press 2014). The importance of initial estimation and its tangible effect on success or failure of a project to the end led us to develop an estimation model based on neural networks in this research. This model is going to receive preliminary specifications of the project, which are determined in the early stages of the project prior to the project design, as the main input and return relatively accurate cost estimation of the project as its output. Though, because of its significant cost contribution and cost estimation variations, in this part of the research our main focus is on the main industrial buildings. Almost in all small-scale industrial projects we studied, including the above mentioned 30 cases, the main industrial buildings were constructed based on portal frame steel structure. So, the model was specifically developed for steel portal frame buildings. With the cooperation of the specialist group for designing and constructing steel portal frame structures for industrial buildings, we designed and used 324 portal frames with various specifications and dimensions based on geographical and environmental features of Tehran province to develop our model, to increase its accuracy, and to train the developed model. Results of validation of the model by using it in actual small-scale industry projects in Tehran province showed a high accuracy in cost estimation.

2 LITERATURE REVIEW

Ellis and Turner in 1986, and Proctor, Brown, et al. in 1993 showed that cost proposals offered by construction contractors were usually higher than the initial estimates and predictions of employers. In recent years, in an effort to narrow this gap, and with the advances made in information technology, new cost modeling approaches based on preliminary project parameters using computer software have been introduced. In 1996, Fortune and Lee compared the reliability and value of these new methods of modeling with those of the conventional ones and demonstrated the new models were more valuable than the conventional ones. Since then, extensive studies were conducted on cost estimation in the early stages of projects by using the new methods developed by computer software.

In 2006, Lowe et al. used multiple regression methods on 286 datasets collected on construction projects carried out in England to predict costs of building construction. They based their cost estimation model on
cost per square meter, cost logarithm, and cost per meter logarithm, and introduced six models by performing the two kinds of forward and backward stepwise regression analysis. Finally, the back propagation algorithm cost model showed the best result with a correlation coefficient of 0.661 and mean absolute percentage error of 19.3 percent. These results were comparable with those of previous studies that reported the mean absolute percentage error of cost estimation using conventional methods was about 25 percent. The data Lowe et al. (2006) used for modeling in 2002 was employed by Emsley et al. to develop a neural network model for estimating the total construction cost. Comparing the results of these two studies showed that the performance of the neural network model was a little better than that of the regression model. Sonmez (2004) also studied the use of regression methods and neural networks in conceptual cost estimation models (predesign cost estimation models) in construction projects. He used 30 datasets related to costs of building projects (houses, treatment centers, and public buildings) belonging to the Social Security Administration in 14 different states of the United States built during 1975-1995, and employed the range estimation method to determine cost ranges. The regression model and the neural network models were compared with respect to goodness of fit and prediction performance using the two criteria of mean square error and mean absolute percentage error. Results indicated the neural network models fit the data better.

Superiority of the artificial neural network method in estimating construction costs in the early stages of projects, and comparison of its results with those of other methods, have been the subject of many other studies as well. For example, Garza and Rouhana in 1995, Bode in 2000, Park et al. in 2002, Gunaydin and Dogan in 2004, Kim et al. in 2007, Arafa and Alqedra in 2011, Petroutsatou et al in 2012, and Kim et al in 2013 conducted similar studies in this regard. In most of these studies, the researchers concluded that artificial neural networks were more useful for cost estimation in the early stages of construction projects and yielded better results. Under conditions of great uncertainty, back propagation neural networks are more suitable for estimating the cost of the finished product, and are a useful tool for cost estimation and for dealing with nonlinear questions. These models do not have the limitations of regression analysis models such as assuming a specific type of equation (e.g., polynomial) for project costs and its related variables, or the limitations of the conventional cost breakdown methods such as the need for accurate costs and detailed quantity information. Of course, one of the challenges faced in using neural networks is that a relatively large number of samples are required for training the model and for testing its efficiency and accuracy.

Although many studies have been conducted on estimating construction costs in the predesign stage, estimation of the initial costs of production buildings in industrial projects has not received much attention. Production buildings have different structures, construction methods, applications, parameters influencing costs, and manner of calculating costs from residential buildings which have mainly been address in previous estimation models. Therefore, this research studied the development of a new model based on using neural networks to meet the need for cost estimation and calculation related for portal frame industrial buildings in the predesign stage.

3 THE COST ESTIMATION MODEL

The cost of steel structure of industrial buildings depends on various factors such as the required workforce, price of steel in the market, transportation cost, etc. One of the main factors influencing costs of steel structures is the weight of steel used or more commonly called the steel structure weight. Therefore, an accurate estimate of the weight of steel to be used must be made before estimating costs. That is why this study was divided into two main phases. In the first phase, a model was built for estimation of the portal frame steel structure weight based on initial specifications. The output of this model, and other parameters influencing costs of steel structures, were then used in the second phase as the input of the second model to estimate construction cost of the steel structure so that a suitable estimate can be made of the costs of the main production building or the steel structure. Figure 1 shows the conceptual cost estimation and calculation model for the production building. The part marked by dotted lines represents the first modeling phase (which is the subject of this article).
3.1 Factors influencing the weight of portal frame steel structure

Portal frame industrial buildings are mostly one-floor structures with pitched roofs and vertical members (e.g., columns), sloping member (e.g., rafter), and diagonal members (e.g., wind braces) which are used to cover large spaces. One of the most important criteria determining the cost of a portal frame steel structure is the weight of the steel used, which itself is a function of various geometric and non-geometric specifications of the project. That is why sessions were held with experts in the design and construction of steel structures to ask their views on factors influencing the weights of steel structures. A joint research group including experts, designers, and builders of portal frame steel structures was formed to identify and evaluate importance of factors affecting the weight of portal frame in industrial buildings. These factors and their effects on the steel structure are briefly described below.

1. Building width: Increase of the building width or building span increases the length of rafters. Therefore, the bending moment resulting from the dead weight of the roof, snow and wind loads is also increased, which will naturally increase the weight of the structure.

2. Height of the hall (from the ground to the apex): With increases in the height of the steel structure, the effects of wind load on the columns and on the rafters will be intensified, and these effects in the moment diagrams of the rafters and the columns will include changes in the second degree. Another important factor in this case is the increase in the tenderness ratio and, consequently, the decrease in permissible compressive stress. These factors together necessitate the use of heavier sections.

3. Hall length: increases in the length of the steel structure will increase its weight, which in fact is the deciding factor in determining how much force an earthquake impacts on the steel structure. This will even more increase the weight of the steel structure.

4. Snow load of the region.

5. Other loads such as the crane, the indoor floors, the false ceiling.

6. The number of spans or the sharing of the base with side steel structures: although increases in the number of spans raise the reliability coefficient of the structure against collapse resulting from wind and earthquakes, the added members increase the weight of the steel structure.
Therefore, the input parameters of the model were selected from these factors to build the neural network model. The reason was that they are not only the most important factors influencing the weight, and hence the cost of the steel structure, but are also among the preliminary specifications of the main industrial building that are determined before the design process in the early stages of project definition.

3.2 Designing various types of portal frame steel structure

Results of research conducted by Gunaydin and Dogan in 2004 showed that the performance of the artificial neural networks in cost estimation strongly depended on the quality and quantity of the samples because neural networks are trained by data related to samples. Prediction error decreases with increases in the number of samples. Therefore, reliable, high quality, and full-scale data concerning costs of various types of buildings under different conditions is required to study modeling methods and to predict and build an accurate cost estimation model. To obtain such data, it was decided to ask the expert design team to design the required samples needed for building the neural network model by changing factors that influence the weight of a portal frame steel structure. In changing these effective factors, it was taken into account that the samples used to train the neural network had to be able to cover the range of values related to steel structure specifications that may actually be used in designs related to small-scale industry projects. Therefore, small-scale industry projects were studied and the opinions of the builders and designers of structures used in these projects were asked to identify the range of changes in factors that influence the weight of the steel structures, and to use this range in selecting samples that formed the input of the neural network. In all, the design specialist team identified 324 steel structures through changing the factors that influence the weight of the steel structure so that we could conduct our research.

The types of loading structures vary in different regions of the country, and so do the snow, wind, and earthquake loads. Therefore, in this stage of the research, structure designs in Tehran Province were studied. The same dead load, live load, and earthquake load were considered for all models, and the geometric specifications of the structures and the snow and wind loads in Tehran were taken into account in considering the base snow, wind, and crane loads. Furthermore, the maximum difference in stress ratios of the main members similar in the structures of various models was considered 10% in order to extract output results with suitable accuracy. Moreover, the standard stress ratio of the main members of the structures was considered 0.9%; and, considering this ratio, we can say that the design process was carried out optimally. The steel materials commonly used in building steel structures in the country are of the ST-37 and ST-52 types. However, taking into account the industrial structures commonly built, considering the consultations we had with design consultants, and as the needed samples were to be used in small industries, the ST-37 type was selected in designing the samples. Furthermore, given the variety in soil resistance in different places, and considering Tehran is located on the southern slopes of the Alborz mountain range, it was deemed suitable to consider soil type to be grade 2 in calculating earthquake coefficient.

Study of changes in the dimensions of the spans in steel structures without ceiling cranes showed that snow load (as expected) was the dominant load combination in large-span structures because of the large area of the ceiling. However, in small- and medium-size structures the snow and the wind loads were of equal importance in the dominant load combination. Changes in the overall length of the structures did not change the dominant load and section specifications. Changes made in the height of the crown also yielded the expected results, and it was found that wind load was the dominant load in structures with great heights because of the large area of the structure, while the snow load was the dominant load in structures with medium and low heights. Changes in the number of spans indicated that the load combination consisting of the snow load and the earthquake load was the dominant load in the middle columns of these structures, while the load combination including the snow load and the dead load was the deciding load in the lateral columns.

All built models were then studied with the presence of ceiling cranes having 10, 20, and 30-ton capacities under the previous modeling conditions. After examining the output of the V16SAP2000 software, it was found that in all of the built models, except for structures with great heights, the load
combination consisting of the crane load and the snow load, and the load combination consisting of the dead weight and the snow load, were the deciding load combinations to similar degrees. In structures with great heights, the load combination consisting of the wind load and the snow load was the only critical load combination. Study and comparison of the models showed the minimum changes in the weight of the structures resulting from increases in the weight of the cranes were those of the structures with great heights because the wind load became the dominant load when the weight of the cranes was added. Moreover, weight changes were not significant in structures with large spans compared to other geometric changes because the snow load was the dominant load. It is worth mentioning that when a crane is added to the structure, the weight of the crane supporting beams must also be included in the weight of the structures and be taken into account in calculations regarding the weight of structures that have cranes.

3.3 Training the neural network of project cost estimation model

In building the neural network model, the data designed in the previous section was used. Creation of network architecture requires the determination of its various components such as the number of intermediate layers, the number of neurons in each layer, and the activation function. This proposed model has five processing elements (neurons) in the input layer and one processing element (neuron) in the output layer. The trial and error method was used in developing the intermediate component of the neural network to obtain a network with the best performance. In the end, the intermediate component with one layer and six processing elements (neurons) was selected for the model because its performance was more desirable compared to other networks.

![Figure 2: The architecture of a neural network model](image)

Table 1 lists the input parameters of the network. These are the same parameters that influence the weight of the pitched roof portal frame and were introduced in section 3.1. Their specifications are presented in Table 1. Considering the explanations offered in section 3.2, and since the proposed model is for Tehran Province, soil type and geographical characteristics are considered constant in this stage and are not included among the model inputs.

</table>

Three hundred and twenty four designed samples were used to train the neural network. The data was divided at random into three groups. The first group with 70% of the data (the equivalent of 227 data items) for training the neural network, the second group with 10% of the data (or 32 data items) for validation, and the third group with 20% of the data (the equivalent of 65 data items) for examining model efficiency and for testing the model. All the stages of building, training, and testing the model were carried out by using Matlab R2014b. The activation function determines network behavior and is of great importance. After comparing the efficiencies of the various functions, the hyperbolic tangent sigmoid function was used for the intermediate layer (equation 1), and the linear activation model was used for the output layer.

\[ \text{Hyperbolic tangent sigmoid} (x) = \frac{1 - e^{-2x}}{1 + e^{-2x}} \]

One of the important points in creating a neural network model is the determination of the algorithm for training the network. Various algorithms have been developed and introduced so far for training neural networks. Based on a study conducted by Rumelhart (1986) et al., the back propagation algorithm, which follows supervised teaching practice, is very efficient for building nonlinear models and is widely used. We also used this method for training the neural network in our research. Accordingly, the method is used in the current research for training Neural Network is forward training of Neural Network relied on Marquardt algorithm and employed the function of minimum squared error (MSE) for correcting weights during the training of the network (Hagan et al. 1994). The network was thus trained and a trained model with \( R = 0.9974 \) was obtained for the training data. After training the model with the 227 samples, its efficiency was evaluated using testing data. In this stage, the weights of steel used in 65 samples were first estimated by employing the neural network model, and the calculated weights were then compared with the actual ones (obtained from detailed design). Figure 3 shows results of the comparison.
Figure 3: Comparison of the actual values with those estimated by the neural network model for testing data

The percentage relative error was used to evaluate the accuracy of the model in estimating the data. The percentage relative error of the testing data was calculated using equation 2. Study of the accuracy of the estimates made by the model in the testing data showed that the proposed model had a suitable performance with 95% accuracy and could well be used in the early and pre-design stages in small industrial projects.

\[
\text{Percentage Error} = \left( \frac{\text{Estimated Weight}(i) - \text{Actual Weight}(i)}{\text{Actual Weight}(i)} \right) \times 100\%
\]

4 CONCLUSION

In this research, a model based on neural networks was developed for estimating the cost of main industrial buildings for small industry projects in the pre-design stage. In the first part of the research a model was developed for estimating the weight of steel used in portal frame industrial building. Coordination was made with the professional group that designed the portal frame and 324 portal frame steel structures were designed by changing values of factors influencing the weight of these frames to increase the accuracy of the calculations. The neural network model was then trained and evaluated using the above-mentioned data and, finally, a model was obtained with the accuracy of 95%. The weight and cost estimation model of the portal frames developed is based on preliminary dimensional characteristics of the structure which helps consultant engineering companies to increase accuracy of their estimates in their feasibility studies. It also enables them to better evaluate the prices offered by contractors. More accurate estimations during initial phase also accelerate the preparation of bidding documents, increase reliability of prices offered, and decrease the probability of deviating from the allocated budgets with the consequent fines falling behind schedule or for delays in the project due to insufficient budget. Moreover, financing banks will be able to use similar models and software to increase their accuracy and reduce their risks. Although the introduced model was developed based on geographical specification of Tehran, it can be easily expanded to other regions by proving the geographical specification of the desire location as inputs to the model. Results obtained from the model will be presented to those active in small-scale
industries including owners of projects, banks, consultant engineers, and builders to make more improve their projects construction phase.

Abstract: The purpose of this paper is to introduce a generalized multi-dimensional joint confidence level model for nuclear refurbishment planning, using the Darlington retube and feeder replacement (RFR) project (which is a multi-billion dollar effort) as a research platform. The intentions of this model are twofold: (1) determining the best set(s) of cost, schedule, and proxies for quality such as radiation expenditures by incorporating the variations of work-shift models on both the activity duration distributions and the logic of the work flow, (2) improve the expected reliability and predictability involved in the resource allocation system (schedule), by “efficiently” integrating the influential project factors, constraints, and labour shift models associated with the schedule. An effective Monte Carlo based time-cost-quality trade-off model is contributed for examining the performance and risk impacts of various work-shift designs and thus supports the choice of an optimal work-shift design.

1 INTRODUCTION

1.1 Background

The four CANDU nuclear reactors at the Darlington Nuclear Generating Station supply about 20 % of Ontario’s power needs. These reactors require a multi-billion dollar Retube and Feeder Replacement (RFR) Project that will begin in 2016 and will continue for approximately 12 years. Research has clearly established that the greatest driver of success in such megaprojects is project definition, which includes engineering, project management, quality, schedule, target costs, and safety plans. This process should optimize productivity and manage resource allocation effectively so that the RFR project is successful in terms of cost, schedule, safety, quality, predictability, and participant satisfaction. In this project, a unique full-scale mock-up of the reactor’s fuel channels and feeders has been constructed and used for testing the functionality of tools, for training personnel, and for optimizing processes to achieve the stated objectives. With 960 calandria tubes, fuel channels, and inlet and outlet feeders, the RFR processes will be repeated cyclically in a manner that challenges conventional concepts of construction project scheduling and resource allocation. Unique constraints abound: radiation dosage limits, number of people allowed in the vault, and schedule milestones are among them. The varying impact on labour productivity of round-the-clock work-shift designs is only one of many additional challenges involved.

The main question that will be addressed in this paper is the optimal allocation and scheduling of resources in such a situation. The primary objective is thus to develop a tool that will support determination of the best strategies based on cost, schedule, and proxies for quality for allocating
resources for nuclear retube and feeder replacement projects by: (1) identifying and including relevant constraints, such as the number of people allowed in the vault and the labour turnover that results from reaching radiation limits; (2) incorporating parameters such as estimated craft productivity and variations in process time; (3) addressing conflicting project objectives; (4) examining "what-if" shift-work designs and discovering possible systematic improvements; (5) estimating the impact of changes; and (6) providing an understandable and practical approach. The full-scale mock-up and training facility constructed in May 2014 helps enable the validation of this tool.

The methodology for this study will build on advances made by colleagues in the construction and industrial engineering and management fields in the area of hybrid models for construction trade-off problems (AbouRizk et al., 2011, El-Rayes & Moselhi 2001, Froese 2010, and Nasir et al., 2003). For example, commercial software exists for incorporating stochastic modelling into critical path method (CPM) schedules for Monte Carlo type simulations and analysis, however the cyclical nature of much of the RFR work lends itself naturally to the logical branching capabilities of discrete event simulation systems. Finding the most efficacious combination of these approaches considering the very unique objectives will be the focus of the next few sections of this paper.

1.2 Planning, Scheduling, and Estimating Complex Refurbishment Projects

Managing a well-structured schedule involves satisfying project objectives, optimizing resource allocation, and mitigating uncertainties. This is in general the problem encountered in this study. Some related insights and challenges are discussed below.

1.2.1 Association for the Advancement of Cost Engineering (AACE) Scheduling and Estimating Classification System

As a recommended practice of AACE International, the Cost Estimate Classification System provides guidelines for applying the general principles of estimate classification to project cost estimates. As noted by the Recommended Practice No. 18-R (2005), the Cost Estimate Classification System maps the phases and stages of project cost estimating together with a generic maturity and quality matrix, which can be applied across a wide variety of industries. The Cost Classification System consists of five estimate classes which are defined based on the level of project definition (known as the primary characteristic). Secondary characteristics on the other hand include: typical estimate purpose, typical estimating method, and typical accuracy range are correlated to the level of project definition. Class 5 represents the lowest level of project definition (with a low range of -20% to -50% and a high range of +30% to +100%) and the Class 1 estimate (with a low range of -3% to -10% and a high range of +3% to +15%) represents the closest to complete project definition (100%). These Class estimates will be used in this study as mentioned below.

1.2.2 Project Operations and Modelling Structures

Modelling project operations is one way to increase predictability and improve visualization prior to project execution (Russell et al., 2009, Mohamed et al., 2007, Zayed & Halpin 2004). Examples of modelling tools in construction are serious gaming environments, 3D and 4D visualization techniques, and discrete event simulation (DES) tools such as CYCLONE, COSYE, and STROBOSCOPE (AbouRizk et al., 2011). DES tools provide intuitive environments and functional elements that can accurately model and simulate construction operations (Puri & Martinez, 2012). However, validation of DES models is challenging. Challenges include: insufficient data causing high variance of output, project managers required to be knowledgeable about simulation tools and their workability, and the assumption that operations and time-slots involved with activities are independent and discrete, meaning that incorporating stochastic modelling for continuous sets of data results in further errors (Puri & Martinez, 2012; Rekapalli & Martinez, 2011). Scheduling and project operations modelling tools are often used for optimization of conflicting project objectives such as time and cost (Al-Hussein et al., 2005, El-Rayes & Moselhi 2001). Approaches used tend to be heuristic or based on advanced algorithms such as genetic algorithms. Linear and integer programming are almost never used for these problems because of the number of decision variables involved.
1.2.3 Uncertainty and Project Scheduling

Critical Path Method (CPM) scheduling is useful for effective completion of most construction projects. Although CPM calculations have proven to be simple and straightforward, CPM-based scheduling is a challenging process, and it may fit reporting and documentation purposes more than decision support systems that reflect reality (Hegazy & Menesi, 2010). Some of these challenges include: problems with interference of constraints in a multi-constrained schedule, problems with multiple complex relationships, and inaccurate schedule calculations. While many studies have been conducted to tackle some of these problems, in 2010 Hegazy and Menesi argued that previous methods led to analysis at rough levels of detail that cause errors in calculations (Hegazy & Menesi, 2010). In addition, most schedules are developed using a deterministic approach. Methods such as PERT are meant to address this problem by providing statistical distributions for activity durations that reflect uncertainty. Unfortunately, these methods have limitations. They assume that activities are independent, more effort is required to provide estimated values, and there is no recognition of critical path variations (Nasir et al., 2003).

One common assumption of scheduling theory is a static environment which may lead to no formal justification for unexpected events. The result is deviation from the project plan (Ahmed at al., 2003), therefore, identifying and classifying uncertainty to model and later reduce it to an acceptable level is an important aspect of project planning (Song et al., 2005). Many models have been developed to classify, model, and reduce uncertainty using artificial neural networks, simulation models, heuristic approaches, and logic work flows. These methods are claimed to be more accurate compared to traditional scheduling approaches such as CPM and PERT (Shaheen et al., 2009; Song et al., 2005; AbouRizk et al., 2011) yet the gap between virtual and actual project schedule environments (i.e. simulated uncertainties versus actual uncertainties) requires more investigation.

1.2.4 Integration of Stochastic Modelling and Project Scheduling Techniques

Capturing the impact of probabilistic project input (e.g., activity durations and cost) on the project output (e.g., total cost and completion duration) can help project managers to execute a more reliable and predictable project. Many tools have been developed to map the stochastic nature of project objectives with the schedule. Among these tools, well-known ones are @Risk™ (Palisade Corporation), Oracle and Primavera project portfolio management products such as Oracle Crystal Ball™ and Oracle Primavera Risk Analysis™ package. As @Risk™ for MS Project™ is used for this study, details follow. The @Risk™ software is an add-on to MS Excel/Project™ and suggests ways to use probabilistic analysis and Monte Carlo Simulation to visualize and quantify the uncertainty in projects and have more accurate cost and schedule predictions. This tool is also used for cost contingency. The approach of this planning method starts by creating a three point estimate (minimum, most-likely, and maximum) or defining a distribution based on historical data for both duration and cost of every activity within the schedule. After subsequent steps including Monte Carlo simulation output in the form of histograms of simulated results, a cumulative probability density graph illustrating schedule variation and exposure analysis graphs must be interpreted. However, such tools are primarily applicable to high level schedule estimation and do not provide complete and descriptive accurate results for intense (e.g. cyclic operations) and complex (e.g. multi-constraint) projects.

1.2.5 Radiation Limits and Impact on Labour

The estimation of radiation expenditures is one of the most important elements and the key constraint in this study, for the following reasons: (1) it has a direct impact on the health of the labourers while they are working at the reactor face, (2) reductions in the radiation expenditures can be achieved by altering the type of clothing (comfo, plastics, etc.) and through shielding in specific work areas which affects productivity; however, it cannot be eliminated, (3) the Canadian Nuclear Safety Commission (CNSC) Radiation Protection Regulations require the implementation of a managed system at nuclear sites in order to keep the amount of radiation absorbed by labourers (and members of the public) from radiation exposure as low as is reasonably achievable (ALARA). Radiation is measured in Roentgen Equivalent Man (REM) which is known as the dosage that will cause the same amount of biological injury as one rad of X rays or gamma rays. This requirement translates into specific radiation limits that are currently determined for each labourer for one-year (1 Rem-person) and five-year (5 Rem-person) time windows.
Once labourers reach either the one- or the five-year limit, they are assigned to non-radiated work areas, (4) while the initial cost and schedule estimations prior to project execution are set to zero, in this case, labourers do not walk in with a zero radiation dose but are expected to start the job with a "pre-existing" radiation rate that can be established and modelled as frequency distribution for a population of labourers, (5) the dose rate absorbed per labourer is reset on January 1st of each year. In this case, “reset” is defined as a radiation rate estimated for each labourer based on the average dose rate over a five-year time window, and (6) different activities are associated with different radiation rates because of varying distances from radiation sources.

1.2.6 Factors Associated with Labour Productivity

To obtain a good level of accuracy with respect to cost and schedule estimated, two items should be considered: (1) identification of factors that drive labour productivity, such as: shift length, temperature, and congestion, and (2) definition of the baseline. The baseline is defined as the neutral work condition, meaning that no additional effort is required from labourers beyond that necessary for them to complete their work during a standard shift (i.e., 5-8s). For this specific project, if a multiplier of one is considered for the neutral work condition (i.e., based on assessed hours), multipliers (i.e., weights) for work conditions other than neutral are assessed. For the proposed JCL model, factors are identified based on the Productivity handbook produced by CII (2014), which synthesizes over 50 years of quantitative research (CII 252-2d, 2014) and are assessed based on documents compiled by the Mechanical Contractors Association of America, Inc. (MCAA).

1.3 Joint Confidence Limit (JCL) Model

A JCL is an integrated uncertainty analysis for cost and schedule estimation, first introduced by NASA HQ-Program Analysis and Evaluation Cost Analysis Division (2009). This model combines the cost, schedule, and uncertainty (using Monte Carlo analysis) associated with a project in order to identify the relative probability that the cost and schedule “jointly” fall within the targeted budget and schedule dates. This process helps update management with respect to the likelihood of the programmatic success of a project. A JCL can be constructed from either of two types of input: parametric models or probabilistic resource-loaded schedule (PRLS) estimates. If a JCL is constructed in the early estimation phase, parametric models can be used, and then as the project estimation phase advances, PRLS can come into play. Information required as part of the input for the JCL includes the recent cost data and project schedule. A final requirement is that statistics such as the mean and standard deviation of the cost and schedule be available (NASA HQ, 2009).

The multi-dimensional JCL introduced in this paper is an extension to the described 2 dimensional JCL model with the third dimension being the quality proxy (i.e., radiation expenditures). This section will be later discussed in section 3.

1.4 Scope of Analysis

As vehicles for identifying the primary characteristics and interdependency of the three objectives (i.e., cost, schedule, quality proxy) within the RFR project, a work package known as the “feeder removal series” has been studied in detail. The rationale behind choosing this work package among many others include: (1) relatively high rates of radiation exposure at the workface; feeders are highly contaminated with toxic particles and labourers will be exposed to significant rates of radiation while removing the feeders from the reactor in the vault, and (2) labour-intensive work; feeders will be removed manually, leading to both expected and unexpected performance and productivity variations. To note that the combination of these two points creates a more challenging trade-off problem. Due to the wide range of variations that may possibly be caused by the two points, as a result of various work shift patterns and their interdependency, it becomes very interesting to explore the impact of these variations on the results of the Monte Carlo analysis and the MD-JCL model.
1.4.1 Feeder Description

Feeders are an integral part of the primary heat transport system (PHTS). The function of a feeder is to transport the D\textsubscript{2}O coolant from the inlet feeders to the fuel channels (FCs) and from the FCs to the outlet headers. There are 960 feeders: one inlet and one outlet feeder for each of the 480 FCs. Feeders must be replaced when significant thinning of the outlet feeders occurs. Removing the feeders is expected to have the added benefit of reducing the overall radiation rates in the vault, which will expedite the fuel channel removal and installation series.

2 MODEL OBJECTIVES

This section defines six interconnected sub-objectives related to finding good sets of solutions (defined mostly in this paper by crew arrangements) with an acceptable joint confidence limit for a complex schedule with the key objectives of minimizing variance while maximizing productivity. This is done through reasonable quantification and modelling of shift models, productivity factors, project constraints, and variations in the duration and cost of activities. The proposed multi-dimensional JCL model developed for the nuclear retube and feeder replacement and other similar projects must provide the following functions:

1. Identify and include relevant time and spatially dependent constraints such as the number of people allowed at the workface (i.e., vault), scheduling milestones, certified craft professionals available, etc.
2. Incorporate estimated probability distributions for craft productivity and process times.
3. Capture the impact of the uncertainty associated with activity durations and cost.
4. Define a quality proxy by measuring and reducing the impact of labour turn-over caused by labourers reaching radiation limits defined by radiation safety practices while being exposed to radiation sources at workface.
5. Address multiple objectives such as cost, schedule, and quality by developing a new multi-dimensional joint confidence level approach.
6. Be understandable, practical, and useful, with the potential to be adapted and applied broadly.

3 MODEL OVERVIEW

3.1 Duration and Cost

In order to produce a more transparent and traceable set of outputs, it is crucial to assess uncertainty which is inherited in the duration of each planned activity. Uncertainty primarily refers to the variability in duration of the schedule activities and the values of the base cost estimates, with the amount of variability dependent on the degree of ambiguity and accuracy in the schedule and cost estimate data utilized. Uncertainty is embedded in the duration/cost values and transforms deterministic values into distributions. Examples of sources of uncertainty include: cost and schedule estimating assumptions, variable productivity rates, variable material costs, and mobilization problems.

For this study, factors such as variable skill sets and levels of experience, inconsistencies between individual workers at different times, lack of knowledge of/or failure to understand the scope definition of project specifications, and inaccurate assumptions made about “unknown unknowns” are considered and incorporated in the determination of ranges during construction estimations.

Currently the RFR project is within the Class 3 estimate. Based on the Recommended Practice No. 18R-97 (2010) the expected accuracy range for the majority of Class 3 estimates is -20 % to +30 % (AACE International, 2010). This range is referenced and assumed in the “Darlington Nuclear Generating Station (DNGS) RFR Project – Project Estimate Plan.” AACEi warns that the range is heavily dependent on the nature of the uncertainties and the technological complexity involved in a project. For this study, the accuracy range suggested by AACEi was modified for the development of the duration distributions for individual activities included in the JCL model.
In order to provide unbiased uncertainty ranges for cost lines and schedule durations, the following requirements have been deemed important for the development of the MD-JCL model.

1. A high-quality project schedule
2. An estimate without contingency

3.2 Quality Proxy (Radiation Expenditures)

Quality is an objective that can be defined and measured through different channels (e.g., process, procurements, and results) (Takim & Akintoye, 2002). Since labourers have an enormous influence on the quality of the work being executed, it is critical to determine the specifications of factors that impact the quality of their production. In this project, being exposed to radiation plays a crucial role in terms of advanced resource training programs (assurance of overlap between current and future set of labourers), learning curves, number of certified labourers, etc. For these reasons, the linkage between labourers and their exposure to radiation is used as a proxy to represent quality.

The preliminary estimation of the radiation rate is based on task duration, scope of work, and comprehensive work package documentation and incorporates as input the resource requirements as well as the time the labourers remain in the radiated work areas. Current radiation expenditure estimates are derived from historical measurements taken when the unit fuel channel contained fuel and the systems were full of D₂O. For this study, the radiation rate per hour per person is used for calculations involving the feeder removal process. A rolled-up radiation rate is used for activities prior to feeder removal, and 25% of the yearly limit (i.e., 0.25 Rem/person) represents the pre-existing radiation expenditure rate. To obtain more accurate results, the pre-existing radiation rate for all labourers over a five-year timeslot is based on a distribution of possible pre-existing dose rates rather than on a single-point estimate (i.e., the average).

The collective radiation expenditure (pre-existing dose rate + hourly dose uptake) determines the number of labourers that reach the radiation limit as the project progresses. This measurement enables further advance evaluation that incorporates a determination of the number of labourers/resources who require training, which can take up to 2 weeks. This calculation is important because failure to train additional resources before the current resources reach radiation limits can create delays and lead to additional costs.

4 INITIAL STUDIES

For demonstration purposes, eight different cases have been considered. The variation between these cases is a result of variation in productivity rates caused by factors such as including different work-shift designs per worker, which are the following: (A) 40 hours a week, (B) 50 hours a week, and (C) 60 hours a week, and different crew arrangements. The basis of shifts A and B are on a 24/7 schedule and the base of shift C is on work continuum from Monday to Saturday, and Sunday considered as the non-working day. This is shown in the Calendar column of Table 1, with Y being a working and N being a non-working day. The number of crew available in the vault is constant for every shift, however various arrangements of labourers at the workface has been considered and represented by three options: I (i.e., 3 workers remove one feeder), II (i.e., 2 workers remove one feeder), and III (2+1/2 workers remove one feeder) for the feeder removal package specifically. As shown in Table 1, the last row is the deterministic estimation of duration, cost, and proxy for quality (radiation expenditures), based on 50 hours of work per worker and crew arrangement I. In the next step, the deterministic estimations were used as the basis for the Monte Carlo analysis and uncertainty was then incorporated by various probability density functions using @Risk. The output of the Monte Carlo analysis using both MS project and @Risk are presented in Table 1 after 1000 simulation runs for each case. As shown in Table 1, case 1 is the most suited option to be explored in detail.

Figure 1 represents the input distributions for duration and cost for the first two crew arrangements and the magnified figure shows the input distributions for the first case. The minimum, maximum, mean, 5th percentile, and 95th percentile of the distributions are also shown in this chart. The advantages of including the mentioned point estimates are twofold: (1) to comprehend and compare the variations of the outputs as the result of (defined) variations of the input sets, and (2) the ability to estimate the variance between the probabilistic objective values for a certain percentile (confidence level) and the deterministic estimates.

Figure 1: Output Results (Distributions) from the Monte Carlo Analysis using @Risk and MS Project
Based on the results, as the level of confidence increases, the gap between the deterministic objective estimation and the @Risk output becomes wider. As shown in Figure 2, there is a difference of 206 Rem between the deterministic estimation and an 80% confidence level for case 1.

![Figure 2: Cumulative Distribution Function: Quality Proxy-Case 1](image)

Each simulation trial of the proposed model produced a quantified range of parameters that impact project schedule objectives. The combined results of all of the simulation trials enables the development of the joint confidence level for cost, schedule, and quality proxy (radiation expenditures), which contributes to the determination of the best of many sets of parameter values and outcomes, thus achieving the research objectives. Figure below demonstrates the multi-dimensional joint confidence limit for all eight possible cases (8,000 data points). In order to demonstrate the functionality of the model, an 80% confidence level has been selected as the pilot study. The yellow points represent all possible combinations of cost “and” schedule “and” quality that meet jointly the 80% confidence level. The blue point represents the deterministic values for all three objectives, and the red point is a single point estimate representing the 80th percentile for all three objectives (based on 8,000 points) with the following values: duration: 45 days, cost: $5,262,051, and quality: 794 Rem. To note that the x axis is the duration (days), y axis is cost ($), and z is quality (Rem) for the entire feeder removal series.

![Figure 3: MD-JCL for Cost, Schedule, and Radiation Expenditures](image)

As shown in both figures 3 and 4, only 145 points out of the simulated 8,000 points jointly satisfy the confidence level of 80%, which is much less than 20% of the data points. For future work, a deep-dive will be done on the points that satisfied the joint confidence level in order to identify the best possible set of solutions within every case.
5 DISCUSSION OF RESULTS

As discussed earlier, primarily the focus was to look at different “possible” work-shift designs, and by incorporating unique factors and constraints, identify the ones that may result in better sets of project objectives. Since running @Risk resulted in a prolonged schedule, the following interpretations are made: (1) a shift schedule without buffers is unachievable, therefore the expected drift (variations from @risk results) and adherence to schedule can be shown by building in the buffers, and (2) since the drift results in the change of work stage (estimated vs. actual) at every shift (i.e. start and completion), therefore the relationship between the percentage of drift and productivity loss can be identified. However, none of the items above can relate to finding suited shift patterns among many, as it is only the “constant” flow of the labourers to the workface and a generator of a labour productivity number. Looking at alternative cases for labour balance can be one of many solutions to this issue.

Although this model has proven to be advantageous, it entails some limitations which are as follows: (1) validation of models that deal with prediction of (problem) objectives is always challenging and without the availability of proper historical data often impossible or misleading, (2) excessive time is required at this point in time to manually enter all inputs for any realistic project schedule (which can consist of several thousand activities), and finally (3) the quality of the results heavily depends on the quality of the input data.

6 CONCLUSIONS

Multi-objective trade-off problems are one of many challenging areas in the construction industry with many proposed solutions. Accurate Incorporation of various factors and constraints as well as considering the uncertainty around project objectives leads to a more challenging problem to tackle. The variation of estimated and actual project outcomes leads to enormous cost overruns and excessive delays in the planning phase of mega-projects. A good initiative toward solving such trade-off problems is to accurately identify and measure uncertainty around cost, schedule, and other project objectives based on expert judgment and historical data. The functionality and contribution of the proposed multi-dimensional joint confidence limit model is to serve as a simulation platform to produce a flexible Pareto-optimal solution set for possible work shift models by incorporating various related factors such as the impact of work-shift designs on labour productivity and constraints such as radiation limits within a non-deterministic framework.

Abstract: This paper presents a cost normalization framework for the National Health Care Facilities Benchmarking program developed by Construction Industry Institute (CII). Since 2009, The CII has been engaged in developing this benchmarking program with government and industry participants. In the effort, the methodology and process were developed to measure health care capital project performance in terms of cost, schedule, change, space, and best practice. Hospitals are complex building systems that are becoming more challenging with ever changing codes and regulations. Reliable comparison of hospitals built in different regions requires unique normalization approach tailored specifically for health care facilities. A single cost index had not achieved the desired results; therefore a combination of indices was employed to normalize various factors for proper benchmarking. In addition to location, time and currency, space was included for proper benchmarking and performance assessment. This paper covers the issues and challenges of normalizing the costs and spaces associated with health care capital projects, and present a practical example on how cost normalization is applied to a health care capital project. Challenges and considerations which are associated with cost indices applicable to cost normalization are also discussed. This study contributes to a better understanding of cost normalization amongst health care capital projects.

Keyword: Health Care, Benchmarking, Normalization, Capital Projects

1 INTRODUCTION

A methodology adopted for normalization for a first of its kind National Health Care Capital Facility Benchmarking program was developed at Construction Industry Institute (CII). CII has been one of the leading organizations in capital project benchmarking for the last 17 years. CII’s Performance Assessment (previously the CII Benchmarking and Metrics Program) has a database of more than 2300 projects worth over $300 billion of total installed cost (TIC) (CII, 2014). The Health care Benchmarking program is a collaborative effort amongst The University of Texas at Austin’s (UT) Construction Industry Institute (CII), the U.S. Department of Defense (DoD) / Defense Health Agency (DHA), and the U.S. Department of Veteran Affairs (VA) among other health care industry leaders. CII’s health care benchmarking program is one of the many industry specific performance assessment programs.
According to Noah (Kahn, 2009), health care construction has been less affected by economy's fluctuations than residential and non-residential construction sectors. He also mentioned, however, that recent upheaval in economy has forced everyone to re-evaluate health care system capital plans. Therefore, health care industry is looking at means to improve project delivery and process controls (Kahn, 2009). Health care costs continue to grow faster than the economy, and health care is forecasted to be 19.3 percent of Gross Domestic Product by year 2023, up from 17.4 percent in 2013 (CMMS, 2015).

Health care projects are the most complex facilities to design, construct, and operate in Architectural/Engineering/Consultants industry (Enache-Pommer et al., 2010). The proposed CII health care benchmarking research first developed a metrics framework to allow meaningful comparisons of buildings from different areas, regions, and climate/code zones. One of the key components to allow meaningful comparisons in the benchmarking program is normalization methodology. The relative metrics such as cost growth do not require cost normalization for comparison; however in order to benchmark absolute metrics (TIC per square foot) cost needs to be normalized for currency, location and time. The Health Care Facility Benchmarking program has 223 health care specific metrics including 102 absolute metrics. This paper highlights challenges associated with cost normalization for health care facility benchmarking, and describes the procedure associated with cost normalization.

2 LITERATURE REVIEW

It is essential to select appropriate indices for cost normalization in benchmarking. Previous studies have outlined various merits and demerits of published cost indices (Dai et al. 2012, McCabe et al. 2002, and Remer et al. 2008, Nasir et. al., 2014). After comprehensive literature review, two types of indices were identified and categorized as input-based cost indices and output-based price indices.

Input-based indices measure various construction process inputs, such as materials, equipment and labor hours usually referred as change in prices of a fixed basket of inputs. An input index measures the changes in the cost of resources to a contractor and it does not record the change in price to a client. It doesn’t account for technological innovations, productivity changes, contractor’s overhead and profit margins (Mohammadian and Seymour, 1997). In spite of input cost index disadvantages it can be used for identifying trends in resource costs and cost fluctuation in contracts.

Output-based price indices represent price to a client, and therefore is a direct measure of inflation. Output-based price indices are developed through model price index, hedonic price index, and bid/unit price index (Mohammadian and Seymour, 1997). The output-based indices under model price index compare the construction cost of a hypothetical structure by location and/or time (Dai et al., 2012). For example, a Producer Price Index (PPI) for an industry is a measure of changes in prices received for the industry's output sold outside the industry (Bureau of labor Statistics, 2015). Bureau of labor Statistics (BLS) producer price index for new health care building construction (NAICS code 236224) follows North American Industry Classification System (NAICS) index codes is a model price index (Bureau of labor Statistics, 2015). Model price index allows for construction heterogeneity by modeling different common building types, and is more sensitive to market change conditions.

Hedonic price index includes quality of the final product as a measure to construct an index (Mohammadian and Seymour, 1997). In United States, the hedonic price index is used to construct indices for single family homes. Hedonic price indexes may be considered a type of component pricing where the component prices are estimated from a cross-section regression. The indices based on hedonic characteristics for other construction sectors have been largely unsuccessful (Pieper, 1991). Considering the indices characteristics, the model price index under output-based price indices synchronizes well with the construction industry.

Time and location adjustment will cover for escalation and inflation adjustment. Various indices provide multiple options to accomplish time and location adjustment. According to the study on construction cost sources (Table 1) conducted by McCabe et al. (2002), the selection and use of location adjustment
indices (input or output) sometimes appears to be unreliable, resulting in significant variation in cost adjustment.

For time adjustment indices, few studies have reviewed industry specific approach for cost normalization, and in particular there are no past studies for health care facilities cost normalization. Therefore, this study reviewed and compared the existing indices to be used for health care facilities’ cost normalization including Turner Cost Index (TCI, 2015), R.S. Means (RSM-CCI, 2014) Construction Cost Index, Engineering News Record Construction Cost Index (ENR-CCI, 2014), Engineering News Record Building Cost Index (ENR-BCI, 2014) and Rider Levett Bucknall (RLB, 2014) Construction Cost Index. Table 1 summarizes the nature of indices along with process inputs considered by different indices.

3 COST NORMALIZATION METHODOLOGY APPROACH

In CII’s experience of developing similar systems for other industry, the key to success has been participation by industry. The development of health care system followed the same principle. The industry leaders come together to develop a system that is defined by the industry for the industry (Mulva et al., 2014). The normalization process also followed the same model as shown in Figure1.
3.1 Selection of Cost Indices for Normalization

In order to choose appropriate cost indices that can be used for cost normalization of health care facilities, the cost indices reviewed in the literature review are evaluated and compared over time. All listed indices are normalized to reference year 2008 with index value of 100 to investigate the impact of late 2000’s economy downturn as shown in Figure 2. This normalization of cost indices to year 2008 helps select an appropriate index based on their sensitivity to economy changes during recession. These indices represent the spectrum of basket of inputs or most common non-residential building types in U.S.

Turner Cost Index (TCI) shows an extreme reaction to the downturn. It is free resource; however its base year is 1967 (TCI, 2015), and is limited to four observations per year. Very little is known about TCI methodology, including the location it considers for their building index. The reference year for RSMeans historical cost index is year 1993 (index value = 100) as well as the computed value of an index based on the current year. RSMeans is a composite average of material, labor and equipment. It measures variation in costs in the nine most common building types constructed in United States (Dai et al., 2012). According to McCabe et al., (2002), RSMeans cost data includes local multipliers through relative factors of material costs, installation costs as well as the weighted average for total in-place costs for each CSI MasterFormat Division. The study further explained that these multipliers allow for location adjustment across 930 cities (of which 62 are Canadian) as well as across time for the same city. The index also responded to economic slowdown in Figure 2.

Figure 2: Comparison of Normalized Cost Indices in 2008
ENR-CCI and ENR-BCI showed very little variation to economic downturn. ENR uses year 1913 as its reference year. RLB Construction Cost Index presents comparative cost of construction in 12 cities on a quarterly basis. According to RLB (2014), comparative cost index is built on bid cost comprised of labor, material, contractor/subcontractor overhead cost and profit. This index also includes sales and use tax for construction contracts (RLB, 2014). The reference year for RLB index is 2001. CII Performance Assessment (PA) committee and health care steering committee members provide their feedback and share their organization experience on the normalization methodology. In a similar exercise, steering committee participated in a study comparing the behaviour of various indices in relation to 2007-2009 economic slowdown. Based on the literature review, comparison of cost indices and industry experts’ feedback, the cost normalization procedure was developed.

The ability to adjust location to 930 cities, and a relatively recent reference year of 1993 made RSMeans a prime index for location adjustment. It was also used in past studies by CII with success. The time adjustment was preferred through RLB with a reference year of 2001. Its ability to include profit and sales tax meant market conditions were also adjusted with time.

3.2 Cost Normalization Procedure for Health Care Facilities

The comprehensive approach is outlined in a flow chart in Figure 3. The approach to a location that is not covered in the selected index is similar to Hwang et al. (2008). The closest city was chosen based on industry experience. During the data validation process the selection is verified again. The closest city approach is also recommended by RSMeans. RSMeans being an input index, using mid-point of construction for location adjustment is an appropriate approach. In other words, it moves composite average of various construction costs to the new location. RSMeans City Cost Index (RSMCCI) is used for location adjustment in health care normalization.

After the selection of RLB index by steering committee, Bureau of labor Statistics producer price index (BLS-PPI) for new health care building construction was launched. BLS-PPI was presented to the steering committee as an option since it is a health care specific index. BLS-PPI, an output-based model price index based on health care construction was immediately preferred over other methods. The steering committee agreed on BLS-PPI for health care, but PPI index had just come into existence in the year 2012. Therefore a hybrid index was created by CII research team with base year as 2012 for normalizing cost for time.

The time adjustment is done using a hybrid index of RLB Construction Cost Index and BLS-PPI for new health care building construction NAICS 236224. Among all industry experts in the steering committee, there was a consensus on hybrid approach with RLB for the years before 2012.

3.2.1 Currency Conversion

The health care benchmarking system was designed for global benchmarking for health care facilities. Owners are required to provide currency exchange rate to allow for conversion to US currency. Exchange rate is also verified during validation process. This part is designed to accommodate future expansion of health care benchmarking to include foreign health care owners and contractors. National Health Care Benchmarking program project cost is adjusted from the project location to Chicago, which is the baseline location for the health care system. The reason for selecting Chicago as the reference city for health care normalization is to maintain consistency with CII’s use of Hanscomb Means International Construction Cost index (HMICCCI) for international projects in all its previous benchmarking systems. HMICCCI also uses Chicago as its reference city. This will allow seamless expansion of health care benchmarking program to include foreign projects.
Figure 3: Health Care Normalization Method
3.2.1 Location Adjustment

The health care benchmarking system employs an online Performance Assessment System (PAS) for data entry. The mid-point of the construction phase is a mandatory data field before the data entered can be submitted. Without the mid-point of the construction phase, normalization is not possible as the system would not allow benchmarking associate to submit projects into database. However, there are exceptions to mid-point of the construction phase that are only discussed during the validation process. And such exceptions are beyond the scope of this paper. The second mandatory data field is the location of a project job-site. In the absence of a location, the costs are normalized to the combined national average of RLB/BLS-PPI construction cost indices. For a case where mid-point and location is available, RSMeans CCI is used for location adjustment.

3.2.2 Time Adjustment

As discussed earlier, the steering committee for health care benchmarking and CII decided to use RLB/BLS-PPI for time adjustment for health care normalization. The BLS-PPI for health care was launched in the year 2012, and therefore, most health care organizations are not familiar with it. The index for NAICS 236224, New Health Care Building Construction, is the latest measure developed and published by PPI as a part of its Nonresidential Building Construction (NRBC) initiative (BLS.gov, 2015). Under NRBC initiative indices yield a national weighted average of output price changes. According to BLS website, BLS-PPI includes an array of health care buildings such as hospitals, mental hospitals, infirmaries, hospital infrastructure (buildings for radiology, CT/MRI, radiation therapy, etc.), medical clinics, medical offices, medical labs, doctor and dentist offices, outpatient clinics, research labs (non-manufacturing, non-educational, or non-hospital), nursing homes, hospices, orphan homes, sanatoriums, drug clinics, rehabilitation centers, rest homes, and adult day-care centers. BLS-PPI is a type of model price index where these models represent typical health care buildings constructed in each of the four major census regions. According to BLS website, multiple health care models were developed to accommodate regional variations in building design. CII health care benchmarking program also follows the same four census regions to categorize projects geographically.

4 NORMALIZATION PROCEDURE EXAMPLE

A hypothetical example is presented for better understanding of the cost normalization procedure for health care facilities. Amongst diverse cost types, TIC is used in an example to present normalization procedure. The different types of costs such as procurement cost, management cost etc. are adjusted with different indices. The currency conversion is excluded as health care benchmarking program is focused within the U.S.

A hypothetical health care project (TIC= $50,000,000) in Indianapolis is considered for this example. Assuming the project was built in 2007, and associated costs need to be normalized to year 2014. The breakdown of the cost is presented as shown in Table 2.

<table>
<thead>
<tr>
<th>Cost Category</th>
<th>Local Currency</th>
</tr>
</thead>
<tbody>
<tr>
<td>Total Installed Cost (TIC)</td>
<td>$50,000,000</td>
</tr>
<tr>
<td>Capital Medical Equipment</td>
<td>$10,000,000</td>
</tr>
<tr>
<td>Total A/E and Construction management Cost</td>
<td>$5,000,000</td>
</tr>
</tbody>
</table>

Table 2: Breakdown of Cost

Total installed cost (TIC) is defined as the total actual project cost (excluding the cost of land) from Programming/Front-end Planning through commissioning, including capitalized amounts expended for in-house salaries, overhead, travel, etc.
• Step 1: Location Adjustment (from Indianapolis to Chicago in 2007)

The procurement and management cost are subtracted from TIC before location adjustment (Table 3). The assumption is that equipment and management cost doesn’t vary with location as the equipment procured and the design teams are generally not located at the location of the construction site of health care facility.

Table 3: TIC Adjustment for Location

<table>
<thead>
<tr>
<th>Cost Category</th>
<th>Amount in 2007 Indianapolis</th>
</tr>
</thead>
<tbody>
<tr>
<td>TIC</td>
<td>$50,000,000</td>
</tr>
<tr>
<td>Capital Medical Equipment</td>
<td>$10,000,000</td>
</tr>
<tr>
<td>Total A/E and Construction management Cost</td>
<td>$5,000,000</td>
</tr>
<tr>
<td>Net Cost to be normalized for location</td>
<td>($50,000,000-$10,000,000-$5,000,000) = $35,000,000</td>
</tr>
</tbody>
</table>

$35,000,000 out of TIC of $50,000,000 will be adjusted for location (Table 4). The rest is capital medical equipment and management cost. These cost items are only adjusted for time.

Table 4: TIC Adjustment for Location

<table>
<thead>
<tr>
<th>Cost Category</th>
<th>Amount (2007)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Net Cost to be normalized for location</td>
<td>$35,000,000</td>
</tr>
<tr>
<td>(Indianapolis2007)</td>
<td></td>
</tr>
<tr>
<td>Location Index Indianapolis - 2007</td>
<td>158.5</td>
</tr>
<tr>
<td>Location Index Chicago - 2007</td>
<td>191.9</td>
</tr>
<tr>
<td>Location Adjustment</td>
<td>=35000000 x (191.9/158.5)</td>
</tr>
<tr>
<td>Adjusted TIC (Chicago 2007))</td>
<td>= $42,375,394</td>
</tr>
</tbody>
</table>

• Step 2: Time Adjustment (from 2007 to 2014 in Chicago using RLB/BLS-PPI)

With this normalization procedure, the health care project database allows for meaningful comparison among projects within the health care framework. The health care framework and algorithms attributed to selecting similar projects are essential in comparisons of health care projects constructed in different location and/or time. Time and location adjustment of various costs is also critical for comparisons. The current process has been validated by the steering committee for health care benchmarking which is comprised of industry experts. Table 5 presents three costs that need time adjustment. They are adjusted TIC (Chicago 2007), capital medical equipment and management cost which are still in Indianapolis dollars (2007).
Table 5: TIC Adjustment for Time

<table>
<thead>
<tr>
<th>Cost Category</th>
<th>Total Amount 2007</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adjusted TIC (Chicago 2007)</td>
<td>$42,375,394</td>
</tr>
<tr>
<td>Capital Medical Equipment (Indianapolis 2007)</td>
<td>$10,000,000</td>
</tr>
<tr>
<td>Total A/E and Construction management Cost (Indianapolis 2007)</td>
<td>$5,000,000</td>
</tr>
<tr>
<td>Total Cost to be normalized for Time</td>
<td>($42,375,394 +$10,000,000+$5,000,000) =</td>
</tr>
<tr>
<td></td>
<td>$57,375,394.32</td>
</tr>
</tbody>
</table>

Total cost $57,375,394.32 in 2007 needs to be adjusted to year 2014. The adjusted TIC (Chicago 2007), capital medical equipment and management cost can also be adjusted for time separately and added later. It will provide the same result.

Table 6: TIC Adjustment for Time

<table>
<thead>
<tr>
<th>Cost Category</th>
<th>Amount in 2007 Indianapolis</th>
<th>Amount in 2014 Chicago</th>
</tr>
</thead>
<tbody>
<tr>
<td>Net Cost to be normalized for Time</td>
<td>$57,375,394.32</td>
<td></td>
</tr>
<tr>
<td>RLB/PLS-PPI Index Chicago</td>
<td>94.8</td>
<td>104.5</td>
</tr>
<tr>
<td>Time Adjustment</td>
<td>= $57,375,394.32 x (104.5/94.8)</td>
<td>$63,246,083.40</td>
</tr>
</tbody>
</table>

As shown in Table 6, $63,246,083.40 is an adjusted TIC normalized to year 2014 and city Chicago. The project’s actual TIC was $50,000,000 in the year 2007 constructed in Indianapolis.

5 CONCLUSION AND PATH FORWARD

Normalization is essential for meaningful comparison. Through literature review on existing cost indices and feedbacks from industry experts, the cost normalization procedures was designed to normalize costs associated with health care projects for the first time. Its efficacy and accuracy can only be validated over time. As stated earlier, the initial validation from health care industry experts have been positive. Health care normalization procedure is different than other industry specific benchmarking systems developed by CII. The published indices have inherent challenges based on their accuracy, compilation method, and reference years. Indices are also not able to capture cost variations due to the regulatory environment, site conditions, and change in code requirements.

Current normalization procedure is susceptible to these drawbacks. However, there are improvements over the past in the procedure developed for the health care benchmarking. The use of RLB/BLS-PPI allows for market conditions to be captured for the first time. Health care benchmarking system collects costs by Construction Specification Institute’s (CSI) divisions. It uses the RSMeans - CSI cost index. Using the CSI index, health care benchmarking system could accommodate productivity data for numerous trades. As in the past, it was a challenge and a shortcoming for normalization procedures as they lacked indices supporting productivity data. According to Goodrum (2001), the CSI index provides unit labor costs, unit equipment costs and physical output data. Labor costs are based on the average wage rates from 30 US cities and the equipment costs on rental rates plus operating costs (Goodrum, 2001).

The use of RSMeans - CSI index will allow for productivity factors in normalizing costs for the first time in CII’s history. The adjustment of space for the final metric calculations is also unique to health care
benchmarking program. As previous studies indicated that the selection of an appropriate indices are critical to valid methodology. A shift in model price index for time adjustment is a positive step in health care normalization methodology. The current scope of this paper did not cover the methodology for CSI and space based adjustment in detail. Study will next focus on challenges associated with CSI and space based adjustment for health care normalization methodology.

A DATA ANALYSIS FRAMEWORK FOR OPTIMIZING OCCUPANT ENERGY USE WHILE SUSTAINING INDOOR ENVIRONMENTAL QUALITY

Tanzia Sharmin1,2, Mustafa Gül1, and Mohamed Al-Hussein1

1 Department of Civil and Environmental Engineering, University of Alberta, Canada
2 tanzia@ualberta.ca

Abstract: Sustaining standard indoor environmental quality (IEQ) is a crucial factor in promoting occupant health and comfort, and a significant proportion of a facility’s energy use is directed toward indoor climate control. Meanwhile, because operation of facilities accounts for a large share of the world’s energy consumption, it has warranted increased interest in efforts to design facility energy management systems that reduce energy consumption. In this context, facility managers aim to achieve the optimal balance between occupant comfort and overall energy consumption. The objective of this paper is to demonstrate a framework that assists facility managers in identifying residential occupant activities that influence energy consumption and also ascertaining any correlation or sequential activities patterns and their association with respect to IEQ. This work is facilitated by the installation of various sensors in a case study, the “Stony Mountain Plaza” project in Fort McMurray, Canada. It is expected that the extracted information and strategies acquired from the framework can be implemented within the facility management system to achieve financial, environmental, and health benefits.

1 BACKGROUND

Generally speaking people spend most of their time indoors in a home or workplace (US Bureau of Labor Statistics 2006), a trend which rings especially true for cold climatic regions like Canada, where winters are cold and long (Statistics Canada 2001). A national survey on Canadian human activity patterns conducted in 2010–2011 indicates that the average Canadian spends 90% of their time indoors, most of which is at home (Matz et al. 2014; Public Health Agency of Canada 2010). Notably, these indoor spaces, which are considered to be safe and secure shelters, for many can become a cause of serious health problems because of poor indoor environmental quality (non-standard CO₂ level, RH level, and/or indoor temperature) (Sharmin et al. 2014). It is observed that, in addition to external air sources, building materials, and furnishings, one of the major influences on indoor environment is occupant activities. Studies indicate that occupant appliance usage (including faulty usage) and comfort-related choices (use of HVAC, electrical duct heating, energy recovery ventilation, window opening patterns) affect indoor environmental quality (IEQ) and may cause indoor air contamination (Building Air Quality 1991).

Meanwhile, operation of appliances and maintaining of occupants’ desired indoor temperature requires considerable energy. In 2007, Canadian households consumed a total of 1,368,955 TJ (terajoules) of energy and in 2011 there was a 4% increase to 1,425,185 (TJ) (Statistics Canada 2011). Statistics indicate that improper use of appliances (both in residential and commercial facilities) accounts for a substantial share of total energy wastage; however, a 30% reduction in energy consumption can be
achieved by eliminating wastage in facilities, which underscores the need for an effective building management system (BMS) to manage/control operational energy usage without compromising occupant comfort.

Along with technological advancements there is a growing interest in improving the intelligence of facilities by means of sensor-based building management systems capable of collecting vast amounts of building-related data. However, it should be considered that in order to take advantage of such systems, all the relevant observations need to be extracted, since less than optimal building performance may be encountered when energy use information is inadequate. Recent studies indicate that adapting different monitoring systems, using modern, energy-saving technologies and providing appropriate feedbacks to building occupants can reduce energy consumption by up to 20% (Abrahamse et al. 2005; Darby 2006; Chetty 2008; Vassileva 2012). However, very few research studies have considered examining occupant behaviour for energy management (Haas 1998). Although sustainable development require behavioural awareness (Wood 2007; Abrahamse, 2007), depending only on occupant behaviour cannot be considered an effective solution. Instead what is required is a holistic user-centric control strategy for building management (Jiang 2009).

This study aims to provide greater insight into occupant activity patterns and their effect on energy consumption and IEQ in order to equip BMS with an effective user-centric energy and IEQ management strategy. This study proposes a framework to extract useful observations pertaining to occupant energy usage patterns by means of sensor-based monitoring, using the case study of a four-storey multi-family residential facility in Fort McMurray, Alberta, Canada. Previous research by the authors has involved extract useful information by studying correlations among occupant activities. In this study, the authors investigate occupant activities to determine whether any sequential activity patterns exist, as well as to identify any correlations among activities, or between activities and IEQ. It is expected that these observations will enhance BMS through effective energy and IEQ management.

2 OBJECTIVE AND METHODOLOGICAL APPROACH

2.1 Objective

The objective of this study is to propose a methodological approach for extracting useful information from sensor-based monitoring for the purpose of user-centric energy and IEQ management of a multi-family residential facility. The study first aims to identify the most significant occupant activities affecting overall household energy consumption. Occupant energy usage patterns are also investigated for different unit types (different directional orientations and unit sizes), based upon which occupants can be categorized based on usage patterns. This study further considers identifying occupants’ sequential energy usage patterns and the correlations among them by analyzing time-ordered energy usage measurements. It is expected that these information will assist facility managers to understand occupant energy load and estimate future energy demand so they can plan accordingly. Facility managers will also be able to calculate internal heat gain from occupant activities in order to estimate optimized heating energy requirements. It is expected that this research will yield insightful observations of occupant energy usage, which may in turn be useful in shaping energy and IEQ management strategies.

2.2 Methodology

To achieve the above mentioned objective, a sensor-based monitoring system is developed to measure occupant operating energy and IEQ. In order to investigate whether occupant energy usage patterns and IEQ are affected by unit characteristics, this study measures occupant usage patterns from different unit types. At each floor of the four-storey case study building, 1 ‘one-bedroom’ unit facing north, 1 ‘one-bedroom’ unit facing south, and 1 ‘two-bedroom’ unit facing north are selected as case units. The sensor network is designed such that sensors are installed and data is collected from these 12 case study units. In order to ensure anonymity, in this study, the case study units are assigned codes (numbered 1 through 12). Figure 1 shows a schemata of the sensors used and their locations in a case ‘one-bedroom’ unit. The locations and types of sensors installed in the ‘two-bedroom’ units are similar to those of the ‘one-bedroom’ units. Table 1 shows the data collected by the installed sensors.

3 ENERGY AND IEQ MANAGEMENT FRAMEWORK

This section describes the energy and IEQ management framework (Figure 2) for observing occupant energy usage patterns by analyzing real-time data collected from case study units during regular operation of the building. The framework first identifies the activities which are the main contributors to energy consumption in the case study units. These energy usage pattern are then studied with respect to different unit types in order to identify the impact of unit size (floor space), directional orientation, and elevation (floor level) on energy usage. This study investigates occupant activity patterns in terms of (1) sequence of related activities and mining of sequential activities, (2) repetition of sequential activities over a period of time, and (3) correlation among different daily activities. Since in this study all occupant activities observed are in the same building, it is possible that they will have a direct/indirect influence on one another (Yu et al. 2011). In order to understand the relationships among different activities and to develop appropriate management strategies, this framework encompasses investigation of the associations and correlations among different activities.

![Figure 2: Energy and IEQ management framework](image)

It is expected that studying time-ordered sequential occupant energy usage patterns and correlations among them will assist in the development of a BMS that takes into account occupant energy load and that can estimate future energy demand by predicting upcoming actions using observed historical data. This energy demand information can be used to develop an appliance scheduling scheme, by taking advantage of the time-varying retail pricing. In many cases utility costs (space heating, electricity, water heating) are included in monthly rental costs of a given unit in a multi-unit facility. Thus, unlike with individual houses where occupants pay for utilities in addition to housing (mortgage or rental) costs, tenants in multi-family facilities may not have a financial incentive to reduce energy consumption (Levinson 2004). Studies indicate that tenants behave differently when they rent apartments with utilities included opposed to if they have to pay energy costs separately from rent (Sjögren, 2007). In this context the proposed framework can suggest separate utility payment for a given unit and also can set consumption limits for a given unit if any irregular occupant usage pattern is identified. The framework also allows for estimation of internal heat gain from occupant presence and activities. It is considered that
radiation from people (Wp) is 4.8 W/m², from equipment (We) is 14 W/m², and from lighting (Wl) is 11.6 W/m² (Grini et al. 2009). Estimating internal heat gain from occupant presence and activities is important for calculating optimum heating energy needed (Papakostas, 1997).

Based on this monitoring the BMS is also able to detect any non-standard IEQ. The ASHRAE guideline suggests that indoor CO₂ levels should not exceed 1,000 ppm (Quinn 2011), since occupants continuously living with elevated CO₂ levels may face health problems such as headaches, fatigue, and eye and throat irritation (Wyon and Wargocki, 2006). Also according to ASHRAE, relative humidity (RH) level should be maintained between 30% and 60% since non-standard RH can aggravate allergies and asthma by increasing the growth of mould, bacteria, and dust mites (Quinn 2011). By identifying relationships between occupant activity pattern and IEQ, the BMS can detect the cause and can take proper measures to address it. Moreover, it is expected that this framework will provide insightful information regarding occupant energy usage patterns and associated IEQ, which can be useful for enhancing energy management while maximizing occupant comfort.

3.1 Energy Usage Pattern for Different Units Types

Studies have identified that a building’s physical parameters play a significant role in the variation observed in energy consumption in different households (Branco 2004; Jeeninga, 2001). In order to determine whether energy consumption patterns vary between north-facing and south-facing units or between ‘one-bedroom’ and ‘two-bedroom’ units, electricity, heating, and water consumption patterns for three different group of units (north-facing ‘one-bedroom’ units, south-facing ‘one-bedroom’ units, and north-facing ‘two-bedroom’ units) are observed. Figure 3 shows that electricity and water consumption are comparatively low in north-facing ‘one-bedroom’ units compared to north-facing ‘two-bedroom’ and south-facing ‘one-bedroom’ units; (it should be noted that some usage data from units is unavailable due to sensor malfunction). Heating energy consumption is comparatively high in north-facing ‘two-bedroom’ units compared to ‘one-bedroom’ units (both south- and north-facing).

![Figure 3: Heating, electricity and water consumption pattern for different unit types](image-url)
Figure 4: Energy usage patterns of different activities for different unit types
Figure 4 shows that, for the above three groups, (representing both ‘one-bedroom’ units and ‘two-bedroom’ units), hot water tank (14%-35%), lighting (13%-19%), and refrigerators (10%-15%) are high energy consumers. It is observed that heating energy consumption is comparatively higher in ‘two-bedroom’ units (14%-18%) than in ‘one-bedroom’ units (2%-13%), presumably due to the larger size of these units. It is also found that south-facing units have lower heating consumption (2%-9%) than north-facing units; solar heat may be the reason for lower heating demand in the south-facing units. With the major energy consuming factors related to occupant usage patterns identified for a multi-family residential facility, it is possible for the facility manager to set energy usage limits for each unit.

3.2 Correlation and Sequential Energy Usage Pattern and their Association with IEQ

A study of the daily energy usage data shows that different sequential activity patterns can be observed among occupants. For example, it is observed that when kitchen plugs are in use (presumably for the purpose of food preparation), the range and range hood fan are found to be in operation shortly afterward (Figure 5). It is also observed that during that time kitchen lighting is also turned on. Data also shows that when bathroom lighting is on, water consumption tends to take place during the same timeframe. These sequential activity patterns for specific units can be used to develop a predictive sequential energy usage pattern model. Facility managers can use this information for estimating future-state energy load for improved energy management.

![Figure 5: Sequential activity pattern](image1)

![Figure 6: Internal heat gain associated with activity pattern](image2)
Correlations across different activities and their association with IEQ can be observed from the measured data. For instance, it is also observed that during the time the above mentioned food preparation activities are performed, the internal heat gain from kitchen appliances increases the indoor temperature even though heating consumption is low for that specific time (Figure 6). Facility managers can take into account this information regarding internal heat gain while estimating heating load. Analyzing recorded data identifies that the apartments generally show peak electricity consumption during hot water consumption (Figure 7). Furthermore, when water consumption is high in a given unit, relative humidity is also high for that unit. It is also observed that the indoor CO₂ level is significantly affected by occupant energy recovery ventilation usage patterns (Figure 8).

![Figure 7: Peak electricity consumption and IEQ associated with water usage pattern](image)

![Figure 8: IEQ associated with occupants' ERV usage pattern](image)
Occupant presence and absence patterns can also be observed by studying the data. Figure 9 shows that occupants of unit 3 were not at home for two days (January 3-5, 2013). It is also observed that three Sundays of this month show higher CO₂ concentration and heating and water consumption, which indicates higher demand during that time. This information can assist building managers to understand demand load for effective energy management.

4 CONCLUSION

The framework presented in this study demonstrates the use of real-time sensor-based data to support identification of occupant energy usage patterns and associated IEQ in order to improve energy and IEQ management. The knowledge generated from this study can be used to assess the demand load and timing of peaks loads. Aggregating the energy demand for all occupants in the multi-family building can assist with the development of an energy demand profile. Accordingly, the BMS can propose an appliance scheduling scheme based on time-varying retail pricing. This information can be used to estimate the internal heat gains (from occupants, office equipment, and lighting) in order to calculate the energy needed to maintain adequate comfort levels. Through the combination of these knowledge the BMS will be able to minimize the consumption of resources while maintaining a comfortable IEQ level.

Abstract: Building and facility asset management is a strategic approach to the optimal capital and operational spending on assets to ensure control of cost and risk, asset life, performance, and stakeholder satisfaction. The decisions for sustainable building operations and infrastructure asset management ultimately rests on owners, stakeholders and building occupants. This paper introduces SocioBIM, an approach for building occupants to interact with their building and to provide valuable feedback to the building management. Our research takes advantage of the state-of-the-art and the state-of-practice Building Information Modeling (BIM) technologies, sustainability assessment techniques, advanced analytics, decision support systems, and integrator platforms. The valuable insight derived from SocioBIM can solve important issues related to model-reality performance gaps, post-occupancy evaluation, sustainability and service level assessment, sustainable building operations and facility asset management. Furthermore, SocioBIM adds value and provides improved competitive advantage to any asset management organization.

1 INTRODUCTION

There has been considerable and well-documented concern about the current state of Canada’s infrastructure (Froese & Vanier 2014), and this warning applies to many of the developed countries of the world. With respect to buildings infrastructure and their sustainable operations and management, the model-reality performance gap and failed post-occupancy and sustainability assessment techniques are the major problems with the current sustainability paradigm identified by many researchers in the field of sustainable building science (Froese 2014):

“In the current paradigm, sustainability is often achieved by assessing models of building performance during the design phase. However, these predictions often fail to agree with the facilities’ post-construction performance, and actual performance of many green buildings has been poor. Further, post-occupancy assessment techniques themselves are often weak, using inaccurate, un-validated tools and sampling strategies inconsistent with statistically significant results. The consequence is that we are currently re-tooling the built environment industry to meet sustainability goals in a way that, in many cases, is not succeeding.”

Froese and Vanier (2014) believe that the solution to the challenges associated with sustainable management of infrastructure lies in the investigation of the following three technical domains:

- Sustainability assessment for infrastructure: To build upon emerging frameworks to develop practical and meaningful techniques for evaluating the sustainability of infrastructure assets.
• Advanced analysis and decision-support for infrastructure management: To provide analysis and decision support that is compatible with—but extends beyond—the capability of current software. The focus includes performance prediction, multi-objective optimization, and data visualization.

• Integrator platform: To develop, test and validate a software system related to decision support and sustainable infrastructure that is compatible with existing commercial systems, integrates disparate data sources, and provides a platform to analyze and visualize infrastructure management data.

This paper introduces SocioBIM, an effective approach for building occupants to interact with their building and provide valuable comments and feedback to the building management, as the decisions for sustainable building operations and asset management ultimately rests on owners, stakeholders and building occupants. The paper presents a preliminary research and conceptual approach for SocioBIM that the authors are currently pursuing. Our research takes advantage of the state-of-the-art and the-state-of-practice Building Information Modeling (BIM) technologies, sustainability assessment techniques, advanced analytics, decision support systems, and integrator platforms [1].

2 BUILDING AND FACILITY ASSET MANAGEMENT

Building and facility asset management is a strategic approach to the optimal capital and operational spending on assets to ensure control of cost and risk, asset life, reliable performance, and stakeholder satisfaction (E. Teicholz 2013). “Asset and property managers are faced with many difficult decisions regarding when and how to inspect, maintain, repair and renew their existing facilities in a cost-effective manner” (Vanier 2000). To enhance making these challenging decisions at different operational, tactical and strategic levels, asset managers need to collect and run analytics on key data systematically to create business intelligence (E. Teicholz 2013). Furthermore, a Knowledge-based BIM has the capability to enhance the competitive advantage of a facility management organisation (Charlesraj 2014).

Facility management is knowledge and information intensive and relies heavily on historical information as well as operational data. To effectively collect and manage such a variety of data for sustainable asset management decision making, data support is required in all phases of the building life cycle, including assessment (sustainability audit, condition assessment, and data gathering), planning (cost/benefit analysis, scope & goal setting, and budgeting), implementation (process documentation and execution, and organizational buy-in) and management (certification, documentation and reporting, and policy management) (E. Teicholz 2013). The insight derived from such a variety of data can be used to answer the following key questions (E. Teicholz 2013):

• What investments are needed in repairs, renewals, and modernizations?
• Which investments should be made with limited funds?
• What are the risks and outcomes of investments made and not made?
• How can those risks be managed with proper investment?

Conventional building and facility management answer these questions in an unsatisfactory way. The conventional management approach would induce high risk, high costs and inferior performance such as: inability to locate the nearest shut-off valves after a water pipe break, overlooking ordering spare parts for a faulty elevator, or failure to access proper exit procedures in the time of a natural disaster or fire (Xu & Zhang 2013). Recently, Building Information Modeling (BIM) has become the preferred method for not only the design of buildings, but it is also gaining a foothold in the domain of building operations and management. BIM creates a digital database of all building assets and can serve as virtual 3D coordination of the construction and operational activities (Liao et al. 2012). Furthermore, BIM techniques are used during post-occupancy evaluation to effectively promote work efficiency of the operation organization, improve quality of service to customers, reduce emergency situations, improve safety, and reduce waste. The post-occupancy and operation phase of buildings and facilities is said to be the most important period of the building’s whole life cycle (Liao et al. 2012).

For example, Frankfurt Airport started using BIM for its operations and facilities management in 2003 to manage more than 2.4 billion Euro worth of a multitude of asset types, property, plant and equipment (Exton 2003). The Frankfurt BIM system aggregated existing documents and large and complex sets of
facility data to form a federated database that is visualized through interactive facility maps. This enabled the engineering, finance, operations, maintenance, security and emergency response teams to visualize mission critical facility information through interactive facility maps, to find relevant data more quickly, and to minimize operations downtime (Exton 2003).

Nonetheless, most BIM models utilized for facility management incorporate asset property information and building inspection data including: asset geometry, spaces, location, age, condition and scheduled maintenance. Moreover, the data is typically gathered by designers, building managers or building inspectors whose works are costly and, more often than not, do not address the concerns of building occupants.

3 SocioBIM – A NEW PARADIGM FOR SUSTAINABILITY ASSESSMENT OF THE BUILT ENVIRONMENT THROUGH INHABITANT ENGAGEMENT

Almost all applications of BIM to date have been targeted at professional users—designers, contractors, facilities managers, etc. While it is appropriate that these are the main users for BIM, this approach excludes an important segment—non-professional or general public users and, in particular, building occupants or infrastructure users. We refer to approaches that link BIM with the general public as “SocioBIM”, an approach for building occupants to interact with their building and its assets and to bring their own view of the issues on the table.

SocioBIM approaches not only strive to make information from BIM models available to the public for appropriate uses and in appropriate ways, but it also strives to obtain input from the public, largely by linking the technology of BIM with the technologies of social interaction, i.e., social networking. This approach goes beyond maintenance issues: SocioBIM provides a means for the end-user to interact with the BIM model and to provide invaluable social information necessary for the sustainable operation of the building. With reference to any particular component (asset) of the building, SocioBIM can provide the building occupant with the ability to:

- Comment on both design issues and service levels
- Comment on the usability, functionality and performance of any asset,
- Comment on the maintenance issues and asset condition,
- Comment on the decorations and visual appearance,
- Comment on indoor climate and raise concerns on socio-environmental issues,
- Express their feelings and sentiments about their living/work condition, comfort level and well-being,
- Make recommendations and propose solutions to existing problems,
- Provide their perceived value of the sustainability features,
- Make recommendations for upgrades and improvements, and
- Attach relevant photos, videos and voice memos or any other document to the comments.

This data can be input and stored for each asset in a BIM model and be accessed, viewed, and evaluated by the facility manager.

3.1 SocioBIM Benefits – Sustainability Assessment & Post Occupancy Evaluation:

SocioBIM exploits Building Information Modeling (BIM) technology to provide a holistic computational platform for integrated sustainability assessment. SocioBIM converts “occupants” (passive recipients) to “inhabitants”, who have a sense of place in, and engagement with, the building. It addresses the sustainability issues by measuring performance of the building after occupancy and the level of service as perceived by inhabitants.

The aim of SocioBIM is to exploit advances in computational sustainability and BIM to empower inhabitants to engage and participate in the operation of their facilities and take control of their management in real-time to optimize their well-being. In fact, SocioBIM shifts "snap-shot", "one-time" or
“discrete” measurement techniques (such as surveys and interviews) to “continuous” assessment techniques and “real-time” monitoring systems.

SocioBIM assists in comparing operational performance with predicted performance and identify “performance gaps”, strengthening understanding of how innovative green buildings are performing once built, assessing whether they are meeting expectations, and identifying the design lessons that can be learned from these buildings. Furthermore, SocioBIM helps with understanding the interactions between comfort factors (thermal, acoustic, lighting) with inherent trade-offs that affect occupant health, comfort and the environmental sustainability.

In fact, SocioBIM leads to more sustainable building operation and facility management, increased occupant well-being, enhanced level of service assessment, and greater community investment in sustainable solutions.

3.2 SocioBIM Benefits – Sustainable Building Operation & Facility Management:

Other valuable insight derived from SocioBIM that can solve important issues related to sustainable building operations and facility management include (Jensen 2008; Hungu 2013):

- Flexibility and ability to adapt to the changing needs of inhabitants over time;
- Enhancement in maintaining the facility and the surrounding area;
- Improvement in health, safety and security of the facility, people and assets;
- Optimization of energy and resource consumption (electricity, heating, cooling, water etc.);
- Greater assessment of socio-environmental impact;
- Enriched assessment of level of service;
- Better analysis of indoor climate and working conditions; and
- Informed decisions on facility management and procurement of new systems.

Therefore, facility managers, using the information received from the building occupants, can better plan for the maintenance of individual assets and assess the social impact of their decisions: from the type of light bulb in any particular fixture to the socially responsible investments decisions using a holistic information system.

4 SocioBIM DATA MANAGEMENT AND ANALYTICS

The SocioBIM database, containing data from building occupants can be comprehensive and include data from all other types of sources: facility inspectors and streamed data sensors, all of them feeding social, environmental, economic, condition and operation data. The analytics performed by the facility manager on this data could include descriptive analytics (what has happened), diagnostic analytics (why it happened), predictive analytics (what will happen) and prescriptive analytics (what, when and in what order are the best courses of action).

The vast potential data sources, however, need to be prepared for analysis. Although some information collected from users may be fully structured data, much of it may be unstructured. To prepare the data received from the previously described sources, we are considering employing advanced computing science techniques such as text mining and machine learning. Therefore, the design of the data-structure system to receive and store the data in the SocioBIM database is an important factor on which we are currently working on. Text comments may include many types of the occupant’s concerns mentioned above such as usability, performance, condition, visual appearance, maintenance issue, sentiments, and recommendations. Therefore, some of the design consideration for the comment analytics tool include:

- understanding the database structure,
- performing data analytics on the structured data of the database (e.g. priority rating),
• performing text analytics on the comment section (unstructured part of the database) and ability to break down the comments into different sections: e.g. usability, performance, condition, visual appearance, maintenance issue, sentiments, and recommendations, and
• performing further text analytics to present statistical inference on individual sections to answer important questions such as: what is the overall performance of an asset based on users' comments, how do users feel about a particular asset and how to adapt to their changing needs over time.

5 SocioBIM INTEROPERABILITY

Additional work is also needed to research the interoperability between different systems in SocioBIM: the BIM model, the data management system and the facility management system. As the data may not be entered into one single model, the data needs to be relayed from the upstream for downstream system use and the systems need to be updated to reflect the changes made. Our research to date has reviewed the applicability of the following multiple approaches to data integration (P. Teicholz 2013):

1. Capture the data into a spreadsheet: This option is mostly suitable for small projects and lacks formal structure. This approach may be prone to errors due to absence of a validation mechanism.

2. Use the Construction Operations Building information exchange (COBie): This option is convenient but does not provide graphic data to show where equipment is located.

3. Create two-way links between the BIM model and the facility management systems: This option is suitable for integrating graphic views with the data (e.g. EcoDomus system).

4. Have direct integration of BIM with the facility management system using APIs: In this option, graphics data is updated in BIM and the data is entered into COBie or directly into the facility management system. A cloud-based server can also be implemented to access data content from anywhere.

Our approach to interoperability between data systems, BIM model and the facility management systems is to develop a cloud-based SocioBIM application interacting with external dynamic databases for facility management systems.

6 USER- SocioBIM INTERACTION

Our research also explores user-SocioBIM interaction. We are considering today's technological advancements in mobile computing and systems (smartphones and tablets) to enhance the process. These smart devices are equipped with powerful CPUs, touch screens, and wireless communication technologies. The integration of BIM with a smart device provides time and location convenience, ease of way-finding, detailed visualization of building components, improvement with identification of issues, and fast interaction with the model (Kim et al. 2013). This in turn translates into an effective SocioBIM management system. To showcase SocioBIM, we are considering development of applications based on the Building Information Model server (BIMserver.org) platform. We have identified the following user-interface scenarios for our applications:

A. An interface for the administrators to manage users, IFC building models, and comments left by the users. The data will be dynamically exported to other facility management software for processing.

B. An interface for the building occupants to view IFC building models, select assets within the models, leave a comment for a particular asset, and view comments posted by others.

C. A dashboard for facility managers to perform and visualize analytics on the data and comments stored in the database.
7 CONCLUSION

Sustainable building and facility management is knowledge and information intensive and relies heavily on a variety of information provided by the building occupant, inspectors and sensor feeds. SocioBIM can enable the development of a knowledge management system that can effectively be used for problem solving and decision making by incorporating the valuable information provided by the building occupant. The user-interface developed for SocioBIM would facilitate user interaction with the BIM-based knowledge management system. The building or facility asset manager could run queries in SocioBIM to retrieve appropriate information provided by the building occupant and perform analysis on the data. This would lead to not only enhanced and real-time sustainability assessment, service level assessment and post-occupancy evaluation, but also identifying the design lessons and greater community investment in sustainable building solutions. Hence, SocioBIM adds value and promises improved well-being of building inhabitants and competitive advantage to sustainable operation of any building or facility management organization.

SYSTEM DYNAMICS MODELLING FOR AN URBAN WATER SYSTEM: NET-ZERO WATER ANALYSIS FOR PEACHLAND (BC)

Gyan K. Chhipi-Shrestha¹, ², Kasun Hewage¹ and Rehan Sadiq¹
¹ School of Engineering, University of British Columbia, Canada
² Gyan.Shrestha@ubc.ca

Abstract: A Net-zero water (NZW) community limits the consumption of freshwater resources and returns water back to the same watershed, so as not to deplete the groundwater and surface water resources of that region in quantity and quality over the course of a year. A NZW study includes the analysis of various combinations of water supply sources, water conservation, and reuse over time. Such dynamics can be modelled by using system dynamics. This article aims to develop a system dynamics model (SDM) to achieve NZW at the urban community level. The SDM was developed by including all life cycle stages of urban water using STELLA® software. The developed SDM was validated using the historical data of Peachland water consumption (BC). Moreover, the model was applied to analyze NZW of the Peachland community during 2015-34 by considering six different scenarios. In the base case scenario, two thirds of the supplied water will be used for irrigation and will not be directly available to the community for reuse. As the community is in a semi-arid region, the Peachland community can only achieve NZW or even net-plus water for the initial five years by considering Peachland as a typical urban community without agriculture, and by implementing various water efficiency improvement measures. However, due to the projected increase in water demand, the NZW cannot be achieved after 2019.

1 INTRODUCTION

1.1 Urban Water Systems and Peachland

The world’s urban population is more than half (~54%) of the total population and is expected to increase rapidly (UN DESA 2014). In Canada, the urban population is very high (~ 81%) and is growing (Statistics Canada 2014a). The growing population requires a large volume of water served by the urban water supply. Urban water processes, such as water abstraction, treatment, distribution, wastewater treatment, disposal, and stormwater drainage are essential in any urban area. They are necessary for the human consumption of safe water and reduction of environmental impacts due to wastewater discharge (Termes-Rifé et al. 2013). These human regulated urban water processes constitute a human hydrologic cycle (Bagley et al. 2005), or simply an urban water system (UWS).

The District of Peachland (DoP) is located in the Okanagan Valley, British Columbia (BC), Canada. The DoP covers an area of 17.98 square kilometres (DoP 2008). The estimated population of the DoP is 6320 in 2014 with an annual population growth of 6.5% (Statistics Canada 2014b). The public water is supplied from two creeks (Trapanier Creek and Deep Creek), Okanagan Lake, and two Ponderosa wells (groundwater) (DoP 2007). Major consumers of the municipal water are residential (indoor and outdoor) buildings, agriculture, public parks, golf courses, and commercial and institutional sectors. The
wastewater generated from the water use is treated at the Westside Regional Wastewater Treatment Plant and then discharged to Okanagan Lake.

1.2 System Dynamics Model (SDM) for Urban Water Systems

System dynamics is a well-established methodology to quantify complex feedbacks in system interactions (Forrester, 1961; Forrester, 1968). The system dynamics model (SDM) is often used to quantify system behaviors with feedback loops for more accurate projections (Qi and Chang 2011). The model allows for the effective trade-off analysis of multi-scenarios and the multi-attributes of UWSs over time (Sehlke and Jacobson 2005). A SDM can help users better understand and express how complex systems function through visualization and computer simulation (Sehlke and Jacobson 2005). System dynamics involves the construction of “causal loop diagrams” or “stock and flow diagrams” to mimic a dynamic system. System dynamics has not been explored much in water demand estimation studies (Qi and Chang 2011; Zarghami and Akbariyeh 2012).

1.3 Net-Zero Water (NZW) Analysis

The concept of net-zero water (NZW) is similar to the carrying capacity of a system (Holtzhower et al. 2014). NZW refers to the balance of water demand and supply within a given areal boundary (Holtzhower et al., 2014). The US Army states that “net-zero water limits the consumption of freshwater resources and returns water back to the same watershed so not to deplete the groundwater and surface water resources of that region in quantity or quality over the course of a year” (US Army 2011). The central theme of NZW emphasizes a balance so that the sum of all input water is offset by comparable output water (Joustra and Yeh 2014). NZW presupposes that a community system can secure an adequate water supply within its boundaries, typically from surface water, groundwater, reclaimed water, and rainfall (Holtzhower et al. 2014). Achieving net-zero water similar to the natural cycle requires both the conservation of water and the creation of balanced water feedback loops (Joustra and Yeh 2014).

A recent report published by the US National Research Council showed that “The use of reclaimed water to augment potable water supplies has significant potential for helping to meet future needs, ….” and also recommended potable reuse with or without an environmental buffer as an alternative water management approach (National Research Council 2012). Similarly, water recycling for the augmentation of drinking water supplies has been promoted by the Australian government, who published guidelines for reclaimed water quality management (EPHC/NHMRC/NRMMC 2008). Also, in Canada, the provincial government of British Columbia has planned for the mandatory construction of dual water-plumbing (additional purple pipes for reclaimed water flow) in new buildings (MoE 2008). These initiatives show an increasing aspiration for reclaimed water use. This research develops a system dynamics model for the urban water system of Peachland and analyze its potentiality to achieve NZW.

2 METHODOLOGY

The system dynamics model for the UWS of Peachland was developed by using STELLA® software (Karamouz et al., 2012; Qi and Chang, 2011). The SDM includes three sub-models: population, water, and wastewater sub-models. These sub-models and NZW analysis method are described below:

a. Population Sub-model

The population dynamics of the District of Peachland was analyzed using the population growth equation as given in Equation 1 (Nasiri et al. 2013). The data required for the population sub-model, such as base population, population growth rate, and dwelling size were obtained from Statistics Canada (2014b).

\[ N_t = N_0 e^{rt} \]

where \( N_t \) = population in a month, \( N_0 \) = Base population, \( r \) = population growth rate (monthly), \( t \) = time duration in months
b. Water Sub-model

The water sub-model represents the flow of supplied water within the Peachland community. The water flow occurs through the urban water stages: abstraction, treatment, distribution, and use. The water use dynamics was modelled using Equation 2. The equation includes the water consumed by different activities of the urban sectors: residential; industrial, commercial, and institutional (ICI); agricultural; public parks; and golf courses over time.

\[ \text{(Water use)}_t = \text{(Residential water use)}_t + \text{(Agricultural water use)}_t + \text{(Institutional water use)}_t + \text{(Commercial water use)}_t + \text{(Industrial water use)}_t + \text{(Parks and golf courses water use)}_t \]

where “\( t \)” refers to a month

The rates of water consumption by different residential indoor activities were obtained from modified Mayer et al. (1999). The extensive study on the end uses of residential water also included Canadian cities. The efficiencies of conventional and efficient water fixtures and appliances were obtained from Mayer et al. (1999), ENERGY STAR (2014a), and ENERGY STAR (2014b). The rate of irrigation demand for different land covers such as agriculture, lawns, community parks, and golf courses of the Okanagan valley (OBWB 2010) was used for Peachland. The agricultural land area (121.6 ha) was estimated from the land use map of Peachland (DoP 2008). The average maximum site coverage of lot area is 48% for different types of residential buildings with an average lot size of 1178 m² in the district (DoP 1996). The site not covered by building structures or paved areas is required to be landscaped. Based on these requirements, the average lawn area per dwelling unit was considered as 50% of the average lot size. In addition, the area of community parks is 14.49 ha and new neighbourhood development is required to maintain a community park of 3.04 ha per 1000 population (DoP 2014a). Also, a golf course of 0.6 ha is located in Peachland (Ponderosa Golf 2015). The rates of commercial and institutional (CI) water use were obtained from the CI water use studies by US EPA (2009) and Dziegielewski et al. (2000). The data on the present industrial, commercial, and institutional floor space and their future growth were obtained from (DoP 2012). However, Peachland has no major industries (DoP 2012).

c. Wastewater Sub-model

The wastewater dynamic was modelled in the wastewater sub-model. This sub-model includes wastewater (WW) collection and its treatment for residential and ICI sectors.

\[ \text{(WW)}_t = \text{(Residential WW)}_t + \text{(Industrial WW)}_t + \text{(Commercial WW)}_t + \text{(Institutional WW)}_t \]

Where “\( t \)” refers to a month

d. Net-Zero Water Analysis

The potentiality of Peachland to achieve net-zero water was analyzed using the developed SDM. Equation 4 was used for the analysis.

\[ \text{(Net water)}_t = \text{(Water use)}_t - \text{(Rooftop rainwater harvested)}_t - \text{(Greywater reused)}_t - \text{(Reclaimed water use)}_t - \text{(Stormwater harvested)}_t \]

Where “\( t \)” refers to a month

The average monthly rainfall data of the past 35 years (1980 to 2014) of the nearby meteorological stations of Penticton and Kelowna (Government of Canada 2015) was used for the estimation of rooftop rainwater harvesting and stormwater harvesting potential.

Prior to the development of a complete SDM, a causal loop diagram (CLD) was developed. A CLD is a foundation of a SDM, and is used to identify relationships between individual system components and to show feedback loops that affect system regulation (Nasiri et al. 2013). The CLD of the SDM of the
Peachland UWS is given in Figure 1. In the CLD as shown in Figure 1, a “+” sign indicates a positive (reinforcing) relationship between two variables. An increase in the arrow tail variable causes an increase in the arrow head variable. A “-” sign indicates a negative (balancing) relationship between two variables. An increase in the arrow tail variable causes a decrease in the arrow head variable (Nasiri et al. 2013). Based on the CLD, a SDM was developed. The SDM was validated using the historical monthly data of municipal water consumption by Peachland from 2010 to 2014.

Figure 1: Causal loop diagram of the urban water system of Peachland

3 RESULTS AND DISCUSSION

3.1 System Dynamics Model for the Peachland UWS

The monthly water consumption of Peachland was simulated for five years from 2010 to 2014. The result was compared with the historical data of Peachland (DoP 2015) and is shown in Figure 2. The coefficient of determination ($r^2$) of the model is 0.85, which is high and is acceptable. Both historical data and SDM result showed an equal average water consumption of Peachland: 1104 L/capita/day for the five-year duration. In particular, the average residential water consumption of Peachland from 2010 to 2014 was 711 L/capita/day based on the SDM. The residential water consumption of Peachland is very high compared to the Canadian average of 343 L/capita/day (Environment Canada 2014), British Columbia average of 490 L/capita/day, and Okanagan valley average of 675 L/capita/day (OBWB 2011). The important causal factor for high residential water consumption by Peachland may be a low density residential neighbourhood with a large area of outdoor landscaping. For example, a minimum lot size of a single family residential building is $1350 \text{ m}^2$ (0-25% slope) to $4000 \text{ m}^2$ ($\geq 35\%$ slope) in an area without sewer connection and is $830 \text{ m}^2$ in an area with sewer connection and can have a maximum site coverage of 40%. Also, a site not covered by building structures or paved areas is required to be landscaped (DoP 1996). In addition, neighbourhood developments are required to maintain the standard of 4.04 ha parks per 1000 population (neighbourhood parks of 1.01 ha and community parks of 3.04 ha) (DoP 2014a).
Figure 2: Comparison of historical (real) and modelled data of monthly water consumption from January 2010 to December 2014

Furthermore, the slight variation of the peak water use in the real and modelled data (Figure 2) could be due to the difference in irrigation water demand. Due to the lack of the monthly irrigation pattern of Peachland, the SDM model used the monthly irrigation rate derived from combining the total annual irrigation rate of the Okangan valley and the monthly irrigation pattern of British Columbia (BC). The monthly irrigation pattern of Peachland may be different from that of the BC average. The accuracy of the model can be improved by using the location specific irrigation rate of Peachland. However, the model’s generalizability will be decreased.

The sectorial water consumption of Peachland from 2010 to 2014 estimated by the SDM is shown in Figure 3. As shown in the Figure, the major water consumer was the residential sector consuming about 65% of the total water supply. In this sector, approximately 37% of the total water was used for irrigating outdoor lawns. The next dominant water consumer was agriculture with about 25% of water consumption. The remaining water was used by ICI sector (5.7%) and community parks and golf courses (4.8%). The ICI sector also includes water uses such as firefighting, street sweeping, system flushing, sewer flushing, and culvert flushing.

Figure 3: Water consumption by different sectors in Peachland 2010 to 2014
3.2 Applications of the Proposed SDM

3.2.1 Prediction of Water Demand

The SDM was applied for the prediction of water demand of Peachland. The total water demand under the base case scenario was simulated for 20 years from 2015 to 2034. The result of the simulation is shown in Figure 4. The total water consumption of 2,772.5 ML/year of 2015 will be gradually increased to 8,220.8 ML/year in 2034. In particular, a high population growth rate of 6.5% per year (Statistics Canada 2014b), a large area of landscaping requirement for residential buildings even in a semi-arid region, a rapid growth rate of 8.3% per year of the commercial and institutional sectors (DoP 2012), and 121.6 ha (6.8% of total land area) of reserved agricultural land (DoP 2008) will demand increased water in the future. In this period, approximately two thirds of water (66%) will be consumed by irrigation including residential outdoor lawns (39%), agricultural land (22%), and community parks (5%). This water is not directly available to the community for reuse. Water license is a permit issued to water users by government authority. The license permits water users to withdraw a given quantity of water in a specified time period (e.g. per year) at maximum from particular water bodies such as lakes, creeks and rivers. Although the District of Peachland has a water license of 17,587.0 ML/year from local lakes and creeks (DoP 2014b), which even exceeds the water demand of 2034, water demand is greatly increasing. In addition, the licensed volume of water does not guarantee the availability of water in sources and only indicates the maximum limit of water withdrawal. In turn, the water availability in the creeks of Peachland is decreasing (Harra, Johnson, and Cohen 2011). Therefore, Peachland needs to plan for sustainable urban water management.

Figure 4: Water demand of Peachland from 2015 to 2034

3.2.2 Net-zero Water Analysis of Peachland

Peachland is located in a semi-arid region. The potentiality of Pechland to achieve NZW was analysed using the developed SDM. Six different scenarios were developed for the analysis. These scenarios are shown in Table 1.
Table 1: Scenarios for net-zero water analysis

<table>
<thead>

<td>6B</td>
<td>Typical urban setting of Scenario 6A</td>
<td>Scenario 6A without considering agricultural water use</td>
</tr>
</tbody>
</table>

The results of scenario analysis for achieving NZW from 2015 to 2034 are presented in Table 2 and Figure 5. As shown in Table 2, the average annual freshwater withdrawal of the UWS gradually decreases from Scenarios 1 to 6. The freshwater withdrawal and water use can be reduced by about 10% by using efficient water fixtures and appliances (Scenarios 1 to 2). However, water withdrawal and use can be reduced by 40% from Scenarios 1 to 3 by using efficient water fixtures and irrigation demand reduction. Peachland can reduce up to approximately 80% of freshwater withdrawal by using harvested rainwater, recycled greywater, treated wastewater (black water), and harvested stormwater (Scenario 6A compared to Scenario 1). Moreover, considering a typical urban setting without agriculture (Scenario 6B), Peachland can reduce up to 90% of water withdrawal by implementing similar measures to those of Scenario 6A.

A typical urban community has no agriculture. The NZW and even net-plus water can only be achieved in Scenario 6B, a typical urban Peachland community (without considering agriculture) for the initial five years from 2015 to 2019 (Figure 5). The annual net-plus water will be approximately 246 ML, 193 ML, 137 ML, 77 ML, and 12 ML from 2015 to 2019 respectively, showing a decreasing trend due to increasing water demand. In a net-plus and NZW condition, the water withdrawal by a community is less or equal to its discharge to the same watershed. In Scenario 6B, the NZW can be achieved by taking the following measures:

- Reduction of per capita water demand by using efficient water fixtures and appliances
- Irrigation demand reduction through xeriscaping, water efficient crops, and efficient irrigation
- Residential water conservation by behavioural change
- Water supply by rooftop rainwater harvesting for portable purposes (≈149L/cap/day)
- Greywater recycling in houses and use of the recycled water for non-potable purpose and some portion for potable use if freshwater is not supplied (≈126L/cap/day)
- Wastewater (black water) recycling and use of the recycled water for non-potable purposes (≈64L/cap/day)
- Stormwater harvesting, treatment, and use for non-potable purposes (≈95L/cap/day)

4 CONCLUSIONS

The system dynamics model for the urban water system of Peachland was developed and validated using the historical data of the monthly water consumption of the Peachland community. The developed model was applied to analyze the net-zero water potentiality of the community by considering six different scenarios from 2015 to 2034. In the base case scenario, two thirds of the supplied water will be consumed by irrigation and will not be directly available to the community for reuse. Moreover, the community lies in a semi-arid region having less precipitation. For these reasons, multiple measures are required to achieve net-zero water in the community. In particular, Peachland can only achieve net-zero or even net-plus water for the initial five years when Peachland is considered as a typical urban community without agriculture (Scenario 6B). In the five-year period, the net-zero water can be achieved by using efficient water fixtures, efficient water appliances, efficient irrigation, behavioural water
conservation, reclaimed water use, rooftop rainwater harvesting, and stormwater harvesting (Scenario 6B). However, due to the projected increase in water demand, the NZW water condition cannot be achieved after 2019.

MODELING EARLY PAYMENT DISCOUNTS AND LATE PAYMENT FEES WITH SINGULARITY FUNCTIONS

Yi Su\textsuperscript{1} and Gunnar Lucko\textsuperscript{1}

\textsuperscript{1} Department of Civil Engineering, Catholic University of America

\textbf{Abstract:} Cash flow management is a vital concern of construction contractors. To break its vicious cycle of ‘pay as late as possible, get paid as early as possible’ in which the project participants may engage to their mutual detriment, potential incentives and disincentives that are used in financial transactions should be systematically investigated. Both are time-dependent functions that define a discount or surcharge based on whether a transaction is performed before or after a deadline. They can thus be expressed by so-called singularity functions, which are activated on said cutoff date. The new model expands prior research on cash flows by linking early (prompt) payment discounts – for which a practical nomograph is provided – directly with their counterpart of late payment fees. The values of both can be calculated from the individual financing interest of the participants to assess different scenarios based on their relative time value of money. They thus gain the ability to make financially informed decisions on offering a discount and imposing a fee appropriately, and accepting the discount or incurring a fee, respectively.

1 INTRODUCTION

Cash flow management is crucial for the success of a project, especially from the profitability perspective. Furthermore, the timely issue of cash flow is critical for all participants in the project. However, different participants’ motivations will lead to diverse behaviours. From a viewpoint of the time value of money (TVM), the payer (participant who pays bill) has the intention to pay late and less if possible, whereas the payee (participant who sends bill) wants to receive payment earlier and more if probable (Su and Lucko 2014b). To a certain extent, the payer’s intention has been realized in construction projects. For example, due to the motivation that the owner requires satisfactory performance from the contractor, retainage and bill-to-pay delay terms are ubiquitous in contractual payment requirements. As a result “the contractor tends to act as financier until the later stages of the project” (Green 1989, p. 55). Worse, pay when/if paid terms and delayed pay seriously impede payees, e.g. first and second-tier subcontractors, and may also create negative consequences for payers: Both public and private owners faced complaints from contractors and subcontractors that they did not receive the pay in a timely manner (Sweet \textit{et al.} 2014). In public projects, according to the Federal Prompt Payment Act, “a contractor must pay its subcontractors for satisfactory performance within seven days of receiving payment from the federal agency. Failure to pay on time subjects the contractor to an interest fee owed to the subcontractor. Subcontractors have the same obligation to pay sub-subcontractors.” (Sweet \textit{et al.} 2014, p.349). In private projects, unpaid contractors and sub-contractors may even have mechanic’s liens on properties (Construction Report 2014), which could make owed payments becoming more enforceable (Sweet \textit{et al.} 2014). Fairness in both timely business transaction is important for the success of projects, which “the contractor should not be required to complete work at a loss, and the owner should not have to pay more than a reasonable amount of profit on any given item” (Gransberg and Riemer 2009, p. 1140). As a result, the fairness of the
contractual payment term should be considered from both the payer’s and payee’s perspectives. As Table 1 shows, the possible deals between payer and payee are either earlier payment with a discount or late payment with a fee, where the former term prompts the payer to pay in a less but earlier manner, while the latter requires the payer to pay more if it pays later.

2 LITERATURE REVIEW

Hill and Rien (1979) modeled a situation that a retail firm offers a discount to those customers who pay their bills earlier than others and searches its optimum discount. The model relied upon assuming that some customers wish to take a discount, while others do not. However, without a bilateral motivational explanation of the feasibility of such discount, such hypothesis of randomness does not explain why they wish to take a discount. As de la Garza and Melin (1986) noted, the construction contract should permit prepayment to mitigate inflation. Ng et al. (1999) systematically analyzed early payment discount terms across various industries, and summarized the factors ruling behind. Touran et al. (2004) researched how prompt payment provisions influence the profitability of contractors in the transportation area. Cui et al. (2010) considered early payment discount in a system dynamics model for cash flow and derived macro-level strategies, however, the micro-level was is omitted, which may encumber its application in industry. Kouvelis and Zhao (2012) explored the discount term (trade credit) between supplier and retailer by using game theory. Yet the precondition – newsvendor-like retailers – is inapplicable for a construction contract, wherein the work scope is explicitly defined. Al-Hussein et al. (2013) advocated floor and ceiling discount concepts for construction transaction, but its utilization is also hindered by lacking a theoretical foundation.

Late payment fee is the counterpart to discount, which many companies do not spell out explicitly. A reason may that the company does not wish to antagonize its customers. This is similar to charging fee for overdue payment of credit card. Another analogy is charging a fee if paying tax or filing a return after the deadline: “If you pay your taxes late, the fee is usually ½ of 1% of the unpaid amount for each month or part of a month the tax is not paid... This fee is in addition to interest charges on late payments” (IRS 2013, p. 91). For construction, the law requires that a “prime contractor who violates the law (prompt pay) is subject to licensing disciplinary action and must pay the subcontractor a fee of 2 percent per month in addition to normal interest” (Sweet et al. 2014, p.349). Su and Lucko (2014b) comprehensively explored the mechanism of prompt payment discount using a synthetic cash flow model with singularity functions, but omitted the early payment fee. A gap exists in comprehensively analyzing and unifying the financial phenomena of early payment discount and late payment fee. For this three Research Objectives are set:

1. Expand the synthetic cash flow model to suit both the early payment discount and late payment fee;
2. Explore mathematically the range of conditions for different values of the feasible late payment fee;
3. Chart graphically in form of nomographs these feasible ranges of conditions for the late payment fee.
MODEL CASH FLOW WITH SINGULARITY FUNCTIONS

A central issue in defining early payment discount and late payment fee is fairness for both sides, which “the payee wants to offer and the payer wants to take” (Su and Lucko 2014b, p. 8). It requires a method that can effectively and efficiently calculate the net cash flow for both payer and payee under different discount or fee rates on early or late pay periods. Previous methods fall short of balancing between them: A chronological approach calculated the balance of cash flow at the end of each period by treating actual simultaneous transactions (charging interest and receiving pay) sequentially by inserting an infinitesimal time $\varepsilon$ (Elazouni and Metwally 2005; Halpin and Woodhead 1998). This is accurate, but lacks efficiency, because it is not formularized. As a result, calculating ‘what if’ scenarios with this chronological method has to arduously repeat the process. Even though it can be automated with computers, vital relations among those variables cannot be easily explored, especially to identify dominant effects. On the other hand, previous studies focused on computational efficiency of numerous types of cash flow models, e.g. linear programming (Yang et al. 1993) or heuristics (Alghazi et al. 2012; Neumann and Zimmermann 2000). Their problem was opposite to the chronological method; omitting or simplifying central details of cash flow to make the model simple enough to be implemented with a computationally efficient algorithm. For example, financing interest, retainage, and periodical phenomena were omitted from some models, which impeded the reliability and realism of their output. An ideal cash flow model should reflect essential characteristics and also provide an advantage in terms of computational efficiency, following the moniker ‘as simple as possible, as complicated as necessary’ as advocated by Ockham’s razor (c. 1287-1347).

3.1 Singularity Functions

Each basic term within singularity functions per Equation [1] is symbolized distinctly by pointed brackets. It performs one case distinction by evaluating the current value of the independent variable $y$ (here time, for consistency with previous research) as to whether it is smaller than the cutoff value $a$ or not. If so, it remains at zero, otherwise it is activated by treating the pointed brackets as round brackets of traditional algebra. The independent variable $z(y)$ here is cost. The exponent $n$ determines the behavior (i.e. shape) of the curve once active; low orders often suffice in models, e.g. $n = 0$ for a step or $n = 1$ for a slope. The factor $s$ then determines the intensity (i.e. strength) and takes its exact meaning from said behavior. Equation [1] can be integrated and differentiated in analogy to traditional calculus. A complete singularity function is the summation of basic terms per Equation [2], where $i$ is a running index within their count $m$.

$$z(y)_{\text{basic}} = s \cdot (y-a)^n$$

for $y < a$

$$z(y)_{\text{basic}} = s \cdot (y-a)^n$$

for $y \geq a$

$$z(y)_{\text{ng}} = \sum_{i=1}^{m} s_i \cdot (y-a_i)^{n_i}$$

3.2 Synthetic Cash Flow Model

The arduousness of a chronological approach reduces its calculating efficiency. Yet calculating the TVM of cash flow is very important for accuracy. A particular phenomenon, periodicity, can be exploited to aid in the formalization: Since progress pay and month-end interest are initiated periodically, then the timing of month-end balances with TVM can be modeled if such repeatable cash flows are modeled by defining a ‘signal’ function. Another concept of viewing a balance, the ‘investment pool’ of engineering economics, is also helpful for the formalization, whereby the balance with TVM is equal to the difference of the future values of cost and of pay at the same time (Park 2011). This new cash flow model was called a ‘synthetic cash flow model’, to distinguish it from traditional chronological balance calculation (Su and Lucko 2014a). The synthetic cash flow model is a group of functions that formalizes variables of cash flow as parameters in equations. Figure 1 shows the steps of the synthetic cash flow model, where general input parameters at the activity level are: $z$ is the dependent variable of cost, total cost $C$, markup $M$, retainage $r$, monthly interest $i$, $y$ is the independent variable of time, duration $D$, shift $d1$ and delay $d2$, bill period $p$,
bill-to-pay delay b, planned start as and finish aF, where \[ a^*_s = a_s + d_1, \quad a^*_F = a_F + d_1 + d_2 \] (Su and Lucko 2014a).

### Figure 1: Steps of Synthetic Cash Flow Model with Singularity Functions

#### 3.2.1 Signal Functions

Signal functions can control a periodic phenomenon like receiving progress pay and charging month-end interest. They are generated by introducing round down \( \lfloor \cdot \rfloor \) and up \( \lceil \cdot \rceil \) operators into the terms with the independent variable y. They work as follows: The term \( \lfloor y \rfloor - a \) is a step function that turns on when y equals a, while the other term \( \lceil y \rceil - (a + 1) \) is also a step function, but turns on when y is just larger than a \((a + 0.000...1)\). Their difference returns a periodic signal. Figure 2 shows the case when the cutoff a is 0: Here \( \lfloor y \rfloor - 0 \) has right-continuous jump discontinuities per Figure 2(a) as represented by solid and hollow circles, whereas \( z_2 = \lfloor y \rfloor - 1 \) has left-continuous jump discontinuities per Figure 2(b). Figure 2(c) is the profile of subtracting (b) from (a), which gives a periodic. Its period, amplitude, and start and finish can be controlled with additional parameters (Su and Lucko 2014a, Su and Lucko 2013). To apply it to a pay signal and charging interest signal per Equation [7] and [8], the bill period p affects the cycle time of the pay signal, it is applied as a divisor (since interest is monthly, the divisor 1 is omitted in Equation [8]). A virtue of signal functions is that it allows the cutoff a to be any fractional number. Thus if an activity start or finish \( a^*_s \) and \( a^*_F \) are fractions of periods due to shifts and delays, Equations [7] and [8] can model fractional signals at period boundaries. This allows potential integration of signals with schedule research.

### Figure 2: Mechanism of Signal Function
The document contains mathematical equations and text discussing pay and cost functions in the context of a financial model. Here is the transcription of the key parts:

### Pay Functions

Since each signal is a value between 0 and 1, multiplying it with the intensity factor performs a periodic sampling. Defining a cost intensity factor $C \cdot (1 + M) / (D + d^2)$ returns each pay per Equation [9]. Note $p$ is for both integer and non-integer bill period cases. To subtract retainage, Equation [10] calculates the retained amount at each pay time and Equation [11] is the pay with retainage, releasing the accumulated sum of the retained amount when the project is finished. Treating the result from Equation [11] as the principal, Equation [12] calculates the future value of pay at any time during the schedule.

### Cost with Interest Functions

Analogous to pay, applying an exact interest formula (Lucko 2013), the future value of cost is calculated by introducing a charge interest signal into the exponent terms per Equation [13]. Different from Equation [9], it is multiplied with an intensity factor $C / (D + d^2)$, because cost does not include markup or retainage.

### Balance Functions

After obtaining both the future values of pay and cost, and applying the aforementioned 'investment pool' concept, Equations [14] and [15] give the balance with TVM, which is the last step in Figure 1. Note that Equations [7] through [16] compose the synthetic cash flow model, whose steps have been explained. Note that all individual equations that are explained for this synthetic cash flow model can be inserted into an overall equation to ultimately return a single general balance function, which is omitted here for brevity.
4 EARLY PAYMENT DISCOUNT

An early payment discount is the first deal between payer and payee in Table 1. Its feasibility has been discussed in previous research by the authors (Su and Lucko 2014b), as is summarized in the following.

4.1 Floor Discount

The lower limit of the early payment discount is called the floor discount, which would be affected by the payer’s interest rate. No matter how generous the discount is, this is the minimum that has to be so that the payer wants to take it (otherwise no deal will be possible). Note the new parameters in the synthetic model, where \( l \) is the early pay period and \( \rho \) is the discount rate (e.g. 2 / 10, net 30, \( l = 10 \) days and \( \rho = 2\% \) base on bill). Here ‘\( \rho / l, \text{net } b \)’ means that the payer can pay the bill less a discount \( \rho \) if paid within \( l \) days, or pay the full amount within \( b \) days. The pay signal shifts leftward by \( b - l \) days. Its cost intensity factor must be \( C \cdot (1 + M) \cdot (1 - \rho) / (D + d) \). As a result, it would use the payer’s interest rate to calculate the future value of pay for both early and normal pay scenarios, to let the former be smaller than the latter per Equation 17. Only in this case it is favourable for the payer to pay earlier but less from a TVM view. The floor discount is also the payer’s indifference discount, because taking it or not has the same effect.

\[
\begin{align*}
\text{floorF} & = \text{payF} \cdot F(\text{pay disc}) \quad \Rightarrow \quad \rho_{\text{floor}} = 1 - (1 + i_{\text{payer}})^{-b} \\
\text{ceilingF} & = \text{balanceF} \cdot d(\text{disc balance}) \quad \Rightarrow \quad \rho_{\text{ceiling}} = 1 - (1 + i_{\text{payee}})^{-b}
\end{align*}
\]

4.2 Ceiling Discount

Similar to the floor, the ceiling discount is the upper limit of the early payment discount, which is defined by the payee’s interest rate. Because no matter how urgently the payer wants to accept a discount, if the payee does not want to offer it, it is still infeasible. In this case, one must compare the balance function of the payee between early and normal pay scenarios, to let the former be larger than the latter per Equation 18. It models that the payee earns more if the payer pays earlier. Since cost is not affected by taking the discount or not, Equation 18 is further simplified to comparing future pay functions for both scenarios. As a result, the ceiling discount has the same pattern as the floor discount. It is also the payee’s indifference discount, because it has the identical effect for the payee, regardless whether the payer takes it or not.

\[
\begin{align*}
\text{balance disc} & \geq \text{balance} \quad \Rightarrow \quad \rho_{\text{ceiling}} = 1 - (1 + i_{\text{payee}})^{-b}
\end{align*}
\]

4.3 Feasible Early Payment Discount Term

The condition for the feasibility of the early payment discount is that the floor discount should be lower than the ceiling discount per Equation 19. Substituting the results from Equation 17 and 18 into this condition returns a simple result: As long as the payer’s interest is lower than the payee’s interest, there exists a feasible range for the discount. Note that not only the feasible discount range can be calculated from the equation; the feasible early pay period \( l \) can also be computed. For example, assume the payer’s interest is 4\%, payee’s 8\%, and the payee wants to give a ‘\( p / 10, \text{net } 30 \)’ discount. Per Equation 20, the feasible discount range is 2.5808\% to 5.0013\%. If the payee wants to offer ‘\( 2 / l, \text{net } 30 \)’, the feasible early period per Equation 21 is any integer time between 15 and 22 days. Users who know two early payment discount variables for their particular case can thus directly calculate the third value using these formulas.
5 LATE PAYMENT FEES

A late payment fee is the second deal between payer and payee in Table 1. This lets the payer pay later but more. From the view of construction law, the term ‘fee’ paid from the owner to the contractor is similar to ‘liquidated damage’, by which the contractor compensates the owner for delaying the project finish time.

5.1 Floor of Late Payment Fee

Note the new parameters in the synthetic model, where \( l \) is the period between the time of normal pay and late pay and \( i' \) is the fee (e.g., \( b = 30 \) days, if pay is overdue, charging \( i' = 2\% \) monthly interest). From the payee’s view, the balance of the delay situation should be larger or at least equal to the normal case per Equation [22]. Solving it returns an apparent result that the late payment fee should be at least equal to the payee’s financing interest, which serves as the floor value of the fee. Moreover, from the payer’s view, a fee actually could have two effects for the payer: It is favorable for the payer to pay late rather than on time per Equation [23]. Or it is favorable for the payer to pay on time per Equation [24]. Obviously, from the payee’s view, wanting the fee can lead the payer to select the second case. Two scenarios of inequalities for \( i_{\text{payee}} \) and \( i_{\text{payer}} \) exist (assuming that the payer borrows to pay): If \( i_{\text{payee}} < i_{\text{payer}} \), then the payee requires a late payment fee between the range of \( \{i_{\text{payee}}, i_{\text{payer}}\} \), and the payer will pay late, because the fee is smaller than their own loan interest. Here the floor fee should be at least larger than \( i_{\text{payer}} \). Otherwise if \( i_{\text{payee}} > i_{\text{payer}} \), then the floor fee is applied. The floor fee is the maximum of \( i_{\text{payee}} \) and \( i_{\text{payer}} \) per Equation [25].

\[
\begin{align*}
C \cdot \left(1 + M \right) \cdot \left(1 - r \right) \cdot \left(1 + i' \right) \cdot \left(1 + i' \right) & \geq \frac{C \cdot \left(1 + M \right) \cdot \left(1 - r \right) \cdot \left(1 + i' \right) \cdot \left(1 + i' \right)}{D + d_2} \\
\end{align*}
\]

5.2 Ceiling of Late Payment Fee

A ceiling of the late payment fee must exist to guarantee fairness for both sides and because a mere punishment is not allowed by courts. However, different from the early pay case, from both payee’s and payer’s views per Equations [22] (payee’s balance of late pay should be larger than the balance of the normal pay case) and [24] (payer’s late pay should be larger than in the normal pay case), both conclude

\[
\begin{align*}
\end{align*}
\]
the same direction of the inequity (≥). As a result, both $i_{\text{payer}}$ and $i_{\text{payee}}$ define $i_{\text{floor}}$. This lacks the condition to define $i_{\text{ceiling}}$. An open-ended late payment fee will increasingly resemble a punishment, not liquidated damages. A possible solution for this is to set a ceiling fee by negotiations between payer and payee.

5.3 Nomograph for Both Discount and Fee

An early payment discount per Equations [17] and [18] has the variables $i$, $l$, and $b$, which can be plotted as nomographs to show their relationships among each other. Since $i$, $l$, and $b$ have two types of units (% from $i$ and time units from $l$ and $b$), two nomographs can be plotted: Interest-discount and time-discount. In the interest-discount nomograph per Figure 3, each line shows how discount changes with growing interest for a specific early pay period case. Since $i$ is the independent variable and exponent $l - b$ is the constant of each line; the profile of each line is essentially a power function. It monotonically increases, because the derivative of such power function is positive. To use this nomograph, first select the line for the planned $l$ value. Second, find the payer’s $i$ (4%) and payee’s $i$ (8%) on the horizontal axis. Third, find the cross on the $l = 10$ profile. Finally, draw a horizontal line crossing the vertical axis to find the floor and ceiling discounts. For the late payment fee, since $i_{\text{payee}}$ is larger than $i_{\text{payer}}$, so the $i_{\text{floor}}$ should equal $i_{\text{payee}}$.

The time-discount nomograph per Figure 4 switches the horizontal axis with time. Each profile represents how discount changes with growing early pay period for a specific interest case. Since the variable $l - b$ in the exponent is the independent variable and the base $1 + i$ is a constant, each line will be essentially an exponential function. It monotonically decreases, because its first order derivative negative.

![Figure 3: Interest – Discount Nomograph](image1)

![Figure 4: Time – Discount Nomograph](image2)

6 CONCLUSIONS

On-time pay is a serious issue for both payee and payer, which directly affects the economic success of the former and keeps project running smoothly for the latter. This paper started at two possible deals that could be made between payee and payer in the payment terms: Early payment discount defines a case that lets the payer pay promptly (before the due date) less a discount, and late payment fee regulates the
opposite case that add an extra charge to the pay if the payer pay the bill late. To analyze such situations, it has established a cash flow model that can model them effectively and efficiently. A synthetic cash flow model was presented as a group of equations with singularity functions, which was explored in previous research by the authors. Then conditions for the feasible early payment discount and late payment fee have been calculated from the cash flow model. They can also be plotted in nomographs, which provide a deeper understanding for such payment terms and helps project participants to make rational decisions.

STRUCTURING THE ADOPTION AND IMPLEMENTATION OF BIM AND INTEGRATED APPROACHES TO PROJECT DELIVERY ACROSS THE CANADIAN AECO INDUSTRY: KEY DRIVERS FROM ABROAD

Souha Tahrani¹,², Erik A. Poirier¹, Gulnaz Aksenova¹ and Daniel Forgues¹
¹ École de Technologie Supérieure, Canada
² souha.tahrani@gmail.com

Abstract: The architecture, engineering, construction and owners (AECO) industry plays a vital role in a country’s economy, and has a great impact on its society and on the local and global environment. Focussing on the performance and the impact of their respective AECO industries, government bodies around the world are increasingly pushing to transform current practices to maximise the value generated by this industry. Recent innovative approaches, notably building information modeling (BIM), integrated approaches (either integrated project delivery (IPD) or integrated design processes (IDP)) and Lean construction, show promise in providing many improvements. However, many challenges and obstacles are hindering the deployment of these approaches; a lack of strong client demand chiefly among them. In response to this, many countries have developed strategies to encourage and accelerate the pace of adoption of these innovative approaches. This often is prompted by requirements for suppliers to implement one or more of these innovations on all their publicly procured projects. The various levels of governments in Canada however have yet to follow suit in this regard. As a consequence, the Canadian AECO industry is seen to be lagging in its adoption of BIM and integrated approaches to project delivery. While certain projects have emerged as beacons of enlightened practice in the Canadian context, it remains that the vast majority of projects are still being delivered in a traditional fashion, with the well-known limitations this entails. This paper investigates the contextual challenges in adoption and implementation of BIM and integrated approaches in the Canadian AECO industry. The objective is to identify challenges and opportunities to create favourable context that ensures that the Canadian AECO industry remain competitive in the face of increasing global competition by leveraging the potential significant benefits of these innovative approaches. This paper is based on a review of the literature of various initiatives around the world. The paper lays out six key factors, which are seen as drivers for the adoption and implementation of BIM and integrated approaches in other countries, and discusses their implication in the Canadian context. Notably, the need for a national policy that structures the adoption and implementation BIM and integrated approaches; the need for leadership from the public sector; the importance of constituent organizations acting as a voice for industry; and the need for investments in research and development.

1 INTRODUCTION

The Canadian architecture, engineering, construction and owners (AECO) industry represented $290 G in capital expenditure in 2013, approximately 20% of the Canadian GDP (Statistics Canada, 2014). Moreover, the construction industry alone employed 1.3 million people or 7.5% of total workforce during this same period (OECD, 2014) distributed across more than 120 000 enterprises (Industry Canada,
As with most countries, the Canadian AECO industry is truly one of the pillars of the Canadian economy, generating significant value for its society. On the other hand, it must contend with many well-known obstacles, such as its fragmentation and complexity which make it a wasteful and inefficient industry. In fact, many countries have invested and put forth national frameworks and initiatives to support the reform of their respective AECO industries to improve performance, productivity and the value that is generated. Over the past two decades, innovative tools, technologies and processes for project delivery and asset lifecycle operations and maintenance, such as building information modelling (BIM), integrated project delivery (IPD), integrated design processes (IDP) and Lean construction have shown much promise in helping the industry overcome these obstacles and shortcomings. These innovative approaches have been adopted and their development made a priority in many countries around the globe. The Canadian AECO industry, however, has yet to initiate this transition. Indeed, there is a general consensus that it is lagging behind many of these other countries in the adoption and implementation of these innovative approaches (Beaudoin et al., 2011). In the current global economic context and facing increasing global competitive pressure, the Canadian AECO industry, cannot afford to stand idle and let pass the opportunities to transform itself through a structured and strategic reform. On the other hand, this relative tardiness can also been seen as a serious advantage in that the industry can learn from other countries and avoid many of the growing pains that others had to go through. In this regard, this paper seeks to answer the following questions:

1. How can the Canadian AECO industry learn from other countries’ experiences in the transition to innovative project delivery approaches?
2. In light of these lessons learned, how can the Canadian AECO industry develop a comprehensive reform strategy in order to improve its performance and efficiency to ensure its sustainability and competitiveness?

The paper first gives a brief overview of the current innovative approaches to project delivery that are being developed around the globe. It then exposes the particularities of the Canadian AECO industry context and discusses the adoption and implementation of these innovative approaches for the Canadian AECO industry across six key factors that were developed by Wong et al. (2010). A comparative analysis between Canadian initiatives (or lack thereof) and various from around the world is performed. Lastly, the paper concludes with a discussion on moving forward with a national framework for the adoption and implementation of innovative approaches to project delivery.

## 2 THE TRANSITION TO BIM AND INTEGRATED APPROACHES

The past decade has seen a rapid growth in the literature, both academic and industry oriented, pertaining to BIM implementation and the deployment of innovative project delivery approaches. These approaches are seen as a solution to target fragmentation and inefficiency of the AECO industry. BIM is perceived as both “Technology” and “Process”. BIM technologies allow to prototype a product, where a building information model is constructed with input of precise digital data to support the design, procurement, fabrication and construction (Eastman et al., 2011). This innovation changes the roles and relationships of all the stakeholders involved in the project delivery process, demanding new ways of work, thinking models and approaches to design and construction. However, BIM adds even more value to the project delivery if it is supported by the integrated design and construction approaches (Eastman et al., 2011) as well as by Lean construction approaches. These integrated approaches are “A holistic approach to building in which all project stakeholders and participants work in highly collaborative relationships throughout the complete facility life cycle to achieve effective and efficient building” (Elvin, 2007). Among the major initiatives regarding the integrated approaches, two main approaches could be distinguished: Integrated Design Process (IDP), which seeks energy optimization and sustainable design; and the Integrated Project Delivery (IPD), which focuses on the optimization of the project delivery process by reducing waste and managing project information flows in integrated way. In an integrated approach, the most important decisions are taken in the early stages of project design process. These decisions have a major impact not only on the progress of the construction phase, but also on the asset’s lifecycle. Lean Construction is a new way of managing projects that look to minimize waste and time, and to maximize value (Ballard, 2000). This approach is considered an optimal solution for managing various project delivery processes, and for taking full advantages of BIM, while maximizing their benefits. BIM is seen as a ‘tool’ to support integrated relational contracts such as Integrated Project Delivery (IPD),
alliancing or Integrated Supply Chain, enabling a tighter collaboration, where the process becomes more efficient and predictable. BIM decisions and protocols are best developed by joint decisions in IPD process that maintains the beneficial relationships between parties (AIA, 2007). Also, many researchers and studies recommended combining Lean with BIM to create a positive team synergy, which generates a great opportunity for improvement in industry (HM Government, 2012, Sacks et al., 2010). These in turn improve efficiency, knowledge dissemination, reduce errors, and enable generation of alternative solutions and expansions of market opportunities. Implementing integrated approach and collaboration with BIM brings more value to the process.

In an attempt to move towards a more efficient AECO industry, several countries have undertaken the reform of this industry by setting up initiatives which promote the adoption of one or more of these innovative approaches. Wong et al. (2010) carried out an extensive review of initiatives targeting BIM implementation from around the globe. The authors performed an overview of these initiatives in the USA, Finland, Norway, Denmark, Singapore and Hong Kong in terms of policy, process and technology. Their study identified some attributes which are seen as strategic steps taken to implement BIM in these countries: 1) The importance of the public sector as a driver for implementation of BIM in all the countries studied; 2) Establishing clear and specific governmental policy mandating BIM on all public projects; 3) Developing standards and guidelines for the deployment of BIM; 4) Clear information exchange capability requirements, and relying on open standards for data and information exchanges; 5) Designated organizations responsible for BIM implementation within a country (either an existing government department or external organization); 6) A constant and consistent reporting and promotion of BIM; 7) A focus on BIM research and the establishment of BIM research programmes. In the 5 years since the paper was published many more countries have sought to establish BIM initiatives, namely the United Kingdom (UK), Australia, New Zealand, France, Brazil and Korea. An analysis of these international initiatives reveals that the successful deployment of the innovative approaches depends largely on strong leadership from the government in the form of interventions and targeted initiatives, and commitment of governments to direct or support these initiatives. To better support this reform, some countries have rethought the structure of their industry by setting an overarching strategy which includes procurement methods, and an integration between government and industry stakeholders and promotes collaborative work, such as in the UK. Other countries have worked closely with the industry by offering financial incentives, and academic support programs such as in Singapore. The technological advancement to promote innovation was a key driver in the Scandinavian countries. While seeking performance and productivity improvement was a key driver in the US. All these countries have developed strategies, set specific milestones, and took considerable action to achieve their goals. To date, some benefits have been observed, many challenges have been encountered and there is still work to do to achieve their ultimate goals. Canada can learn from these initiatives to inform and structure its transition to innovative project delivery approaches.

3 THE CANADIAN CONTEXT

The Canadian AECO industry plays an important role in the Canadian economy, influences Canadian society and has a major impact on its environment. However, the context in which the Canadian AECO industry evolves is very particular. First, the AECO industry is based on provincial jurisdiction. As such construction projects are governed by provincial laws with the exception of federal projects (military, federal infrastructure such as certain bridges, airports, sea ports and projects for First Nations communities). These laws vary between provinces, especially in Quebec, which is subject to the Civil Code. The Canadian AECO industry is also very diverse; each province has its own professional associations, which govern all aspects related to professional accreditation and certification. Furthermore, there is a lack of industry-wide organizations to support innovation in Canada as discussed by Froese and Rankin (2009). This particular context makes it difficult to establish comprehensive initiatives that are consistent across the country, and can be endorsed by various levels of government as well as the public sector. For example, the National Benchmarking Initiative initiated by the Canadian Construction Innovation Council (CCIC) (Rankin et al., 2008) was discontinued when the CCIC was closed due to a lack of funding. The Canadian Construction Innovations (CCI) was created in 2013 to fill the void. This particular context also influences the speed of innovation, namely in adopting new technologies and approaches.
Little empirical work has looked into the adoption of integrated approaches and BIM in the Canadian AECO industry. As such, actual adoption rates in Canada are still largely unknown. However, there have been more attempts at quantifying the BIM adoption rate in Canada. In this regard, various surveys have been conducted over the past 6 years. The principal sources of data are the McGraw-Hill surveys (2009, 2012 and 2014) that showed a 49% BIM adoption rate in Canada in 2009, which grew to a 72% adoption rate in 2012. These results were on par with adoption rates in the US (McGraw Hill Construction, 2012). Recently, McGraw Hill Construction (2014) published results of a new survey presenting BIM adoption by contractors around the world. The report shows that 87% of Canadian contractors have adopted BIM, and that most report a positive return of investment. Again, this report still considers Canada and USA on par in terms of BIM maturity. The results of these studies are limited mainly due to the small sample size: 175 respondents from Canada compared to 2,053 from the US in 2009, 29 respondents from Canada compared to 553 from the US in 2012, and 39 respondents compared to 291 respondents in the US in 2014. In a similar study, carried out by NBS (2013), four countries took part in a survey measuring BIM adoption rates: Canada, UK, Finland and New Zealand. The survey indicated that 64% of Canadian respondents (78 respondents) were aware of and were using BIM, compared to 65% (more than 400 respondents) in Finland, where BIM is obligatory for public projects since 2010. The author of the study highlights the fact that for all the countries except Canada, the confidence rate was high and that the data was largely representative of the respective industries. For Canada, however, the results of the survey may have been skewed by the fact that the respondents were likely to be people that were familiar with BIM instead of an accurate statistical representation of the Canadian AECO industry. Other work looking into BIM adoption in the Canadian AECO industry has found that BIM implementation in Canada is currently being led by the industry and by looking at what is happening in the US. In this regard, Forgues and Staub-French (2011) have conducted a study comparing the adoption of BIM between early adopters in the Canadian AECO industry and BIM users in the American one. They observed important gaps between these two industries. The main gap noted was that the overall level of use of BIM tools on projects was systematically lower in the Canadian industry than in the U.S. industry. This study showed that BIM adoption in the U.S. industry was more advanced, and discussed how BIM implementation is related to market demand, particularly on the part of the client. To close the gap, the study argued that the transition to BIM would have to be endorsed by public clients, and that support from research and professional associations is critical. In other words, specific drivers were needed to provide impetus for widespread BIM adoption and implementation in the Canadian AECO industry.

4 KEY DRIVERS FOR CANADA

Specific attributes, also seen as drivers, for widespread adoption and implementation of BIM, and to a certain extent other innovative project delivery approaches, at the national level have been developed by Wong et al. (2010). Using those specific drivers, we discuss the implications for the Canadian AECO industry and compare them to what has been done elsewhere.

4.1 Public Sector As A Driver

Better satisfying client requirements and improving asset management has led various public organisms to look into the use of innovative project delivery approaches. Namely, the United States Government Services Agency (GSA), Statsbygg, the Norwegian Directorate of Public Construction and Property, and Senate Properties, the Finnish state owned enterprise responsible for real property acquisition and maintenance, and Her Majesty’s Government in UK have acted as drivers for innovation in their respective AECO industries by taking active steps in pushing for the widespread use of BIM and integrated approaches on their public projects. One of the most telling examples is that of the GSA who since 2003, has established a program to develop BIM guidelines to better meet and deliver its clients space requirements. Between 2003 and 2006, the (GSA) carried out 9 pilot projects to test and develop BIM implementation for various uses. This allowed the GSA to develop its 3D-4D BIM program and the accompanying guides. During that same period, the Danish government initiated Det Digitale Byggeri (Digital Construction) (bips, 2011), a public-private initiative, aimed at providing a number of requirements governing the use of BIM and ICT for consultants and contractors (The European e-Business Market Watch, 2005). While the Danish government does not possess a large property portfolio, its support of the
transition to innovative approaches has had a strong impact in the Danish AECO industry and can continue to do so. For instance, the report of COWI (2009) demonstrated that by developing projects in a fully digital environment, this would contribute an additional € 2.3 billion per year to the Danish economy. Lastly, the UK has a long history of questioning the practices of its AECO industry and developing programs to overcome the limitations of this industry, the most famous being the Latham and Egan reports (Latham, 1994, Egan, 1998). More recently, the government has set aggressive targets in their Construction 2025 industrial strategy: 33% lower costs, 50% faster delivery, 50% lower greenhouse gas emissions and 50% improvement in exports (HM Government, 2012). Further to these telling examples of public sector leadership, one of the main lessons learned from the exploration of innovative approaches around the globe is that successful implementation has been supported by investment from the governments either for research and development (such as in Finland and Norway) or to support the industry (such as in the UK). A specific example of this is the Singaporean government who has introduced the BIM Fund that covers training, consultancy services, purchase of software and hardware. Other investments by the public sector are illustrated in table 1.

</table>

As mentioned, the Canadian government has put forth some initiatives targeting the AECO industry. However these have either been short lived or their impact has not been fully felt. When looking at other countries, most of these initiatives were undertaken within a specific government department and treated as a priority within this department. These countries have recognized the significant power of the public sector as a key actor in the reform of the AECO industry. In this regard, the Canadian public sector represents 22.40% of the total capital expenditures in Canada, or $ 65.18 B (Statistics Canada, 2014). These capital expenditures are distributed across three levels of government. At the national level, public bodies include: Public Works and Government Services Canada (PWGSC), the Department of National Defense (DND), and its representative Defense Construction Canada (DCC). At the provincial level, each government has a specific organization, a crown corporation, which assists other government agencies in their construction projects and asset management. Lastly, at the municipal level, most large municipalities will have departments responsible for overseeing construction projects. It is also at the municipal level that building codes and bylaws will be enforced through development applications, public consultation and plan review. The complexity inherent to this multi-layered governmental context is a core issue to the lack of national initiatives that can truly take root in the Canadian AECO industry. The authors believe that while a national initiative is relevant, the bulk of the work must happen at the provincial and municipal levels. Therefore, this national framework for innovative project delivery must be multi-tiered and consistently adopted and adapted at all three levels of government.

4.2 Governmental Policy Mandating BIM on All Public Projects

The principal way through which the countries mentioned above have driven the adoption and implementation of innovative project delivery approaches, namely BIM, has been through a national
policy mandating their use on all public projects. For example, the US, Finnish and Danish governments have all been mandating BIM on all public projects since 2007. The Norwegian government has stated its commitment to succeed in BIM adoption in 2010 (The BIM Issue, 2011). Both Hong Kong and Singapore are making BIM obligatory in 2015, while the UK government is mandating “level 2” BIM, or a “managed 3D environment held in separate discipline “BIM(M)” tools with attached data” on all its projects in 2016 (BIM Task Group, 2012). No such timeline exists in Canada either at the national, provincial or municipal level. While there exists no formal policy mandating BIM implementation on all public projects in Canada, several governmental bodies, at varying levels, have initiated pilot projects to begin framing a mandate. In this regard, the authors are aware of four separate initiatives where BIM is being looked into by a government body: The work in the field of space management and open BIM initiated by DND and DCC since 2009, the Royal Alberta Museum pilot project initiated by Alberta Infrastructure, several small pilot projects initiated by the Société Immobilière du Québec (SQI) and finally, the Moose Jaw Hospital initiated by the Government of Saskatchewan, which incorporated BIM and more importantly is one of the first IPD contracts with lean approach in Canada. These individual efforts across Canada show a willingness on the part of governmental bodies to move towards these innovative project delivery approaches. However, there is a risk that these individual efforts lead to fragmented policies across the county. There is a need for a concerted effort across all levels of government, to develop a unified mandate regarding the implementation of BIM and other approaches on public projects.

4.3 BIM Standards and Guidelines

The number of BIM standards and guidelines has grown exponentially over the past years. Representatives from both the US and the UK have mentioned that the presence of so many different standards was problematic in broadcasting a consistent message and gaining traction within the industry. In particular, the US is faced with the challenge of having many different standards, which have been produced, at the National level (GSA, US Army Corp of engineers, US Veteran, US Coastguard), at the state level, at the municipal level and from private owners (ie. universities). The presence of so many guidelines and standards has created confusion in the US industry, namely with the professionals who have to contend with these different standards. On the other hand, the Finnish, Norwegian, Danish and Singaporean examples are particularly interesting in their strategy of developing standards from a single source, with inputs from industry, academia and government. For example, Senate Properties in collaboration with buildingSMART Finland, construction companies, big cities, hospitals and consulting companies produced their BIM requirements in 2007 and updated them in 2012 (COBiM, 2012). In Denmark, bips is responsible for the producing the Digital Building Code and the Danish Building Classification System (DBK) based on buildingSMART. The Building Construction Authority (BCA) is the sole source of BIM standards in Singapore.

Canada has a big advantage to benefit from the efforts and lessons learned of other countries in developing its standards. Some guidelines have begun to appear, namely the AEC (Can) BIM Protocol published by the Canadian BIM Council (CanBIM) and modeled on the AEC(UK) BIM protocol, developed by the AEC(UK) initiative. These protocols serve as tools to generically inform model structure and the modeling process, and have not been adopted as a governing standard by either the Canadian or the UK industries. The Institute for BIM in Canada (IBC) has published a series of ‘toolkits’ aimed at supporting the implementation of BIM by Canadian firms (IBC BIM, 2014). IBC has also published a contract language document to be used as an exhibit or appendix to other contracts and spells out the roles and responsibilities as well as the uses of BIM on the project. While these documents serve to better inform the implementation of BIM in Canada, they have not yet been endorsed by any governmental bodies. There are other efforts to create national standards in Canada, notably, the Canadian Construction Documents Committee (CCDC), a national joint committee responsible for the development, production and review of standard Canadian construction contracts, forms and guides, and the National Building Code of Canada (NBCC), issued by the Institute for Research in Construction (IRC), which is part of the National Research Council of Canada (NRC). Whereas, the standard contract documents produced by CCDC are now widely used by the Canadian AECO industry, they still are used on a project basis. On the other hand, the model code produced by the IRC must be adopted by a jurisdiction to take effect. Many provincial jurisdictions have adopted the NBCC as is. Some provincial and even municipal jurisdictions have modified the NBCC, as is the case in British-Colombia, Quebec and in the city of Vancouver.
However, they possess the same structure and much of the same content. In light of these efforts, there is potential for the creation of unified standards and guidelines for the Canadian AECO industry. While these standards could be informed by existing standards such as versions 1 and 2 of the National BIM Standard, produced by the NIBS, as well as the Common BIM Requirements produced in Finland, these standards could be endorsed at all government levels, similarly to the National Building Code. Furthermore, they should be consensus based and originate from a unique organization that is comprised from members of industry, academia and government.

4.4 Clear Information Exchange Requirements and Open Standards

One of the core concepts of BIM is the seamless production and exchange of information across a project’s lifecycle (Eastman et al., 2011). In an effort to ensure this seamless information flow, open exchange standards are critical so as to not be reliant on a specific platform or proprietary mechanism. These open standards have been developed over the past two decades, namely the Industry Foundation Classes (IFC) by buildingSMART international (formerly the International Alliance for Interoperability (IAI)). Recognizing the importance of this open data exchange, the GSA, Senate Properties, Statsbygg and DECA (Denmark) signed a joint statement in 2008 to support open BIM based on IFC (Winstead et al., 2008). The question of data requirements is more complex. What information is to be produced at what time and for what use is a difficult question to answer; it is highly dependent on the stakeholder’s perspective. From a public owner’s perspective, two perspectives emerged from the various initiatives around the world. The first is for specific uses such as program validation (GSA) or code compliance checking (Singapore). The second is to ensure the reuse of information over the product lifecycle. In this case, the standards indicate how the information should be input to ensure consistency across projects, as is the case in the Finnish and Danish standards. Lastly, the question of information evolution has been addressed by the UK government who has developed COBie drops to allow public owners to validate the information received from their project team in a structured manner (The National BIM Library, 2012).

Canada can benefit from the development and work in this field performed in other countries. While the mandating of IFC compliant deliverables on public projects is relatively straightforward and the international consensus around the use of this exchange standard provides relative stability and confidence, the exchange requirements will have to be further investigated. While government bodies can look to these requirements to fulfill their business processes, they should also look to leverage these in order to prompt the reconfiguration of practice that is called for in the transition to BIM and integrated approaches. In other words, while the value of this open data for public bodies lies in its reuse over their asset’s lifecycle, in their role as catalysts for change, these public bodies should look at structuring the information requirements to push project teams to innovate and become more efficient.

4.5 Designated Organizations Responsible for BIM Implementation

Further to the development of standards and guidelines originating from a single source, an organization responsible for driving BIM adoption and implementation in Canada should be mandated. This has been the case in other countries such as the BIM Task Group, a UK Government-funded group, which plays an active role in the reform at the national level by helping the AECO industry become more efficient and to adopt collaborative work practices for all public projects. Although the group has a small number of personnel (10 people), they work on creating links between industry, government, public sector and academia around collaborative work and BIM; and on developing open standards to facilitate interoperability and data exchange to reduce barriers in this exchange (HM Government, 2012). Another example is the BCA in Singapore who is primarily responsible for the implementation of BIM and integrated approaches within the Singaporean AECO industry, more specifically, introducing BIM Fund incentives as mentioned earlier.

The role of professional associations in the deployment of BIM is very important. In the US and the UK, professional accreditation is done through national bodies such as the American Institute of Architects (AIA) and the Royal Institute of British Architects (RIBA). This results in a very large constituent base for these associations. Both the AIA and RIBA have been instrumental in advocating and developing tools for the implementation of BIM and IPD in their respective countries. The same can be said for the
Association of General Contractors (AGC) in the US. In Canada, construction being of provincial jurisdiction, professional accreditation becomes the responsibility of provincial associations. This reduces the capability to understand and support changes in the professional practices and body of knowledge at the same time. Some associations, such as the Royal Architecture Institute of Canada (RAIC), Engineers Canada (EC) and the Canadian Construction Association (CCA) operate at the national level and assist provincial bodies in terms of certification of education. However, they mainly serve as advocacy groups and hold little power over day to day practice, contrary to their American and British counterparts. This limits the impact of national initiative put forth through professional associations. To push a national mandate for BIM and integrated approaches, it will be important to get all professional associations to support and buy into the initiative. Lastly, two national advocacy groups have been founded which promote BIM in Canada: the Canadian BIM Council (CanBIM) and the Institute for BIM in Canada (IBC) of which the Canadian chapter of buildingSMART International is a council. Both these groups have put forth considerable effort to engage the industry in moving BIM forward. While these organizations are gaining traction, they largely rely on individual effort to push the Canadian BIM agenda. At the provincial level, several "grass roots" organizations or committees have emerged in recent years. These could include Alberta Center for Excellence and aceBIM chapter, the BIM BC user group, as well as BIM Quebec group. These groups work in silo, and are not integrated. Again, the presence of an organization that is backed by all professional associations and is supported and funded by all levels of government can act as a unifying front to push a coherent Canadian mandate.

4.6 Reporting and Promotion of BIM

The reporting and promoting of BIM and innovative project delivery approaches is a very important component in driving widespread adoption and implementation. Experience has shown that there is a lack of distinction between promotion of these approaches by vendors and AECO organizations serving marketing purposes and objective reporting by independent bodies. Many claims have been made that are unsubstantiated and as such creates some scepticism in the industry. As such, an independent reporting of lessons learned and outcomes is needed to foster industry wide acceptance. In many countries, this responsibility is taken on by the organizations mandated to drive the initiative such as the BCA in Singapore and the BIM Task group in the UK. Both these organizations work on developing and monitoring activities such as forums, presentations, training, workshops, etc. The BIMForum in US also represents an important resource to address multidisciplinary practice and to keep industry up to date regarding advances in BIM.

In Canada, there are several activities that promote BIM, such as trade shows, conferences and symposiums. At the national level, bSC, IBC and CanBIM promote innovative approaches through conferences and workshops. At the provincial level, some private organisations are working on promoting new technologies and approaches such as Contech in Québec. Some professionals associations are beginning to be more involved in promoting BIM through conferences and workshops by inviting researchers and pioneer adopters to exchange their experiences and practices. Although the main goal is promoting BIM, the majority of these activities do not go beyond being purely informative in purpose. At the project level, as mentioned above, most of the promotion is led by firms who have worked on innovative projects and who use these cases for marketing purposes. In light of this, a centralized resource, which supports the objective capturing of lessons learned and outcomes for the Canadian AECO industry is needed. This resource should be maintained by the organization mandated with leading the national initiative.

4.7 BIM Research Programs

Lastly, the importance of research and development in this field is vast. The countries, which have succeeded in leading the reform of their AECO industries, all have invested in research programs to develop internal competencies and develop tools and technologies to support the transition. For example, Finland is famous for its research initiatives, innovation programs and establishments of international networks. The earliest research on BIM was initiated in the 1980s. Just after the recession in the early 1990’s, the Finnish technology policy and industry leaders agreed about the need to develop the cluster [focussing on the AECO industry] and identified some key problem areas in the industry with a focus on
'information sharing and management in all processes during an asset’s lifecycle (Kiviniemi, 2006). This led to the emergence of TEKES’s technology programs and later on, in 1994, to emergence of International Alliance for Interoperability (IAI) with the focus on the development of IFC data specification internally and since 1996 at the international scale. This was followed by developments such as VERA (1997-2002) and SARA (2003-2007) (Froese, 2002, Kiviniemi, 2006). The outcomes of these programs were first BIM guidelines in 2007 in Finland. More recently the PRE project, led by RYM OY has received important funding from both the government and industry. The US also has heavily invested in R&D. For example, the National Institute of Building Science (NIBS) and the National Institute of Standards and Technology (NIST) are the two main organizations, which carry out research on BIM. Whereas NIST is a governmental agency, NIBS is a Not-for-profit, which regroups representatives from the government, industry and academia. The American chapter of buildingSMART is integrated within NIBS. NiBS oversees the development of open data exchange standards such as IFC and COBie as well as the National BIM Standards. There are other organisms that conduct research in the AECO industry in the US such as Fiatech and the Construction industry Institute (CII).

In Canada, many research groups; universities and organizations are involved in the study of BIM and integrated approaches. Research groups, such as the BIM Topics lab at the University of British Columbia; research groups at the University of Calgary, the University of Alberta, the University of Ottawa and University of Waterloo, Concordia University and the GRIDD at the École de Technologie Supérieure, work with the industry through pilot projects to develop better practices for BIM and other construction innovations based on industry needs. The Canadian government has some programs to fund these researches and to create bridges between industry and academia and research centers such as Engage Grants or Industrial Research Assistance Program (IRAP). These programs allow industry to have access and to exchange knowledge with researchers. However, many of these research projects are one off and remain fragmented and the findings are highly contextual. Another key issue that must be addressed is related to adapting educational program to current realities. According to Forgues and Farah (2013), Canada needs to swiftly update and reform its university curricula to reflect the innovation and integration. There is a need to redefine professional curricula to fit the new context of integrated approaches. Certification of these new programs must be standardized and governed by a certifying body, as is the case with other programs that lead to professional accreditation.

5 CONCLUSION
This article has outlined the various initiatives from around the world that are driving the reform of the AECO industry. Innovative approaches to project delivery and asset management, such as BIM, IPD, IDP and Lean construction, are increasingly being relied upon to improve the performance and value generated by an industry that has long been seen as inefficient and wasteful. Many countries consider that their respective AECO industries contribute significantly to the development of their society, economy and have a very big impact on their environment. By acting as a driving force, and by providing the impetus to the industry to transform itself, governments around the world are tooling their AECO industries to become better and to remain competitive in light of increased global pressures such as global competition, move towards sustainability and carbon neutrality and increasing economic pressures on governments to deliver projects on-time and on-budget.

In this regard, Canada cannot afford to remain idle. Active steps must be taken to follow suit to these other countries. This paper has discussed six attributes to successfully drive the adoption and implementation of BIM at a national scale. While the context in which the Canadian AECO industry operated is unique, there exists some mechanisms and strategies which can structure and adapt the adoption process to this particular context. Learning from abroad, a Canadian mandate can rely on international efforts to inform its initiatives, namely by adopting Open standards and developing guidelines that are inspired by best practices from elsewhere. More importantly, the Canadian initiative must share a single vision. It will need the backing from constituent organizations and professional associations across Canada as well as being endorsed by all levels of government.

Abstract: Construction CALS/EC is introduced in public works projects over the whole life cycle for the purpose of reduction of the construction period, quality guarantee, and cost reduction. Especially recently, environmental improvement of the information-oriented construction using 3D data attracts attention for engineering works stage. In the construction site, it is expected to create 3D model from the point cloud data obtained by surveying the site with the total station or the laser scanner. However, it is necessary to solve the problem of how to handle the great amount of point cloud data obtained at the survey based on their characteristics, as well as the problem of required accuracy for the information-oriented construction. The authors have devised a technique to make 3D model of the river embankment, which satisfy the required accuracy of the information-oriented construction from a large quantity of point cloud data. This technique used the point cloud data of the river embankment measured with the laser scanner and DM data of it. Then, the boundary line (breakline) between the crown surface and the slope face of the river embankment is extracted automatically to create 3D model on CAD. However, the following problems were revealed; the freshness depending on the update cycle of DM data, and wrong extraction of a breakline due to the noise such as the vegetation between the crown surface and the slope face of the river embankment. In this research, we devised a method for automatically extracting a breakline by inferring the crown surface area of the river embankment from the point cloud data, and a method for removing any point cloud data that are the noise such as the vegetation on the crown surface of the embankment. Then we performed evaluation experiments and proved the usability of the devised solution.

1 INTRODUCTION

Public institutions in Japan are promoting measures for constructing a data circulation environment using ICT (Information and Communication Technology) over the whole life cycle for reduction of construction period, quality assurance, and cost reduction of public works. Recently, there are efforts underway by academy, industry, and government to apply this in product models in construction stages such as development of Road Alignment Data Exchange Standard, as well as advanced efforts for intelligent construction (Tanaka, 2009).
Against this background, a workshop on establishing a data circulation environment for river projects was set up in Kinki Regional Development Bureau, Ministry of Land, Infrastructure, Transport and Tourism for the purpose of promoting new technology development with public and academic sectors as its core (Fukumori, 2009). This workshop aims to develop technologies for generating high-precision three-dimensional (3D) models useful in construction management or maintenance using the survey data concerning the present topography of rivers. Relevant researches suggest methods of generating 3D models automatically from the point cloud data (Shaohui, 2013) (Choi, 2008) (Tanaka, 2010) measured with high-precision scanners (Ohtu, 2007). However, there are two potential problems in the 3D models created from the point cloud data collected by the laser scanner: how to handle a large amount of point cloud data, and wrong extraction of the boundary line of aspect change (hereinafter referred to as 'breakline').

To solve these problems, the existing researches propose a method to extract breaklines, leaving geometric characteristics and thinning out an enormous amount of point cloud data, through a method of using relative positions of point cloud data (Shaohui, 2013), or a method of using reflection intensity of point cloud data (Choi, 2008). However, it is impossible to uniquely identify the boundary lines between planes of the river embankment because it is a space where artifacts and natural objects coexist. Accordingly, it is difficult to create a 3D model with high precision of reproducibility. Therefore we have been working on the research on controlling wrong extraction of breaklines (Tanaka, 2010). Firstly in specific, point cloud data was superimposed on DM data developed nationwide by public survey. Next, a 3D model was automatically generated using the road alignment contained in DM data as a clue. However, there are two problems of "Freshness due to the update cycle of DM data" and "That noise such as vegetation inhabiting the top plane of a river levee (hereinafter referred to as "crown surface")".

Based on these problems, this research aims to establish a method of automatically generating a 3D model from a large amount of point cloud data in consideration of boundaries of planes of the river levee. This method assumes the outline of the crown surface estimated from the point cloud data as a candidate breakline. Furthermore, wall-shaped noise is eliminated from the point cloud data on the crown surface automatically to restraint wrong extraction of breaklines.

2 OVERVIEW OF OUR RESEARCH

This research proposes an automatic generation method of 3D models that solves two problems: "problem of freshness due to the update cycle of DM data" and "problem of wrong extraction of breaklines because the boundary between planes becomes vague due to the wall-shaped noise".

2.1 Measures against the problem of freshness due to the update cycle of DM data

This method identifies an area showing the crown surface from point cloud data. The outline of the identified area is assumed the candidate breakline. Therefore, a 3D model is constructed from point cloud data without depending on DM data.

2.2 Measures against the problem of wrong extraction of breaklines because the boundary between planes becomes vague due to the wall-shaped noise

This method estimates ambiguous ground surface from features of the shape and the noise of the river embankment.

2.3 Processing flow

Figure 1 shows the processing flow proposed in this research. This research adds a function of generating candidate breaklines and a removal processing of wall-shaped noise to the existing method (Tanaka, 2010). Thus the proposed method is comprised of three functions: candidate breakline generation, breakline extraction, and thinning out point cloud data. The processing procedure of each function is shown below.
The function of candidate breakline generation is comprised of three kinds of processing: process of dividing elevation, process of clustering density, and process of identification crown surface. Process of dividing elevation is the process of entering the point cloud data and divided them into multiple layers using elevation values. In order to distinguish the layer on which the point cloud data are concentrated, the point cloud data on each layer is clustered based on the relative distance between points, and a cluster of micro area is removed as noise. Process of identification crown surface is the process of evaluating the density of point cloud data of each layer to estimate the crown surface layer. Then the outline of the point cloud data region contained within the crown surface is obtained as a candidate breakline. Function of breaklines extraction comprises 5 kinds of processing; limiting the extraction range, generating a cross-section model, removing wall-shaped noise, identifying the cross-sectional change point, and creating breaklines. Process of limiting the extraction range limits the extraction range of the cross-sectional change points using the candidate breaklines acquired from the point cloud data and the candidate breakline acquisition function. Process of generating cross-section model acquires cross section models of the levee from the point cloud data contained in the extraction range. Wall-shaped noise removal processing removes the point cloud data with the altitude higher than the crown surface and acquires cross section models from which the influence of noise has been removed. Identification processing of cross-sectional change points acquires an intersection point of the line segments showing the crown surface and the slope from the cross section model from which wall-shaped noise has been removed as the cross-sectional change point.

Process of creating breaklines creates a breakline by connecting cross-sectional change points through process of identification acquiring cross-sectional change point. Function of thinning out point cloud data comprises process of creating a filter and process of interpolation of the point cloud data. Process of creating a filter creates a breakline filter by superimposing breaklines and a grid-like filter. Next, process of interpolation of point cloud data interpolates the point cloud data using the breakline filter. This process converts the point cloud data measured at irregular intervals to the thinned-out point cloud data in a grid-like shape with breaklines taken into consideration.

3 FUNCTION OF CANDIDATE BREAKLINE GENERATION

The function of candidate breakline generation creates candidate breaklines from the point cloud data. Here we assume the point cloud data measured by the laser scanner as \( P = \{ p_1, p_2, p_3, \ldots, p_i \} \). This function solves the aforementioned problem of freshness due to the update cycle of DM data.

3.1 Process of dividing elevation

This processing divides point cloud data into multiple layers as pre-processing to distinguish the region of the crown surface from the point cloud data. Specifically, the point cloud data \( P \) is divided at regular intervals at every height \( h \), as shown in Figure 2. The layer set acquired from this processing is assumed as \( L = \{ l_1, l_2, l_3, \ldots, l_j \} \).
3.2 Process of clustering density

In order to distinguish the layer on which point cloud data are concentrated, this processing performs clustering by the density of points over the layer and calculates the region area of each cluster. The characteristics of the point cloud data obtained by measuring a river levee with MMS shows that the density of the point cloud data of the crown surface close to the measurement vehicle tends to be high, and that the point cloud data density of those away from the measurement vehicle such as slope or foot of slope tends to be low. For this reason, this processing used DBSCAN method, which is one of the data mining methods, as a method for clustering based on density. DBSCAN is a clustering method based on the point density using two values: distance threshold $Eps$, and threshold of target numbers $MinPts$. Figure 3 shows a method of process of clustering density. First, the point cloud data contained in an arbitrary layer $l_j$, $P_{dbscan} = \{pd(j, 1), pd(j, 2), pd(j, 3), ..., pd(j, l)\}$, is clustered by DBSCAN. When arbitrary point $pd(j, l)$ in the point cloud data $P_{dbscan}$ and neighborhood point $pd(j, l+1)$ contained in the neighborhood point cloud $N_{Eps}(pd(j, l))$ within the distance $Eps$ from that point satisfy the following conditional equations [1] and [2], the neighborhood point $pd(j, l+1)$ is classified as the same cluster with the point $pd(j, l)$.

\[
\begin{align*}
[1] & \quad pd(j, l) \in N_{Eps}(pd(j, l+1)) \\
[2] & \quad |N_{Eps}(pd(j, l+1))| \geq MinPts
\end{align*}
\]

Assume the clustering result by DBSCAN from an arbitrary layer $l_j$ as $Cl_j = \{cl(j, 1), cl(j, 2), cl(j, 3), ..., cl(j, k)\}$. Then obtain the region outline of each cluster $cl(j, k)$ of the cluster set $Cl_j$ by the active contour method. In addition, assume the point cloud data applied to the active contour method as $P_{snake} = \{ps(j, 1), ps(j, 2), ps(j, 3)\}$. Figure 4 shows the outline of the active contour method used in this research. The active contour method is a method for capturing the contour of an object by repeating movement and deformation of the closed curves that contain the object. First, create a circle so that it circumscribes the target point cloud data $P_{snake}$. Second, create point-series $P_{tangent} = \{pt_1, pt_2, pt_3, ..., pt_n\}$ arranged at equal intervals on the
circumference, and a tangent line of the circle \( T = \{ t_1, t_2, t_3, \ldots, t_n \} \) passing through \( p_{tn} \). Then, translate the tangent line of the circle \( t_n \) passing through the point \( p_{tn} \) on the circumference towards the center point of the circle until it overlaps with the target point cloud data \( ps(j, m) \). Then the distance translated by \( p_{tn} \), range is calculated using equation [3]. Here \( t_n \) is a straight line formula \( ax + by + c = 0 \). \( x_t \) and \( y_t \) are assumed as \( x \) and \( y \) coordinates of the translating point \( p_{tn} \), whereas \( x_s \) and \( y_s \) as \( x \) and \( y \) coordinates of the target point cloud data \( ps(j, m) \).

\[
\text{Range} = \frac{|ax \cdot x_s + b \cdot y_s + c|}{\sqrt{a^2 + b^2}}
\]

![Diagram](image)

Figure 4: Outline of the active contour method used in this study

The set of tangent lines of point cloud data obtained by this processing is assumed as \( T' = \{ t'_1, t'_2, t'_3, \ldots, t'_n \} \). The set of intersections of a tangent line set \( T' \) is assumed as the region outline \( F = \{ f_1, f_2, f_3, \ldots, f_o \} \). Then the region area \( S_l = \{ s_1(j), s_2(j), s_3(j), \ldots, s_l(j) \} \) of the cluster set \( Cl_j \) is calculated from the region outline \( F \) of the cluster obtained by the active contour method. Region area \( S_l \) of each cluster is calculated by calculating the area of the following polygons using equation [4]. \( x_o \) and \( y_o \) in equation [4] are \( x \) and \( y \) coordinates of vertex \( f_o \) of the region outline \( F \). \( x_{o+1} \) and \( y_{o+1} \) are \( x \) and \( y \) coordinates of the point \( f_{o+1} \) adjacent to vertex \( f_o \).

\[
s_l(j, i) = \frac{1}{2} \sum_{o=1}^{l} (x_o - x_{o+1}) \cdot (y_o + y_{o+1})
\]

3.3 Process of identification crown surface

Figure 5 shows the process of identification crown surface. The process of identification crown surface identifies the layer of the crown surface in order to acquire the candidate breakline. The layer of the crown is estimated using the ratio of the region area of the point cloud data belonging to the layer to the sum total of region area of each cluster \( S_l(j) \) or the region size where there are point cloud data. Then, the region area of each layer is assumed as \( S = \{ s_1, s_2, s_3, \ldots, s_j \} \). These region areas are different from layer to layer since they depend on the result of clustering processing of each layer.

First, when it is a micro cluster of which the region area is threshold \( \text{MinSize} \) or smaller, the micro cluster is removed from any layer \( l_j \). Next, the region outline and region area of any layer \( l_j \) is calculated using the active contour method like the preceding term. Then using the region area of the layer and the region area of the cluster contained in the layer, layer \( l_j \) that is to be the crown surface is identified using equation [5]. Finally, the region outline of the layer \( l_j \) of the crown surface is obtained as the candidate breakline \( BL \).
4 EVALUATION EXPERIMENT

4.1 Experiment outline

Aiming to verify if the two problems (of freshness due to the update cycles of DM data, and of wrong extraction of breaklines because the boundary between planes becomes vague due to the wall-shaped noise) are solved, this experiment compares the precision of reproducibility of 3D models by the existing and proposed methods using the following indicators.

- Comparison using breaklines
- Comparison using a cross section drawing generated from a 3D model

The former compares and evaluates the breakline of a 3D model generated by each method with the breakline acquired by manual operation as the evaluation criteria. The latter compares and evaluates the cross section drawing created from a 3D model of each method with a measured cross section drawing used in the actual river management.

4.2 Experiment environment and experimental data

Table 1 shows the specifications of the equipment and experimental data used in this experiment. The point cloud data used in this experiment covers the area ranging from 7.2km to 8km in the distance from the river mouth (hereinafter referred to as "distance mark") divided at every 200m (approximately 40m in width and 8,000m² in area). The area to measure in this experiment was set to the right bank of a section along the Yodo River levee circled in an ellipse in Figure 6. Figure 7 shows the result of visualizing point cloud data using MMS, and Table 2 shows the details of point cloud data. In addition, the existing method (Method a) uses road alignment contained in DM data as candidate breaklines. This experiment adopted DM data of the Yodo River levee (map information level 2,500).

4.3 Experiment description

First, three 3D models are generated by entering the point cloud data.

- Existing method (Method a) (Tanaka, 2010)
- Proposed method with a function of candidate breakline generation added to the existing method (Method b)
- Proposed method with a function of candidate breakline generation and process of removal wall-shaped noise added to the existing method (Method c)

Next, cross sections are obtained from the generated 3D model. Using the longitude and latitude of the distance marks in the measured cross sections of correct data, information on the same place is extracted as to cross sections. Finally, the cross sections is compared with their correct data for evaluating the precision.

4.4 Experimental results and discussion

This experiment evaluates the precision using the difference in elevation of each cross section by superposing the cross section of a 3D model created through each method with the measured cross section. For the measured cross sections to be used in this experiment, 5 drawings were prepared at every 200m between the distance marks of 7.2km and 8.0km points contained within the measurement area using MMS. Figure 8 shows an image of comparing cross sections. Here comparison of the difference in elevation is calculated over the evaluation points created by dividing the measured cross section at intervals 1cm. Moreover, the comparison results are classified into three sections: all, section A and section B, and totalized as shown in Figure 9.

Section A is assumed as the range including the width of the crown surface with 5cm added on both sides. This is determined with reference to the value of the work progress control standard for filling works of river earthwork providing the accidental error for the crown surface should be within 10cm.

Section B is assumed as the range not contained in Section A except the crown surface. Table 3 shows the totalized results for 3D models created using each method and the measured cross section drawing.
This experiment totalized to what degree the difference in elevation between cross sections is contained within 15cm at intervals of 5cm. This is a reason there is absolute error of 15cm (in the vertical direction) in the measurement data using MMS. Furthermore, for each totalized section, underlines were added to the values with the lowest error between the cross sections created using three methods and the measured cross section drawings. The experimental results proved the following three points.

</table>

First, the total average in Table 3 reveals that the proposed method c realized the smallest errors compared with the measured cross sections throughout the overall part, Section A, and Section B. The average of the total results for Section A reveals that about 95% is included within 15cm, which is the allowable error for MMS, indicating that a 3D model with high precision has been generated. This is a reason the vegetation noise in the upper part of the crown surface is properly removed.

Second, Section A with the distance mark of 7.6km in Table 3 reveals that the 3D model generated by Method c is able to reproduce the crown surface more precisely than the ones created by the other two methods. Figure 10 shows the result of superposing the cross section at the distance mark of 7.6km with cross section drawings created from the 3D models by each method. Figure 11 reveals that the cross sections of 3D models created by Methods a and b do not agree with the measured cross sections in the part of crown surface, indicating that the 3D models are generated at higher position than the measured cross section. On the other hand, the 3D model created by Method c is able to have represented the present shape, showing the similar shape of the crown surface as that of the measured cross section. When analyzing the point cloud data at the distance mark 7.6km, there were wall-shaped noises at the upper part of crown surface including the top of slope. On the other hand, the 3D model generated using the proposed method was able to remove the wall-shaped noise on the crown surface with high precision.
Third, Section B in Table 3 reveals that approximately 30% of points fall into the range within 15 cm of difference in elevation by all the methods. It is considered that this is due to the characteristics of measurement with MMS that it allows obtaining a great amount of point cloud data in front of the measurement vehicle or neighborhood areas but the number of obtainable point cloud data decrease at the places where laser is hard to reach such as the slope face or toe of slope. Consequently, it is considered that the precision dropped in Section B compared with that on the crown surface because it was necessary to generate a 3D model depending on a small number of point cloud data.

### 5 CONCLUSION

This research proposed a method for automated generation of a 3D model from a large amount of point cloud data in consideration of boundaries of planes of the river levee. The experimental results show that the two problems left in the existing method are solved: the problem of freshness due to the update cycle of DM data and the problem of wrong extraction of breaklines due to wall-shaped noise between the crown surface and slope face of the river levee. In other words, technologies are successfully developed for automated generation of a 3D model reproducing the present topographic features with high precision by referring only to an enormous amount of point cloud data with vague boundary planes. Specifically, technologies for handling the following point cloud data were developed:

- Technology to estimate the crown surface of a river levee using the density of point cloud data from the point cloud data measured with MMS.
- Technology to remove wall-shaped noise contained in point cloud data from the point cloud data measured with MMS using geometric characteristics of the river levee.
In this research, all the point cloud existing on the crown surface was assessed as noise in order to estimate the boundary lines of vague planes represented by point cloud data. In the future, demonstration experiments will be conducted to verify to what degree of differences occur between the 3D model generated using such a noise removal method and actual present topographic features, and the applicability to practices and effects to be enjoyed will be made clear.

This research generated 3D models for a river levee, and since the proposed method of this research has high versatility, its applicability to other civil engineering structures (roads, tunnels, or dams) will be examined in the future. Moreover, though the applicability was verified with focus on construction stages (information-oriented construction), some of the challenges to solve in future can be development into a method for assisting creation of register maps for maintenance as well as a management approach using spatial-temporal model added with time base.

Finally, this paper is part of the outcome of the activities of "Workshop on establishing a data circulation environment for river projects" set up in Kinki Regional Development Bureau, MLIT for the purpose of promoting new technology development with public and academic sectors as its core. We plan to make further studies to realize environment for smooth data circulation.

Abstract: Civil infrastructure drawing data are normally generated by computer-aided design (CAD) software in the design phase, and are also frequently needed during the construction and maintenance phases. An environment would be provided in which 3D construction information can efficiently and smoothly be used throughout the project lifecycle. Then, a 3D-CAD engine should be developed and operated to create and modify 3D structure information, but Japan’s CAD vendors have not had a product of the 3D-CAD software. Therefore, the purpose of this research is to spread 3D-CAD rapidly and at low cost throughout the construction industry in Japan. To achieve this purpose, we designed and developed a 3D-CAD engine. Our research and development made progress step by step with the research, the outline design, the primary design, and the detailed design. To verify the designed algorithm, we developed a prototype. After this we developed a 3D-CAD engine, and also simple 3D-CAD software equipped with this engine.

1 INTRODUCTION

It is important for the construction industry in Japan to build an environment where 3D-CAD data are used for BIM, CALS/EC, and IT-based construction to improve productivity. The current use of 3D-CAD data in the industry is infrequent because a quality affordable 3D-CAD engine does not exist. 3D-CAD software use the kernel for modeling, which is expensive for Japanese construction CAD software companies to use their CAD software. Such a 3D-CAD engine must be designed and developed in order to enable low-cost use and quick implementation, leading to its deployment in various stages of the life cycle of construction projects.

The purpose of this project is to spread 3D-CAD rapidly and at low cost throughout the construction industry in Japan. To achieve this purpose, we designed and developed a 3D-CAD engine. Our research and development made progress step by step with the research (use cases, seeds, standards), the outline design (3D representation models, functional requirements), the primary design (3D data exchange specifications, user interface, user operation), and the detailed design (data model, algorithm, API functions). To verify the designed algorithm, we developed a prototype. After this we developed a 3D-CAD engine, and also simple 3D-CAD software equipped with this engine.

Using the 3D-CAD engine that we developed, we created 3D geometric shapes by parametric modeling. We also designed data structure in conformity with ISO10303 (STEP). In addition, settings of diverse
attributes such as the time terms were realized. These are the contents of our research as follows: Outline of Kaiser Project in Kansai University, Design principle of 3D-CAD engine, Data structure in the 3D-CAD engine and its relationship with ISO, and Future expansion.

2 OUTLINE OF KAISER PROJECT IN KANSAI UNIVERSITY

The master plan of the project is shown in Figure 1. The project started from the fiscal 2008. As the product of research aid by Ministry of Land, Infrastructure, Transport and Tourism (MLIT), we prepared the investigation report and the primary design document. As the product of Kaiser Project in Kansai University, we prepared the outline design specification, the detailed design document, and the prototype. Finally, we developed the 3D-CAD engine and the simple 3D-CAD as the final product.

An overview of the 3D-CAD engine is shown in Figure 2. At the center is a 3D model. The model is composed of a sketch, modeling operational histories, and 3D geometric shapes. Connecting them with each other allows a 3D model to be generated. A 3D model also maintains diverse attributes. At the bottom are application program interfaces, which provide various features for creating, editing, and operating a 3D model, as well as for processes including volume and surface area calculation. Moreover, using API for data conversion into drawing data, the data can be converted into the drawing data on the right. The data can also be converted into the exchange data on the left by converting in conformity with the 3D data exchange specification.

The organization of research of this project is shown in Figure 3. The project management office plays a central part. Participating members of the project include research institutes, IT vendors, trading companies, and CAD and GIS vendors. The total amount of the fund is 100 million yen, offered by companies such as Mitsubishi Electric, as well as MLIT.

As to the operation of the project, we established the project management office, which is abbreviated to PMO. PMO plays a key role in the project operation as shown in Figure 4. Activities of PMO include the confirmation of budget execution, the order and inspection, the quality corrections in the project, the risk detection and direction of preventive measures, and the operation of progress meetings. Meetings were
held 43 times over 4 years and a half in this project. Each time about 15 members attended the meeting, including CAD vendors, IT vendors, construction consultants, and university researchers.

3 DESIGN PRINCIPLE OF 3D-CAD ENGIN

3.1 Preconditions of Design Principle

As the preconditions of the design principle, we developed only 3D-CAD engine in this project. We also developed simple 3D-CAD software for verifying the 3D-CAD engine. Using the 3D-CAD engine that we developed, IT vendors and CAD vendors in Japan can develop domain CAD software, such as for roads, bridges, rivers etc.
3.2 Modeling Techniques

There are two kinds of 3D-CAD modeling: the direct modeling and the parametric modeling. The direct modeling directly creates and edits 3D geometric shapes to make drawings. It is easy to handle with its intuitive operation, but inefficient for making modifications. In contrast, the parametric modeling is a technique for defining the geometric shape of a model by setting variable parameters such as coordinate and size values to the model and giving values to the parameters. The parametric modeling is characterized by its easiness to edit because it allows the user to represent the design intent of a structure. The 3D-CAD engine developed in this project adopted parametric modeling. The CAD kernel is used for parametric modeling in commercial CAD software, which is expensive for Japanese CAD companies to use.

3.3 Basics of 3D Modeling

There are two basics of 3D modeling: the plane view drawing using sketches, and the 3D modeling based on plane view drawing. Regarding sketches, plane views are created to use as the foundation of CAD. In a plane view drawing in 3D-CAD, unlike 2D-CAD, it is not necessary to draw a plane view precisely since the length and angles of elements are determined by constraints later. After making plane view drawings, we go to the process of 3D modeling. As an example of 3D modeling, Fig.5 and 6 show some examples of creating a plane view drawing with sketches and 3D modeling with sweep.

3.3.1 Sketch

First of all, a sketch surface is made as shown in Figure 5. On the initial state of the sketch surface, a rectangle is created. Geometric constraints are applied to the rectangle to create a square. In this example, a square is created by constraining all lines to have the same length, and constraining all angles between the lines to be 90 degree.

![Sketch surface](image1)
![Making rectangle](image2)
![Specify target of geometric constraints](image3)
![Making square](image4)

Figure 5: Sketch Surface

3.3.2 Sweep

A sweep action as shown in Figure 6 is applied to the square created with a sketch. To make a sweep action, a sweep line is created. A sweep line is created as a 3D geometric element. After this, a combination of a sweep plane and a sweep line is specified, and a sweep action is executed. Then a sweep model is generated based on the sweep surface and sweep line.
3.3.3 Extrusion

As to the extrusion as shown in Figure 7, someone can create an extrusion model by extruding the sketch by the specified length.

3.3.4 Chamfer

Figure 8 shows an example of the chamfer. After specifying the chamfer distance, the chamfer process is performed.
3.3.5 Fillet

Figure 9 shows an example of the fillet. This generates a round surface based on the specified radius.

![Whole view and Enlarged view of Fillet](image)

Figure 9: Fillet

3.3.6 Boolean

Figure 10 shows an example of using the boolean. A pipeline is connected to a pipeline to a manhole.

![Boolean for Connecting Pipeline to Manhole](image)

Figure 10: Boolean for Connecting Pipeline to Manhole

3.3.7 Example of Creating Alignment

Figure 11 shows an example of creating an alignment by using the sweep. An alignment model of road or railroad can be created by generating a cross-section using Sketch, and making a sweep action.

![Example of Creating Road Alignments](image)

Figure 11: Example of Creating Road Alignments
4 DATA STRUCTURE IN 3D-CAD ENGINE AND ITS RELATIONSHIP WITH ISO

We explain the data structure in the 3D-CAD engine and its relationship with ISO.

4.1 Data Structure of 3D Model

Figure 12 is the data structure of a 3D model to be generated by the 3D-CAD engine. 3D models designed in Kaiser Project conform to ISO 10303, which is also called STEP. This figure shows elements of a 3D model and their corresponding parts in ISO 10303 that they conform to. Sketch conforms to Part 108, the modeling operational histories to Part 55 and Part 111, the 3D geometric shapes to AP 203 (ISO 10303-203: 1994) and Part 42, and the attributes to Part 41.

![Diagram of 3D CAD Engine with ISO](image)

Figure 12: Data Structure of 3D-CAD Engine with ISO

4.1.1 Part 108

For the sketch, we adopted part 108 (ISO 10303-108. 2005.), which is about the parameterization and constraints for explicit geometric product models. Part 108 specifies the resource constructs for representing model parameters and constraints, together with the mechanisms necessary for associating them with geometric or other elements of models.

4.1.2 Part 55 and 111

For the modeling operational histories, we adopted Part 55 (ISO 10303-55. 2005.), which is about the procedural and hybrid representation, and Part 111 (ISO 10303-111. 2007.), which is about the elements for the procedural modeling of solid shapes. Part 55 specifies the representation of constructive operations used to build models, in other words, elements to record operational sequence. Part 111 specifies feature-based modeling commands, prescribing input parameters, output parameters, command specifications and so on.

4.1.3 AP203, Part 41 and 42

For the 3D geometric shapes, we adopted AP 203, which specifies the configuration controlled design. And Part 42 is referred to for geometric elements in AP 203. The conformance class, or CC, is CC4, which is the surface models with topology. For the attributes, we adopted Part 41, which specifies the fundamentals of product description and support.

4.1.4 Part 109

For the assembly, we adopted Part 109 (ISO 10303-109. 2004.), which is about the kinematic and geometric constraints for assembly models. Part 109 specifies the schemas for representing assembly feature relationship and for representing assembly constraints.
4.2 Assembly Process

Figure 13 shows the examples of the assembly process. For instance, a viaduct can be created easily by the assembly modeling, using data of the viaduct pier and the viaduct superstructure. Addition of the time attribute to 3D model, which is actually one of the features of the developed engine, enables the construction simulation to be performed.

![Viaduct assembly process](image)

Figure 13: Assembly Process

4.3 Roads on Terrains with Point Cloud Data

Other functions of the engine include a function of reading the point cloud data. As Figure 14 shows, this function makes it possible to read the point cloud data to generate a terrain, to create a road there, and to connect it with the viaduct created previously.

![Roads on terrain with point cloud data](image)

Figure 14: Creating Roads on Terrains with Point Cloud Data

5 FUTURE EXPANSION

5.1 Future Vision

We mention how to expand the project in the future.

5.1.1 Kensetsu System Co. Ltd.

One of the participating companies of the project, Kensetsu System Company draws its future vision like Figure 15. This company is planning to introduce the 3D-CAD engine into Dekispart and SITECH 3D, both of which are the software products of Kensetsu System.
5.1.2 Forum 8 Co. Ltd.

Also one of the participating companies of the project as shown in Figure 16, Forum 8 Company is planning to realize efficient construction of 3D spaces by introducing 3D-CAD engine into different applications such as UC-win/Road, Engineer's Studio, and CAD for 3D bar arrangement.

5.2 Life Cycle Business using 3D information

The spread of 3D information by using the developed 3D-CAD engine is expected to contribute to the exchange, linking, sharing, and reuse of 3D information as shown in Figure 17. For example, using GIS data for Road database, engineers can make 3D evaluation with digital topographic maps. Using this, they can work out a design, and use the design data to perform structural modification or estimation. Then they can create execution data through the work progress control system and information-oriented construction, which they can add to GIS data. Finally they can deliver the GIS data to the road database. It is possible to realize such a cycle.

6 CONCLUSIONS

The project, which we have been working on for 5 years, started for the purpose of spreading 3D-CAD rapidly and at low cost throughout the construction industry in our country Japan. To achieve this purpose, we designed and developed a 3D-CAD engine. We also developed simple 3D-CAD software that implements an engine, for the purpose of verifying the 3D-CAD engine and its free provision to educational institutions. We expect that the 3D-CAD engine which we developed will be implemented in domain CAD software.
Under the policy of spreading the 3D-CAD engine, we are promoting its implementation in the domain CAD software of the participating companies in the project, as well as providing it free of charge to high schools, technical colleges, and universities all over the country. We are also considering its use in CIM, that is, construction information modeling. We believe that the life cycle realized by 3D models can contribute to productivity improvement for overall construction projects.

Figure 17: Exchange, Linking, Sharing, and Reuse of 3D Information

Acknowledgements

The name of the project is named after the athletic association of Kansai University, which is called “Kaisers”. Since this is a big project of university-industry collaboration, we named it Kaiser Project.

AN INTEGRATED MODEL FOR AUDITING CONSTRUCTION PROJECTS – A CASE STUDY OF OIL AND GAS PROJECTS

Ahmad Teymouri¹ and Ahmad Jrade²
¹ Graduate Student, Department of Civil Engineering, University of Ottawa, Canada
² Assistant Professor, Department of Civil Engineering, University of Ottawa, Canada

Abstract: Nowadays, organizations implement projects for many purposes. Using the project as a strategic success factor for project-oriented companies is increasing continuously. However, most of the time, the results are not the same as they had been planned. Some projects fail to achieve their objectives; others are canceled, where some others have to re-plan their strategy. Project-oriented companies know that maintaining an ideal and logical balance between the project's time, cost, and quality constraints can vastly guaranty project success. One of the most applicable tools to assess and monitor project performance and thus find the associated issues is Project Audit, which is a comprehensive and organized assessment of effectiveness and efficiency of project performance, management, and compliance. This paper presents an integrated model for project audit that incorporates a detailed design module, which shows the model's structure, questionnaire module, and a scoring module. The model is developed as an integrated project audit application where the user is easily able to select, plan, implement, and report a project audit. The model's output consists of two parts: 1) a comprehensive report that shows project situation in five main project processes and nine project functions (i.e., planning cost or closing procurement); 2) useful analytical reports and graphs of the project performance, which compares project's planned and actual time and cost, calculates variances, and forecast the final cost and time based on the current performance. The model is validated by using an actual Oil and Gas project to test its workability and capabilities.

1 INTRODUCTION

Projects are considered as critical strategic success factors for organizations, especially for those who are project oriented. The importance of the project success is continuously increasing. Results of projects are used for many purposes but these projects do not always achieve the planned results. Some projects are not successfully implemented because they are either over budget, behind schedule, or fail to achieve the required quality, whereas others have to be cancelled, and in many cases organizations should re-plan the project strategy. It is rare to find a successful project in which the results are better than what was planned. Usually, spending higher cost and using more resources in a project can be due to lack of efficiency while planning the project deliverable. Poor Project's quality is a result of failing in clearly defining quality requirements and specifications. Project-oriented organizations know that maintaining an ideal logical balance among project constraints such as time, cost, and quality can vastly improve the chances of project success. In construction projects, because of the huge amounts of work, time, and money that are spent, it is very important to know the status of the project and to determine if it meets the predetermined objectives and to ensure its successful implementation. To save time, reduce costs, and improve quality of projects, it is necessary to improve the performance and efficiency during their whole
life cycle. This is attained only when organizations switch from applying traditional project management methods to modern, scientific, and up-to-date project management methodologies. There are different tools and techniques (i.e., project control methods, risk management methodologies, cost management applications, value engineering techniques) that can be applied during the implementation of construction projects. Heavy infrastructure projects (i.e., oil and gas, roads, and dams) require huge amount of investments around the world, organizations should not only use valid standards, rules, and regulations for this type of projects but they must also always assess the outcome of them. Project Audit is one of the most useful tools by which project-oriented organizations can assess their project success, find project’s issues, and monitor its performance. Project audit will result in a positive outcome, whether a project manager and his/her team passes or fails the project. An audit is defined as a systematic, integrated, and independent assessment to determine the level of achieving project requirements and progress. A project audit is an assessment of the effectiveness and efficiency of project performance, management, and compliance. A construction project audit is a detailed evaluation of all its functions in order to discover the project’s concerns, issues, and challenges so that sets of corrective actions can be provided. A project audit can be formal or informal. Also, it may be quick or comprehensive. It can be done anytime during the project life cycle including the conception stage, the implementation stage, or the closing stage. Finding the reasons for uncomfortable symptoms is the primary purpose of a project audit.

The main achievement of a project audit is to identify the lessons learned that would result in a positive impact on the performance of new projects by avoiding repeating the same errors and mistakes. A project audit may be done by asking the project team simple, rather than complicated and technical questions related to: a) project performance, b) project management approach, c) project current status, d) project plan status, e) project requirements, and f) project team and organization. Therefore, in project-oriented organizations, the project audit is highly beneficial for the following reasons: 1) Providing an idea about the current status of the project to know whether it is on-track or off-track; 2) Defining the project success factors (i.e., being on-time, being on-budget, having acceptable quality, satisfying stakeholder expectations); 3) Defining the necessary corrective action plan that is needed to address current problems and enhance the likelihood of success in future projects; 4) Providing a list of guidance for risk management based on all the issues and concerns that are mentioned in the project audit report under project risks; 5) Identifying the lessons learned from previous projects that can be applied by the organization in future projects; 6) Providing list of recommendations to prevent potential problems and challenges; and 7) Showing the project’s performance trend, especially for projects that their construction span over a long period of time, such as oil and gas projects that take more than 5 years, by doing periodic project audits. The main objective of this paper is to describe the methodology used to develop an integrated project audit model, which interrelates several modules, that can be used as a tool during the project implementation. This developed model is based on actual problems (i.e., delay, over budget, quality/safety, resources, and project management) that organizations and project team face during the project life cycle. The said model can be applied for any construction project regardless of its location (National/International) and report the status of project processes, functions, and performance. The methodology is implemented through number of steps, starting by a condense literature review, passing through analysis and development and ending by validation.

2 LITERATURE REVIEW

The focus of the literature review is on reviewing and evaluating the models that are commonly used while doing project audit and accordingly identify the advantages and disadvantages of each of these models. A project is "a temporary endeavor undertaken to create a unique product, service, or result" (PMBOK, 2012). According to Spinner (1997), a project has several distinguishing characteristics such as: 1) well-defined objectives; 2) specified product or result; 3) no repetitive endeavour; and 4) limited sources to consume. Construction projects not only meet the definition of projects but also contain a high degree of risk related to time and cost. However, according to the Michigan Office of Project Management, there are three specific characteristics for every project: temporary, unique, and progressive elaboration. They are temporary because every project has a finish time. They are unique because the product or service of every project is different from those of others although they may have a similar platform. Progressive elaboration integrates the two prior characteristics and means that the
project will be developed step by step and in detail (Woodward, 1997). Although an oil and gas refinery project may have similar engineering specifications and may need the same types of equipment during its construction, it has specific uncertainties about its time, cost, and quality constraints.

Generally, there are five main groups of processes for every project that are also used for construction projects: 1) Initiating; 2) Planning; 3) Executing; 4) Monitoring and Controlling; and 5) Closing Process Groups. According to Lester (2014), most construction projects pass through different life cycle based on their type, complexity, and size. However, any construction project passes through four main periods during its life cycle: 1) beginning the project, 2) arranging and setting up, 3) carrying out the project work, and 4) finishing the project (Chou, 2012). On the other hand, project functions include set of tasks, concepts, and definitions. These functions are mostly defined based on number of factors: 1) project type (i.e. construction, IT, research and development); 2) size (i.e. small, medium, or large), and 3) complexity (i.e. simple or complex). However, project functions are relatively similar in every project. While, Woodward (1997) classified cost, time, scope, and quality as project functions, Spinner (1997) added to these functions the integration, risk, procurement, human resources, and communication. Construction Extension of Project Management Body of Knowledge (2007) added safety, environment, finance, and claim to the nine functions defined by Spinner (1997). Figure 1 shows the changes in the project functions during the last two decades.

![Figure 1: Comparing project management functions over two decades](image)

According to the National Institute for Further Education of Netherlands (2010), the project audit is described as: “the process of verification of the extent to which the project realisation complied with the rules and principles of project management for that specific project”. The project audit has many goals, one of which is to inspect and evaluate the current situation of the project. It also helps the project team to find whether the project is complying with all the defined criteria or not. Moreover, the project audit identifies the points of strength and weakness in the project and provides an idea on whether that project is moving toward success or not. Generally, project issues, challenges, and concerns, which usually happen during the construction phase of a project, are not covered by the conducted project audit. It is worthwhile for the project team and other stakeholders to spend time considering what has gone well in the project and which parts need to be improved so that the project will be completed successfully. According to Ruskin and Estes (1984) project failure is mostly due to problems arising during the planning and executing processes that are not corrected because of many reasons such as either the project team does not notice these problems or there is no time to fix them at that stage. McDonald (2002) believes that the main reasons for a project audit are: 1) to force the project team to develop a reliable project plan that will likely result in a successful project; 2) to increase the possibility of identifying the risks associated with the project; 3) to determine the corrective actions that should be taken to have the project within
budget, time, and quality. Project performance can be assessed by measuring critical success factors (CSFs). Although lots of researchers have tried to identify the CSFs for projects but these have not been clearly defined specifically in the project management body of knowledge. Mian et al., (2004) think that CSFs may be different from one project to another, however, there are some common CSFs (i.e. cost, time, quality) while other researchers focus on new types such as productivity, contract disputes, and procurement strategy where Young and Poon (2013) identify success factors specifically related to the construction process. Bates and Coles (2012) list the steps that should be taken to implement a project audit as follow: 1) Development of project success factors; 2) Development of a questionnaire; 3) In-depth investigation; 4) Final report. To start, collaboration between all the project’s stakeholders is needed in order to define the appropriate success criteria because these are extracted from stakeholders’ expectations. Next, a questionnaire is developed by the auditors and may either be sent directly to the project team or may be answered through personnel interviews. Then, one or more project site-visits is/are planned to collect detail information about the project beside reviewing all project historical data and documents such as the Project Plan, Milestone Report, Team Structure, Business Requirements, Meeting Minutes, Issue Logs, Change Logs. Finally, all collected information from the previous steps are compiled, analysed, and reported. To design an integrated and comprehensive model, the following eleven (11) different project audit and improvement models have been reviewed and analysed: 1) Portfolio, Programme & Project Management Maturity Model (P3M3); 2) Prince2 Maturity Model (P2MM); 3) Capability Maturity Model Integrated (CMMI); 4) Kerzner Project Management Maturity Model (KPM3); 5) Project Management Process Improvement (PMPI); 6) ISO 10006:2003 Standard for Project Management (ISO 10006); 7) Roland Gareis Model (Ronald); 8) German Association Model for Project Management (GPM); 9) Lynn Craford Maturity Model (Lynn Craford); 10) Project Excellence Model (PEM); and 11) Organizational Project Maturity Model (OPM3). The results of this review and analysis help in identifying the advantages and disadvantages of these models.

Tables 1 and 2 show the advantages and disadvantages of the reviewed models respectively, where the “+” annotation means that the model includes an advantage or disadvantage and the empty cell means that the model includes none.

To rank the models, the Technique for Order of Preference by Similarity to Ideal Solution (TOPSIS), which is a multi-criteria decision analysis method, is used. TOPSIS has many features such as: 1) an understandable logic; 2) considers both the best and worst alternatives simultaneously; 3) a straightforward calculation process; and 4) considers several criteria to rank alternatives. Also, in this method, all the alternatives are compared based on defined criteria. The result of TOPSIS shows that the Project Excellence Model (PEM) has the highest rank and therefore its advantages can be included in the proposed model while the Portfolio, Programme & Project Management Maturity Model (P3M3) has the lowest score and thus its disadvantages should be excluded from the proposed model. Figure 2 shows the results of ranking the models by TOPSIS.

Figure 2: Final score of the models

## 3 DEVELOPMENT OF THE MODEL

The results of TOPSIS are considered in developing an integrated and comprehensive model for project audit. Figure 3 illustrates the model’s architecture. Generally, the project audit can be conducted by considering the following three critical aspects: 1) project processes; 2) project functions; and 3) project performance. Series of questions and their associated documents are assigned to both the processes and functions needed to audit the project and measure its status. The project performance is computed by applying the Earned Value Method (EVM).

The project processes include four main parts: 1) project planning; 2) project executing; 3) project monitoring and controlling; and 4) project closing. Planning includes all the processes required to establish the project plan, to cover the project scope and to achieve the project objectives. Executing consists of all the processes required to complete the project work as planned and to satisfy the project specifications. Monitoring and controlling includes all the processes responsible to track, review, and
regulate the project work and progress. Closing consists of all the processes related to finalizing the project activities and closing it.

Project functions include nine parts: 1) Project Cost; 2) Project Time; 3) Project Quality/Safety; 4) Project Scope; 5) Project Human Resources; 6) Project Communication; 7) Project Risk; 8) Project Procurement; and 9) Project Integration. Cost is related to estimating, budgeting, managing, and controlling project costs so that the project can be completed within the determined budget. Time includes project activities duration, scheduling the project and completing it on time. Quality/Safety consists of activities, which need to be performed in order to determine policies, objectives, and responsibilities to quality of the project specifications with defined safety. Scope is required for ensuring that the project works will be completed and any other type of works that are out of the project scope will be reported. Human Resource part is necessary to organize, manage, and lead the project team. Communication consists of collecting project information, generating appropriate reports, and distributing reports. Risk is related to identification, analysis, response, and control of project uncertainties. Procurement includes activities, which are needed to purchase or acquire products, services, or results needed from outside the project team. Integration combines and integrates project management activities. As for the project performance, it is computed through the application of the Earned Value Method (EVM). This part provides useful analysis related to the project indices. EVM relies on three key data points; 1) Budgeted Cost of Work Performed (BCWP); 2) Budgeted Cost of Work Scheduled (BCWS); 3) Actual Cost of Work Performed (ACWP). First, two important indices, Schedule Performance Index (SPI) and Cost Performance Index (CPI), are computed by the model. SPI shows how efficiently the project used its time. CPI indicates how efficiently the project used its budget to date. SPI is computed by dividing the BCWP by the BCWS. SPI is a number that can be either lower than 1 (under schedule) or bigger than 1 (ahead of schedule). CPI is computed by dividing the BCWP by the ACWP. CPI is a number that can be either less than 1 (over budget) or greater than 1 (under budget). Two other important values that EVM calculates are: 1) Schedule Variance (SV) and 2) Cost Variance (CV). SV indicates that a project is ahead of or behind schedule and it is calculated by subtracting the BCWP from BCWS. A positive value is a favorable condition and a negative value is an unfavorable condition. CV indicates that a project is over or under budget and it is calculated by subtracting the BCWP from ACWP. A positive value is a favorable condition and a negative value is an unfavorable condition. There are some other useful values that can be computed with the earned value method; 1) Time Estimate at Completion (TEAC); 2) Estimate to Completion (ETC); 3) Estimate at Completion (EAC); and 4) Variance at Completion (VAC). While the EVM results are numerical numbers that their interpretation is clearly explained there is a need for a scoring system to compute the quantitative values of the project processes and functions. The proposed model uses equation 1 and equation 2 to compute the scores for both the process and function. The total obtained score divided by max score that can be achieved for the process or function. Table 3 provides a guideline of the scoring used by the model.

\[
\%\text{process} = \frac{\sum \text{scores related to the process}}{\text{Max score that can be achieved for the process}} \times 100
\]
Six modules are considered for developing the model: 1) table relationship module; 2) project information module; 3) audit questions module; 4) plan a project audit module; 5) record audit results module; and 6) reports module, as shown in Figure 4.

The development has been implemented using Visual Basic for application Programming language for Microsoft Access 2010, and Microsoft Excel 2010. Table relationship module shows the tables, which are needed to store the project data. These data consist of the project main information (i.e. name, code, start and finish date) and project progress data (i.e. time and cost). Also, some tables are needed to store the questions and the results of the calculations. Project information module store the information needs to be provided to implement the audit effectively. The information is divided into seven groups: 1) construction process; 2) construction function; 3) construction stage; 4) contract type; 5) scoring levels; 6) project plan; and 7) project information. Audit questions module consists of several questions to audit project processes and functions. Each question is related to a project process and a project function. Furthermore, to satisfy each question, two or more documents need to be prepared. Plan a project audit module is needed to plan and schedule audit. In other words, some information (i.e. audit date, project name, project stage, and auditors) need to be selected from the form that has been designed for this purpose. Two approaches are considered to audit a project: 1) comprehensive; 2) quick. Comprehensive audit includes all processes and functions to audit a project. Quick audit is used when project managers need to prepare a report for a specific function or process and they do not have enough time or resources to implement a comprehensive audit. Record audit results module is divided into two categories: 1) question results, which include the results of all the questions related to project processes and functions; 2) performance results, which consists of the project progress information that should be entered in the model (i.e. actual progress and actual cost). Reports module is able to generate several types of reports and to generate a variety of new user-defined reports. In other words, some reports are generated from the main information (i.e. project information, processes, and functions) and others are the result of the analysis and computations that the model implement. Two groups of reports have been designed in this model: 1) main reports, which generate from the main information menu (i.e. project information, processes, functions); 2) analytical reports that present results of the project audit.
4 TESTING AND VALIDATION

The capability and workability of the developed model, showed in figure 3, is tested by auditing a real construction project. Information from a real Oil and Gas project is used to implement an audit for that project. It is commonly known that an Oil and Gas project is classified as a heavy infrastructure project because it consists of different construction projects including un-industrial and industrial buildings, pipelines, roads, warehouses, refinery, tanks, vessels and etc. The project has a starting date of October 2011 and the planned finishing date is October 2015. Using the developed model to audit this project shows that owners, project manager, project team are provided with a very useful tool that helps them to assess all aspects of a project (process, function, progress performance) during the project lifecycle. The process is implemented in four steps: 1) Entering related information; 2) Planning (schedule) a project audit; 3) Recording project audit results; 4) Analytical reports. First, the project information must be entered into the model. As shown in figure 5, the user should click on the “Related Information” button to open another tab that provides the main menu from which the user can select and input related information.

![Figure 5: Related information menu components](image)

The project audit should be planned and scheduled as mentioned earlier. Because the audit of the case project covers processes, functions, and performance, comprehensive audit is selected from the menu. There are two options in the “Plan Audit” form, comprehensive audit and quick audit. There are several fields that should be entered. Audit ID is a six character field in which the first four characters are for the year and the two other characters present the number of the audit in that year. As shown in figure 6, for that actual project the ID is 201402. The date that the audit will be implemented and the project name should also be entered in this case it is 01/06/2014. To record project audit results, there are two types of data that should be entered in the model to be analyzed: 1) entering the answer of the audit questions; 2) updating the project progress. Usually, there is a project management office in project oriented organizations that supports project managers during the project lifecycle and it is responsible for performing project audit. Therefore, the project audit results are entered to the developed model by this office. Once all the audit data is entered, the model will analyse all these data and generate two different types of reports as mentioned earlier, main reports and analytical reports. The main report provides all reports of related information menu. The analytical reports of the model have been divided in two categories; audit questions and progress performance. The final score of the project audit is 50.63 or
medium. Project performance reports also can be generated by the model. These reports represent all the analytical indices of the project based on the project plan that was input into the model during the first step. Also, the model can generate a comprehensive report of the project performance indices that contains useful data and an interpretation of these results.

![Figure 6: Project audit results - processes and functions score](image)

Two related data should be entered in the model: 1) audit ID; and 2) audit date to generate the report. For the real case project Audit ID is 201402 and 23/05/2014 is entered. Figure 7 shows project performance indices and factors.

![Figure 7: Project performance indices and factors](image)

For example, in May 2014, the project schedule variance (SV) is a negative number and the Schedule Performance Index (SPI) is a number less than 1. These indices support the finding that the project is behind schedule. Also, indices related to cost performance, project cost variance (CV) and Cost Performance Index (CPI) are negative and less than 1 respectively. This means that the project is over budget. The value of ETC (t), which represents the estimated time to completion, is 55 months. Comparing 55 months to the project planned duration, of 48 months; it means that with the current performance the project will take seven months more than had been planned. Cost forecast value also show that the project needs $105,831,190 from the project audit date, 2013/06/01, to be completed. This
means the project final cost will be $299,113,636 instead of the $214,000,000 as planned, which means an extra cost of $85,113,636 from what is estimated. The system provides a guideline for interpretation of earned value indices if the user clicks on the blue question mark sign on the top-right of the form.

5 CONCLUSION

In this paper, the steps followed in developing an integrated model for construction project audit during the project life cycle were described. The model was developed based on the advantages and excluding the disadvantages of other project audit and improvement models. The developed model has several advantages. It assesses all aspects of a project (process, function, progress performance) and reports critical project performance factors at the same time. Also, users have the ability to customise the audit to do a comprehensive audit or quick audit, which is applicable to all project stages and compatible with the project life cycle. With this model all project data can be stored and pulled up at anytime even after the project implementation. Reviewing the project audit results during the project implementation helps the project manager to find project problems, issues, and concerns and to try to address them on time. Users can plan, schedule, and implement a project audit with this model and analyse the results within a minimal time frame. It provides valuable analytical information of the project, which presents the current status of the project.

MULTI-AGENT SYSTEM FOR IMPROVED SAFETY AND PRODUCTIVITY OF EARTHWORK EQUIPMENT USING REAL-TIME LOCATION SYSTEMS

Faridaddin Vahdatikhaki¹, Amin Hammad², ³ and Seied Mohammad Langari¹

Abstract: The growing complexity and scope of construction projects is making productivity and safety of earthwork of a great concern for project and site managers. In earthwork operations, where heavy machines are being used, various safety and risk issues put the timely completion of a project at stake. Additionally, the construction working environment is heavily susceptible to unforeseen changes and circumstances that could impact the project, both cost and schedule wise. As a response to the looming safety threats or unforeseen changes of working conditions, re-planning is almost always required. In order for re-planning to yield the optimum results, real-time information gathering and processing is a must. GPS and other Real-time Location Systems (RTLSs) have been used for the purpose of real-time data gathering and decision-making in recent years. Similarly, Location-based Guidance Systems (LGSs), e.g., Automated Machine Control/Guidance (AMC/G), are introduced and have been employed mainly for the purpose of high-precision earthwork operations. However, the current application of LGS is limited to the machine-level productivity optimization, which is not sufficient to address the project-level monitoring and decision-making needs. In the context of complex earthwork operations where several teams are concurrently working towards different ends, the globally optimized operations should coordinate the actions of multiple teams of equipment to eliminate the productivity lost by organizational, logistics and operational management. Therefore, the objective of this paper is to develop a Multi-agent System (MAS) structure to orchestrate the machine-level information (i.e. states and poses) induced based on RTLSs to a coherent project-level system committed to support operations towards the enhanced productivity and safety of the overall project. In the proposed MAS, several layers of agents are processing and managing the huge amount of collected sensory data into useful information that can be used in decision making at different operational levels. The proposed MAS has a semi-distributed structure to strike a balance between the optimality of the outputs and the required computational efforts. A case study is developed to demonstrate the applicability of the proposed MAS. Also, a two-layer safety mechanism is proposed based on which near real-time collision-free path planning and real-time collision avoidance can be performed. In the light of the results of the case study, it is found that the the proposed MAS structure is able to effectively address the team-level coordination of different pieces of equipment and improve the safety of construction site using the proposed two-layer safety mechanism.

1 INTRODUCTION

The construction industry is concerned with Improving the productivity and safety of construction projects (Beavers et al. 2006). In earthwork operations, where heavy machines are being used, various safety and
risk issues put the timely completion of a project at stake. Additionally, the construction working environment is heavily susceptible to unforeseen changes and circumstances that could impact the project, both cost and schedule wise. As a response to the looming safety threats or unforeseen changes of working conditions, re-planning is almost always required. In order for re-planning to yield the optimum results, real-time information gathering and processing is a must. The Global Positioning System (GPS) and other Real-time Location Systems (RTLSs) have been used for the purpose of real-time data gathering and decision-making in recent years (Perkinson et al. 2010). Similarly, Location-based Guidance Systems (LGSs), e.g., Automated Machine Control/Guidance (AMC/G), are introduced and have been employed mainly for the purpose of high-precision earthwork operations. LGS integrates geopositioning technologies with 3D design models and Digital Terrain Models (DTMs) to either (1) support the machine operator through the provision of continuous guidance on a digital screen mounted in the cabin of the machine, or (2) control the position and movements of the equipment (or part of it). While GPS and total stations are the main tracking technologies used in AMC/G, other types of emerging Real-time Location Systems (RTLS), e.g., Ultra-Wideband (UWB), can be integrated with similar monitoring mechanisms to provide monitoring and guidance capabilities for earthwork equipment.

The current application of LGS is limited to the machine-level productivity optimization in large projects, which is not sufficient to address the project-level monitoring and decision-making needs. There are several challenges that have to be overcome in order to maximize the benefits of using this technology in the 3D surveying-design-contract-construction-inspection workflow (Dunston and Monty 2009, Torres and Ruiz 2011, Vonderohe 2009). The problem of providing near real-time guidance or control support for the operators of earthwork equipment based on the consideration of the entire fleet can become complex, in line with the fleet size and equipment interactions. For such complex problems, the conventional approach of central problem solving becomes far-fetched, attributable to the fact it is difficult or impractical to globally grasp and analyze the multi-dimensionality and dynamisms of such problems. Distributed intelligent systems are designed to address such complex problems in terms of several collaborating intelligent agents, who try to solve the overall problem by synthesizing limited views of individual agents (Ferber 1999). Such systems are referred to as Multi-Agent Systems (MASs), which consist of several intelligent agents capable of interaction.

Furthermore, despite the growing availability of LGS, its application for safety is limited to real-time proximity-based object detection and warnings. In the existing systems, the increasingly affordable advanced sensing and location systems are used to mitigate the collision risks by warning the operators against the potential dangerous proximities in real time (Burns 2002, Carbonari et al. 2011, Zhang and Hammad 2012, Guenther and Salow 2012, Wu et al. 2013, Zolynski et al. 2014, Vahdatikhaki and Hammad 2015a). Cheng (2013) proposed to use the pose and speed data for the generation of the workspaces. This method does not consider the equipment state as a means to economize the use of space around the equipment and does not cover the equipment with rotary movements, e.g., excavators. Therefore, there is a need for a solution that is able to reliably predict the operation of the equipment for a long-enough time window to enable different pieces of equipment to adjust their planned paths to avoid collisions in near-real time.

Therefore, the objective of this paper is to develop a MAS structure to orchestrate the machine-level information (i.e. states and poses) induced based on RTLSs to a coherent project-level system committed to support operations towards the enhanced productivity and safety of the overall project. The paper also aims to develop a two-layer safety mechanism: the first layer of which enables the equipment to plan a collision-free path considering the predicted movement of all other equipment, and the second layer is acting as a last line of defense in view of possible discrepancies between the predicted paths and actual paths. The structure of the paper is as follows. First, the proposed method is introduced, followed by the explanation of the implementation and a case study. Finally, the conclusions and future work are presented.

### 2 Proposed Method

Figure 1 shows an overview of the scope for the proposed MAS framework. The main assumptions are that every piece of equipment on the construction site has a sufficient number of RTLS Data Collectors.
(DCs) attached at specific locations to track its movement, and that every equipment operator is supported by an agent that can communicate with other agents in a MAS framework. The proposed MAS supports the project at three different levels: (1) Planning, (2) execution and monitoring, and (3) re-planning. At the planning level, the MAS is able to streamline the operation and task assignments to different equipment as well as to perform equipment path planning (Zhang and Hammad 2012), which is operationalized in terms of strategic and tactical planning. At the execution and monitoring level, MAS is committed to (i) provide visual guidance to equipment operators, (ii) collect and process RTLS data, (iii) apply appropriate error correction techniques to identify the pose of the equipment (Vahdatikhaki et al. 2015), (iv) identify the state of the equipment (Vahdatikhaki and Hammad 2014), (v) apply the Near Real-time Simulation (NRTS) (Vahdatikhaki and Hammad 2014), (vi) generate equipment workspaces, i.e., Dynamic Equipment Workspaces (DEWs) (Vahdatikhaki and Hammad 2015a) and Look-Ahead Equipment Workspaces (LAEWs) (Vahdatikhaki and Hammad 2015b), and (vii) report the necessary information to pertinent agents. The aforementioned two types of workspaces differ in that while DEWs are generated based on the equipment pose and speed in real time to form a safety buffer around the equipment that can help prevent collisions, LAEWs are built based on the predicted future motion of equipment and operator visibility in near-real time to help find a collision-free path for the equipment, as explained in Section 2.2. Finally, at the re-planning level, the proposed MAS framework addresses the need for task-reassignment, path re-planning, and design change requests, which may become necessary in view of the potential unforeseen safety risks identified at the monitoring level. As can be seen in Figure 1, while the proposed MAS framework offers advantages at both the operational and managerial levels, only the operational aspects of framework are addressed in this paper.

![Figure 1: Overview of the Scope for the Proposed MAS Framework](image)

The authors have previously presented the overview of the proposed MAS (Hammad et al., 2013). This paper extends this research by providing a more in-depth discussion of the agents’ functionality in the MAS and how the LAEWs are being used by different agents to avoid collisions.

A multi-layer agent architecture is proposed in which agents supporting the operators of single machines constitute the lowermost layer of the agent hierarchy. These agents process and manage the huge amount of sensory data, provided by an UWB system or other types of location systems, into useful information that can be used in decision making at different operational and managerial levels. Figure 2
shows the proposed MAS architecture where several teams working in the proximity of each other are supported by different types of agents, with different tasks and project views. Three functional agent types can be distinguished according to the distribution of the responsibilities, namely, operator, coordinator and information agents. In a nutshell, Operator Agents (OAs) support the equipment operators and have the essential knowledge about their current task, state and pose. In a construction site, often a group of equipment is teamed up to serve one particular operation, for instance several trucks and an excavator work together to move the earth. The team coordinators are supported by Team Coordinator Agents (TCAs), whose main objective is to track the progress of operations based on the data gathered from their subordinate OAs and to ensure safe and smooth delivery of the operations’ objectives. Depending on the level of coordination each TCA offers, several layers of TCAs and a General Coordinator Agent (GCA) can be defined. Further, these different types of agents are fed by information agents who provide the required site, design or project-related data to the agents, and frequently get updated based on the changes happening in the site as the construction progresses.

![Multi-Agent System Architecture](image)

Figure 2: Multi-Agent System Architecture (Adapted from Hammad et al. 2013)

Information Agents are in charge of handling the information required for MAS and encompasses the Site State Agent (SSA), Project Document Agent, (PDA), and Design Document Agent (DDA). The SSA provides and updates the Digital Terrain Model (DTM), which is often obtained from Light Detection and Ranging (LIDAR) scans by surveyors. Additionally, the SSA uses a variety of local sensors coupled with the information from weather agencies to constitute a database of weather as expected at the planning time, at the current time and as forecasted. The main functionalities of the SSA are to provide information to TCAs and OAs, when needed, and to update their data whenever a change befalls. The DDA, on the other hand, encapsulates the designer-provided 3D models and updates them should any changes be made in the course of the project. The 3D design model is used by all the coordinator and operator agents as a reference for decision making and task execution. Finally, the PDA hosts all the basic project documents based on which an earthwork project is typically managed, including safety regulations, available resources, project schedule, construction methods, and available sub-contractors.

2.1 Agents Responsibilities and Functionalities

2.1.1 Operator Agents

The OA requires information about its surroundings, task and environment. These combined types of information are referred to as external information because they are provided by external sources. Surroundings information contains the poses, states and DEWs of other pieces of equipment. This information can be directly used by the OA to identify safety threats and take immediate actions, if required. Task information allows the OA to perform its (semi-)autonomous operations and contains safety warnings, LAEWs, a strategic plan, and NRTS-generated schedule provided by the TCA and 3D design model made available by the DDA. High-level flowchart of the functionalities of an OA is shown in Figure 3(a). Given the unequal priorities of various functionalities of the OA, and in order to embed these priorities in the MAS structure, a modified subsumption architecture is chosen for agents. Subsumption
architecture is based on breaking the activities of an agent in vertical modules where every module has limited responsibilities and the results of the higher modules always supersede those of the lower modules, if there is a conflict between various modules (Ferber 1999). In a nutshell, OAs constantly monitor the operations and perform the routine calculations for the equipment condition monitoring, pose and state-identifications, cycle time, generation of tactical plans, generation of risk maps, detecting underground utilities, and generating DEWs.

Figure 3: High-Level Flowchart of (a) the OA Functionalities, and (b) the TCA Functionalities

2.1.2 Coordination Agents

Coordination encompasses agents representing team coordinators who are responsible for making critical decisions, e.g., new work schedules or command for the suspension of the operation, using data from all other agents, and further communicating their decisions with the appropriate OAs for the execution. Essentially, this component consists of one GCA and several TCAs. However, depending on the characteristics of the project, the phase of the project and simultaneous operations, several layers of teams and sub-teams can be formed. Each team is coordinated and supported by a TCA.

The role of a TCA is to assign tasks to the subordinate OAs or sub-TCAs and to collect information from them. Figure 3(b) shows the high-level flowchart of the TCA functionalities. The main functionality of a TCA is to assign and monitor the tasks of the OAs. At the top of the flowchart, the TCA determines whether a new operation is assigned or an operation is ongoing. In the first case, the operation is broken into OA-executable tasks and assigned to the relevant available OAs. Next, in view of the reports from subordinate OAs, the progress monitoring, NRTS, and LAEWs (if any risk is identified), either the tasks are rescheduled if the problem can be resolved locally, or the GCA (or higher level TCA) is informed for directions. Local resolvability means that the problem can be solved by the information present to a single TCA, without the need to engage into negotiations with other TCAs. The negotiation between agents in a decentralized MAS structure is outside the scope of the present paper.

The GCA is responsible for monitoring and controlling the operations to ensure the smooth execution of the project. The GCA also generates the operations' schedule and the resource distribution based on the available resources, project schedule, the chosen construction methods and available sub-contractors. The functionalities of the GCA are realized through the accumulation of information about the project and the progress of different operations. The project information is the combination of all essential documents/information based on which an earthwork project is executed. At a high-level abstraction, safety regulations, available resources, project schedule, construction methods, and available sub-
contractors, all of which are coming from the PDA, are the main ingredients of the project information. Safety regulations are used to derive basic safety rules that need to be observed throughout the project. Available resources and available sub-contractors are used for the resource configurations and distribution. The project schedule is used for the generation of operation schedules that can be assigned to different TCAs. The Construction methods provide the GCA with the initial information needed to retrieve the right operation procedures.

2.2 Safety Management in MAS

As stated in Section 2, the safety of earthwork operation in the proposed MAS structure is supported through a two-layer mechanism which includes near real time collision-free path (re-) planning using LAEWs and real-time collision avoidance using DEWs. These two layers are running independently in parallel with different update rates. Given the nature and functionality of DEWs, they are updated in real time with the same rate offered by the tracking technology \((dt)\). LAEWs, on the other hand, require intensive computations and communications between various agents, and thus they are updated with a rate less than DEWs. The LAEWs are generated over every \(\Delta t\) and whenever a deviation from the predicted path of various equipment is observed. While the details of the two types of workspace are presented in the previous work of the author (Vahdatikhaki and Hammad 2015a, Vahdatikhaki and Hammad 2015b), a brief explanation of each workspace is presented in the following sections.

2.2.1 Look-Ahead Equipment Workspace (LA EW)

The flowchart of the proposed method for the generation of the LAEW of one piece of equipment (equipment \(q\)) is shown in Figure 4(a). As shown in this figure, the input of this method comprises the sensory data, the equipment specifications and its accurate 3D model, the current pose and state data generated by the OA of the equipment \(q\) (OA\(_q\)), and future state data coming from the NRTS that is performed by the TCA. A rule-based system is used to identify the states of different equipment with a high accuracy by leveraging a set of equipment proximity and motion rules that determine the states of the equipment (Vahdatikhaki and Hammad 2014). Also, a robust optimization-based method that uses geometric and operational characteristics of the equipment is used to improve the quality of the pose estimation (Vahdatikhaki et al. 2015). Additionally, the updated 3D model of the site, and the project’s detailed plan (including the location of different scheduled tasks, their time frame, and the site layout) are available through the Information Agent. Finally, a set of heuristic rules that define the operation of a skilled operator is also required to be available to each OA. The generation of LAEW is based on the discretization of the entire site space into cells, and then calculating the risk associated with each cell given the future expected states of different pieces of equipment, which is performed by each OA. As shown in Figure 4(b), the pose data are used to identify the current state, which is then passed on to the TCA to perform the NRTS in order to generate the operational pattern of each OA. These data are then communicated with the OA\(_q\) who will first integrate the equipment pose with its 3D model and the updated 3D model of site to situate the equipment in the virtual environment. Then, the OA will use the project plan, and the rules that govern the operation of the machine by a skilled operator to generate the risk map of the equipment. Finally, the OAs transfer their individual risk maps to the TCAs who will first combine these risk maps and then use the tolerable risk level of each OA to generate the LAEW. It should be highlighted that LAEW\(_p\) for equipment \(p\) is generated based on the combination of the risk maps from all pieces of equipment surrounding equipment \(p\), excluding equipment \(p\) itself. LAEW\(_p\) can be used by the OA\(_p\) to perform path re-planning, if required. Similarly, the path-replanning performed by the OA\(_q\) at the end of the flowchart shown in Figure 4(a) is realized using LAEW\(_q\).

2.2.2 Dynamic Equipment Workspace (DEW)

DEWs aim to use the pose, state, and speed characteristics of the equipment to generate a space around the equipment that would allow the prevention of immediate collisions with other pieces of equipment or obstacles on site, considering the equipment stoppage time \((t_s)\). \(t_s\) can be used to determine how much of the space in the moving direction of equipment is unsafe after the operator becomes aware of a potential collision considering the operator reaction time and braking time. In addition to the DEWs of the equipment, semi-dynamic obstacles (such as trenches, temporary or permanent structures, etc.), also
need to be represented by their own corresponding safety zones to enable effective collision avoidance at
the global level.

![Diagram](image)

Figure 4: (a) Flowchart for the Generation of LAEW, and (b) Schematic Representation of LAEW
Generation Process

For the DEWs to be effectively used for the purpose of collision detection and avoidance, every OA needs
to be able to generate its own DEW and have near-real-time information about the DEWs of other OAs.
Figure 5(a) shows the flowchart for the generation of the proposed DEWs. With the 3D model of the
equipment and its pose and state information available, the method proceeds to determine the linear and
angular speeds of the equipment. For instance, an excavator can travel on its tracks with the linear speed
of \( \dot{v} \), move its bucket with the linear speed of \( \dot{v}_{bp} \), or swing with the angular speed of \( \dot{\omega}_{bp} \). Upon
the determination of the speed vectors, the DEW can be generated based on the type of the equipment and
the equipment state. For example, two distinct types of states can be identified for an excavator, namely
stationary states (swinging, loading, dumping, and waiting) and traversal states (relocating,
maneuvering). Figure 5(b) shows different DEWs of an excavator for different states. Next, to avoid
redundant computation, an OA can perform pairwise comparisons of DEWs only with the OAs that are in
its vicinity. To determine the equipment in vicinity, the multi-layer workspace concept (Chae 2008, Wang
and Razavi 2015) can be applied. In this method, the pairwise distances between every two pieces of
equipment are calculated and if the two pieces of equipment have a distance less than a threshold, then
the collision detection between their DEWs is performed. In order to further reduce the computation
efforts and avoid redundant calculations, the priorities of the different equipment can be used to delegate
the calculation to the OA of the equipment with the lower priority. If a collision is detected between
the two, the equipment with the lower priority will stop and send a warning to the OA of the other equipment.
If both pieces of equipment have the same priority, then the OAs of both should perform the collision
detection and if a collision is detected they should both stop.

3 IMPLEMENTATION AND CASE STUDY

In order to demonstrate the feasibility of the proposed MAS approach in improving safety using LAEWs
and DEWs, a prototype system is implemented using Unity3D game engine (2015) and two simulated
scenarios are examined. The scenarios used for the case study consider an excavation operation for a
specific day of the project where two excavators are scheduled to dig a ditch and load two trucks, which will haul the soil to the dumping area, dump it, and return to the excavators for the next load.

![Flowchart of the Generation of DEW, and Examples of Excavator DEWs in Different States](image)

Figure 5: (a) Flowchart of the Generation of DEW, and (b) Examples of Excavator DEWs in Different States (Adapted from Vahdatikhaki and Hammad 2015a)

In the first scenario, the feasibility of applying LAEWs for collision-free path planning is investigated. The scenario covers a portion of the earthmoving cycle where Excavator A, which is assumed to have a higher priority than Excavator B, is expected to swing to Truck A, and Excavator B is expected to swing away from Truck B, as shown in Figure 6(b). The algorithm for the operation logic of excavators is shown in Figure 6(a) (Hammad et al 2014). The articulate digging and dumping movements of the excavator parts at a Digging Station (DS) are planned initially using parametric scripting. If the results of the LAEW-based safety check revealed a potential collision, the path re-planning is done using Rapidly-exploring Random Tree (RRT) (La Valle 2006). Figure 6(b) shows the initially planned paths for Excavators A and B. Since Excavator A has a higher priority, its initial planned path is approved. However, while the initial path of Excavator B would require it to swing counter-clockwise to the truck, given that this path had a collision with the LAEW, a new clockwise path is generated using RRT, as shown in Figure 6(c).

In the second scenario, the effectiveness of DEWs is investigated in another simulated scenario. In this scenario, as shown in Figure 7(a), while Truck A is hauling the material to the dumping point, Truck B is returning from the dumping point to the DS. It is assumed that although their planned paths have been collision-free, Truck A fell behind its planned path, which could lead to a potential collision. In this case, as explained in Section 2.2, DEWs can be used as the last line of defense to avoid the collision by requiring one of the equipment to stop. The algorithm shown in Figure 5(a) is implemented in Unity for the real-time generation and collision detection of DEWs. As shown in Figure 7(b), upon the detection of collision between the two DEWs, Truck B, which has a lower priority, is stopped, and Truck A is allowed to continue its path to the dumping point, as shown in Figure 7(c).
Figure 6: (a) Algorithm Representing the Operation Logic of Excavator, (b) Current Poses and Initial Paths of Excavator, (c) LAEW of Excavator B and Final Path of Equipment B

Figure 7: (a) The Layout of the Second Scenario, (b) Collision Detection between DEWs, and (c) Collision Avoidance Decision made by OAs

4 CONCLUSIONS AND FUTURE WORK

In this paper, a MAS structure is introduced for improving the safety and productivity of automated guidance and control of earthwork equipment. In the proposed MAS structure, every piece of equipment is supported by an operator agent to oversee the task and provide guidance whenever needed. A multi-layer agent hierarchy assigns monitors and coordinates the task executions, and a set of three types of agents feed the system with the relevant information. The functionalities, jurisdictions and the input-output scheme of every type of agents were discussed. A two-layer safety mechanism was introduced, where the first layer enables the equipment to plan a collision-free path considering the predicted movement of all other equipment and the second layer acts as a last-line-of-defense in view of possible discrepancies between the predicted paths and actual paths.

In view of the results of the case study, it is shown that the MAS is capable of effectively handling the harmonization of various pieces of equipment on the site beyond what is available by the conventional
LGSs. The combination of LAEWs and DEWs are found to be an efficient approach to deal with collision-free path planning and real-time collision avoidance. The authors are planning to investigate the negotiation between different levels of agents as part of their future work.

Abstract: Roofers have long suffered from low back disorders (LBDs), which is a primary non-fatal injury in construction. Until present, most of the research on roofing safety is mainly focused on fatal injury risks such as falls from height, leaving much to be desired in the risk assessment of non-fatal, cumulative musculoskeletal disorders among roofers. Ergonomics studies have identified several physical risk factors associated with LBDs in workplaces and applied selective ones to develop predictive models for general LBD risk assessments. However, these models cannot be used for roofing assessments in that they are designed for general tasks without considering different roofer working postures and the effect of working on uneven rooftops. To understand the relationship between the risk factors (i.e., slope angle, posture, facing direction, and working pace) and LBD incidence in roofing shingle installation, a factorial in-lab experiment is conducted with the aid of the Vicon camera system and Electromyography (EMG) sensors. The bending angles and muscle strengths in the low back, which are measured by the two sensor systems, are analyzed as facts that indicate the LBD risk. The proposed experiment finds out the risk factors with significant effect on the LBD injury and interaction between the studied factors. The findings may be used to study the detailed ergonomic safety guidelines for roofing contractors, which will be useful for eliminating LBD risk factors on the roofing sites.

1 INTRODUCTION

As a major construction workforce, roofers have long suffered from low back disorders (LBDs), which is a primary non-fatal injury in construction. For roofing workers, it was found that 30% (i.e., 3,300 of 10,815) cases of injuries and illnesses occurred in the trunk (Fredericks et al. 2005). In roofing, shingles are widely used as roof covering materials, and shingle installation is a most time-consuming activity where most injured cases take place (Wiki 2015; CPWR 2015). Without enough knowledge of the nature and disease formation of LBDs, roofers tend to adapt themselves to the harsh workplace environments (e.g., steep rooftops) and fast work pace. In addition, the roofers’ working postures can vary due to their personal preference. It has not been revealed what factors are prone to cause LBDs and needs to be rectified. Till present, there are only general guidelines available, which are designed for general industrial tasks (e.g., manual material handling) (Wang et al. 2015), ignoring the differences in environment settings, working procedures, job rotations, and alternative postures. The research in roofing safety mainly focuses on fatal injuries, while existing efforts in non-fatal studies are focused on sample studies and disease diagnosis. In order to better understand the relationship between the LBD incidence among
roofers and the potential risk factors, in this study, the main risk factors in the roofing shingle installation are identified. Then, a factorial experiment is designed to study their effects and their interaction on LBDs. Advanced motion capture system Vicon and skeletal muscle signal recording system Electromyography (EMG) are utilized to conduct the LBD risk measurements. Through this experiment, it is expected to reveal the effects of the risk factors on the LBDs and to report the risk level at certain conditions, which may be helpful to the study of detailed ergonomics guidelines for roofing workers.

2 RESEARCH BACKGROUND

2.1 State of Practice

In the United States, there is a total of approximately 132,700 workers employed as roofers whose main jobs include repair and install the roofs using shingles, asphalt, metal, and solar panels, etc. (BLS 2015a). Roofing work can be categorized into commercial roofing on low-pitch roofs (below 10°) and residential roofing on a relatively steep roof (10°~45°) (National Contractors Inc. 2015). Roofing work can be hot and physically demanding. It involves heavy lifting, as well as climbing and bending. According to the survey (BLS 2015b; Fredericks et al. 2005), roofers spent over 60% of their working time on roofs. Shingle installation is a major repetitive task for roofers. The time roofing workers spent on crawling, squatting, stooping and kneeling is among top 7 of all industrial activities (O*NET 2013). The cumulative effects of stooping, kneeling or squatting may not only lead to low back pains, but also can increase forces in the knee (CPWR 2015).

Roofers have a higher incidence rate of injuries and illnesses than the national average. Among all construction sectors, roofing workers have the second largest WMSD (work-related musculoskeletal disorder) incidence rate (i.e., 50.7 per 10,000 full worker year) (BLS 2013). Roofing workers suffer from not only fatal injuries, but also non-fatal injuries. In terms of fatal injuries, workers may slip or fall from scaffolds, ladders, or roofs. Through proper safety protection, most accidents can be prevented (EU-OSHA 2015). In contrast, roofing installation contractors frequently conduct labor-demanding operations, including stooping, kneeling, lifting, twisting, bending, and drilling. Although such operations would not cause acute pain after a short period of work, high repetition could accumulate the burden on the musculoskeletal system in the back and pose roofers to a threat of LBDs (Wang et al. 2015).

Till present, there are very limited guidelines promoted to protect roofers from non-fatal injuries like LBDs. The documented guidelines simply list the causes of hazards, such as severe stooped postures, keeling, lifting and carrying (CPWR 2015). Comparing to fatal injuries, the non-fatal issues are not receiving enough attention. In industry, the sacrifice of safety for productivity is common (Lynch Ryan 2015). An agricultural study revealed that reduced productivity outweighs the benefits brought by knee support intervention which is designed for LBD injury prevention (Jin et al. 2009). However, non-fatal injuries can have a significantly negative impact on productivity by resulting in long days away from work. Besides, workers who had a history of WMSD injuries are reported to have a higher possibility of recurring and can decrease the productivity, in that the risky posture can cause pain in body parts and consequently affect productivity (Serranheiro and Smith 2014).

2.2 State of Research

Plenty of roofing research has been conducted with a focus on fatal injuries (e.g., fall, slips). The implemented studies covered risk assessment, communication, and prevention (Hisao 2014). In contrast, the up-to-date studies in non-fatal injuries are still at the stage of performing sample studies and injury formation analysis. Hunting et al. (2004) have conducted a survey study of the nature and cause of injuries among 2916 injured construction workers by detailed occupation. It revealed that half of injuries among the roofers are in the back and most non-fatal cases are caused by overexertion and strenuous movement. Fredericks et al. (2005) has analyzed the U.S. Bureau of Labor Statistics (BLS) data in roofing and revealed the trends and causes of both fatal and non-fatal injury incidences among roofers. It was reported that roofers spend 61% of their time on roofs and typically spend 3-4 hours daily on manual lifting/carrying. In addition, they have conducted a self-report survey of injuries and risk factors, including
personal information, working environment, and lifting/carry strength to identify the most frequent roofing injury combination.

In epidemiological and ergonomic studies, a lot of efforts have been put in studies of injury nature and risk assessment methods for WMDSs and LBDs (Wang et al. 2015). However, these methods are mostly developed for general industrial tasks, for example, lifting, bending, and carrying (Pan et al. 1999). Up to date, observation tools and predictive models have been developed by summing up the detected risk factors multiplied by assigned weights to evaluate the LBD risk in the workplaces, such as NIOSH lifting equation (Waters et al. 1994) and 4D WATBAK (Neumann et al. 1999). However, for roofing construction activities, no specific studies have been conducted to identify and measure the risk factors on roofing sites.

3 RESEARCH PROBLEM STATEMENT

All the presented data brings forward the problem of LBDs among roofers, which requires actions taken to study and alleviate LBDs among this population. The existing observation tools are able to detect the LBD risk in the workplaces, but provide no clue on how to redesign the work procedures and the environment settings in order to reduce the LBD incidences (CPWR 2015). Epidemiological studies have identified certain physical risk factors for LBDs in workplaces and predictive models are developed based on those selected factors. However, the models cannot be used for roofing activities due to dissimilarity in the survey sample that determines the coefficients and the raised risk factors need modification before applying to roofing tasks. These models do not take into account a diversity of roofer working postures (e.g., stooping, kneeling) and effects of working on slanted rooftops. In addition, in roofing, the effect of gender can be ignored as the majority (over 90%) of workers on construction sites are male (BLS 2015a). Through abundant literature review and site observation, the main risk factors in roofing tasks are detected and summarized as follows for the examination of the experiment.

3.1 Postures: Stooping and Kneeling (or Crawling)

Through on-line search and site observation, two main postures in shingle installation were found: stooping and kneeling. Roofers can use different working postures due to personal preference. Stooping posture, which requires the roofers to bend forward while holding their legs upright, is illustrated in Figure 1. In contrast, kneeling typically requires the workers to kneel on the roof and make the trunk parallel to the roof (Figure 2). However, the existing risk assessment methods do not examine the relationship of an injury to stooping or/and kneeling. Reducing the incidence of work-related LBDs among roofers requires a new focus on identifying and describing stooping and squatting postures as specific LBD risk factors in the workplace (Fathallah et al. 2004).

![Figure 1: Stoop posture on the roof](image1)

![Figure 2: Kneel posture on the roof](image2)

3.2 Environmental Conditions: Roof Slope

For the work environmental setting, the risk of working on a slant roof surface to the LBDs is not well investigated. There are studies on fatal fall risks exploring the effects of the roof slope. One of these is to study the influence of the surface slopes (18°, 26°, 34°) and frequencies on postural balance in shingle installation with stooped postures (Choi et al. 2008). For each surface slope, the Maximum Acceptable
Roof Shingling Frequency (MARSF) was reported. It is found that as the slope slant increases, the MARSF decreases from 206 shingles per hour to 168 shingles per hour. The influence of the slope slant was revealed by this experiment, but it did not indicate that it is the same decreasing trend for the LBD risk as the slope rises.

3.3 Task-Related Factors: Facing Direction on the Roofs

The experimental setup was designed to mimic a shingle installation task in a laboratory setting. Based on our video database search and on-site observation, it is noted that different roofing materials require different installation methods on certain pitches (NINDS 2015). For three- or four-tab residential shingles, roofers are used to installing them parallel to the ridge, which requires the roofers stand facing uphill. For solar panels, the roofers usually stand perpendicularly to the ridge while installing them in order to avoid stepping on these panels. This means that the roofers will work on the roof facing side (hip). In the most recent ergonomics study, it is found that manual handling sudden loading on uneven surface can have a significant difference with on the ground on the LBD risk (Zhou et al. 2015), which provoke the needs for studies on jobs conducted on uneven surfaces such as roofs.

The identified three risk factors, each of which can have at least two factor levels, indicate that there can be different combinations of the slope slants with the roofer working behavior. In order to study the risk on a certain combination, a factorial experiment is designed to analyze the influence of each factor, expected to study the effects of and among different factors to the LBD risk.

3.4 Limitations of Existing Research

It is mentioned that the promoted guidelines and practices still lack practicality. Most guidelines are in rough description and still require expert observation to reveal on-site LBD risk factors and improper work design (CCOHS 2013; Wang et al. 2015). The workers’ insurance compensation put much more emphasis on medical care than preventive efforts, and the injury statistics data is driven by an event or an acute injury rather than cumulative trauma (Fathallah et al. 2004).

Upon the review of the state of practice and research, the main risk factors in roofing industry have been summarized. However, the authors have identified that there are still several areas that need exploring in order to understand and eliminate the LBD risk among roofers. That is: 1) the development of risk measurement for LBDs among roofers, 2) the knowledge of the effects of different risk factors and their combinations on LBD risks (i.e., slope, posture, facing direction, frequency), and 3) comparison of two different postures (i.e., stooping and kneeling) on the effect of developing LBD risks.

Given above limitations, in this study, a sensor-based ergonomics experiment is designed to reveal the relationship between roofing activities and risk factors through lab empirical studies.

4 EXPERIMENT AND IMPLEMENTATION

The purpose of this study is to understand the relationship between the risk factors (i.e., roof slope, posture, facing direction, working frequency) and LBDs in roofing shingle installation. A factorial experiment is designed with advanced EMG to estimate the forces and loadings on the trunk, and motion capture system Vicon to capture the bending angle of the trunk.

Four factors are selected as the independent variables for factorial analysis from the view of individual factors, environmental settings, and task-related factors: 1) Slope: 0°, 15°, 30°; 2) Posture: stooped and kneeling; 3) Facing direction: uphill and side; 4) Frequency: slow (12 seconds/shingle), fast (6 seconds/shingle). Based on the site observation data and studies on maximum acceptable working frequency on roof slopes (Choi et al. 2008), a duration of 12 seconds is set for one shingle installation at slow frequency level; a duration of 6 seconds is set for fast frequency. Given that shingles are usually prepared beforehand, the process of carrying shingles and walking on the roof is ignored. In this simulation, we particularly focus on the nailing process. The participants are required to hold a same nail
gun while simulating shingle installation process on the platform. A total of 16 combinations of the four risk factors are tested and 2 repetitions for each condition are conducted.

In our experiment, there are two independent variables which are generated from data captured by Vicon and EMG.: 1) Maximum lumbar trunk flexion angle which measures the angular difference between the T12 and S1 motion sensors in the sagittal plane (Hu et al. 2014); 2) Average normalized EMG signals which measure the activeness of the muscles on the back (with detailed discussion in 4.4 Data processing). The two independent variables (response variables) are utilized to help establish measurements of the LBD risk and could also verify each other. In addition, the two variables are synchronized using Vicon Nexus software (Vicon, Oxford, 2002). Analysis of variance (ANOVA) is a popular statistics technique which is used to investigate the relationship between the independent variable(s) and the response variable (Miller 1997). In our study, ANOVA is conducted to study the effects of each factor and interaction among risk factors. For all statistical analysis in this study, the criteria p-value is set at 0.05.

4.1 Participants
There were 4 participants in this study. The age, stature and whole body mass (with standard deviation) of this study population were 25.2 year (1.3), 176.4 cm (3.4), and 70.6 kg (8.4). All subjects had no history of low back injury. The research involving human experiments was approved by the Institutional Review Board of West Virginia University (Hu et al. 2014).

4.2 Apparatus
The experimental setup was designed to simulate a shingle installation task in a laboratory setting. The shingle installation simulation was conducted on a 1.4m by 1.7m wood platform (Figure 3). The platform was connected to a hydraulic lift table. By elevating the lift table, the wooden roof could be lifted to a slope angle ranging from 0 to over 60°. In this experiment, a Vicon camera system was utilized to capture the human motion data; and EMG sensors were utilized to capture the signal of the main muscles on the back. Video streams were also recorded for off-time observation.

The Vicon system is a 3D motion capture system that involves multiple cameras surrounding the capture volume where human motion can be tracked (Richards 1999). Vicon data was recorded at a frequency of 100Hz. To capture the posture of the lumbar spine, five Vicon markers are attached to each participant. Three sensors were placed on the spine to calculate the trunk flexion angle: one at the C7 area (near the neck), one at the T12 area (around the chest) and the other at L5 area (lumbar). The three sensors provided measures of angle in the sagittal plane and were then used to estimate the lumbar flexion angle (Dolan et al. 1994). Another two sensors were placed on the shoulders to help recognize the postures and facing directions. They could be used to calculate the trunk twisting angle in the future.

EMG was mainly applied in human kinematics experiments by attaching a group of muscle sensors on the skin (Marras and Granata 1997), as shown in Figure 4. It features in synchronous recording of muscle tension and computerized analysis of myoelectric signals, and is widely used to evaluate muscle actions and the loading in body parts (Reaz et al. 2006). The EMG data was collected at a rate of 1000 Hz. In this experiment, 4 pairs of surface electrodes were placed on the abdomen and low back of the subjects that were used to collect the electromyographic (EMG) muscle activity of the sampled muscles. The sampled muscles included two pairs on the abdomen (Ab1, Ab2), and two pairs on the back (erector spinae (ES), multifidus (MF)). These muscles were chosen as they were reported to have a direct impact on spinal loading (ES, MF). In ANOVA analysis, signals of those muscles were hypothesized to be affected by shingle installation posture (Fathallah 2004; Zhou et al. 2015).
4.3 Procedure

The first phase of the experiment consisted of a series of static trials that focused on collecting the maximum voluntary capacity and static low back posture. The second phase of the experiment consisted of two repeated trials on each condition which is a combination of the selected factors, such as, stooping on a 15° slope at a fast working pace while facing uphill. At this phase, both Vicon markers and EMG surface sensors were placed on the subject’s trunk and low back. This way, kinematics data and muscle signals were recorded simultaneously and synchronized for post-processing. The stooped trials were simulated first, and then kneeling postures.

4.4 Data Processing

The trunk kinematic data collected from the Vicon during the trials were used to compute the trunk flexion angle. The three markers placed on the trunk were reconstructed in the 3D space using Vicon Nexus. The derived 3D coordinates were used to track the trunk motion and compute the bending angle.

The EMG data collected during shingle installation cycle was rectified, filtered using butter filter, and averaged over the whole nailing period. These data were then normalized to the percentage of the Maximum Voluntary Capacity (MVC) of the muscle. During the experiment, the subjects were required to follow the same time schedule (trunk flexion, nailing, and trunk extension) during a working cycle. Nailing process was extracted by defining the starting and ending time of the nailing process. As denoted in Figure 5, two peaks were captured during a single shingle installation cycle. The first peak of EMG signal reflects the trunk flexion process, and the second peak reflects the trunk extension process. The flat curve between the peaks represents the nailing process.

![Figure 5: EMG signal process and nailing process extraction](image-url)
5 RESULTS

Prior to conducting the formal analyses, the assumptions of the ANOVA technique (normality of residuals, and independence of observations) were evaluated using the graphical approach advocated by Montgomery (2001). Interval plot each factor vs each response variable was drawn to show the sample’s tendency and variability. In addition, F-test was conducted to investigate the effects of each factor on the response variables (Flexion from Vicon, ES (erector spinae) and MU (multifidus) from EMG data) and presented in Table 1. “+++” denotes a significant effect and “/” denotes no significant effect. For example, frequency difference has no significant effects on the flexion angle captured by Vicon. It is because either for slow cycle or faster cycle, the participants followed the exact same posture and procedures, which would result in no noticeable difference.

The subsequent univariate ANOVA showed that the response of the erector spinae and the multifidus followed a consistent trend on most conditions. Besides, the Vicon and EMG data supports each other in effects of slope angles, but contradicts each other on certain conditions. As mentioned, both Vicon and EMG data serve as the risk measurements of the loading on the back. As stooping and crawling are two totally different postures, correspondingly, the back muscles and the rest of the body parts can differently be involved in the procedure. At this stage, the comparison of stooping and crawling is not discussed. In the following section, the results of stooping and kneeling postures are presented. For each posture, we respectively conduct ANOVA analysis to study the effect of each factor on the LBD injury development.

5.1 Stooping Posture

5.1.1 Influence of slant

The effects of slope angles on maximum flexion angle can be revealed in Figure 6. The flexion angle calculated from Vicon data shows the trend that the flexion angle is decreasing as the slope angle increases, which indicates a decreased LBD risk. Survey score from the subjects also indicates a same trend.

Figure 6: Effects of slope angles on flexion angle (stooped)

This result is verified by EMG data as a same trend is detected both in ES and MU muscles, shown in Figure 7.

Figure 7: Effects of slope angles on EMG (stooped)
5.1.2 Influence of facing direction

From the flexion angle, we can detect that the flexion angle of working facing side tends to be higher than that of facing uphill, as shown in Figure 8. Besides, as to facing side, a more severe twisting of the trunk is reported by the subjects in the survey. For each degree of slope, except the flat ground, a higher risk for facing side than facing uphill is indicated. But as mentioned, the EMG data contradicts the trend on some conditions, which still needs further studies.

![Figure 8: Effects of facing directions on flexion angle by slope angle (stooped)](image)

5.1.3 Influence of speed

The Vicon data shows there to be no evident differences between slow and fast working paces in flexion angles. On the contrary, the response of EMG shows the trend that the muscle signal in both MU and ES muscles become stronger as the working rate accelerates, which indicates an increased LBD risk (Figures 9 and 10).

![Figure 9: Effects of frequencies on MU EMG signal (stooped)](image)

![Figure 10: Effects of frequencies on ES EMG signal (stooped)](image)

5.2 Kneeling Posture

For kneeling postures, the facing direction was assumed to be uphill as only uphill was detected in video observation. The effects of the slant and frequencies are discussed respectively as follows.

5.2.1 Influence of slant

The response of Vicon shows the trend that the flexion angle decreases as the slope rises, which indicate a decrease LBD risk, as shown in Figure 11. For both fast and slow frequencies, Figure 12 shows that there is a consistent trend. That is, as the slope rise, the flexion angle decreases, indicating a decreased LBD risk. As we increased the slant to 40 degrees, the trend is consistent. EMG signals verify this finding as well.
5.2.2 Influence of frequency

Similar to stooped postures, the response of EMG shows a trend that the muscle signal becomes stronger as the working rate accelerates, which indicate an increased LBD risk for kneeling postures.

6 DISCUSSIONS AND CONCLUSIONS

This paper proposed a method to examine the effects of the common risk factors in roofing jobs. A factorial experiment was designed to reveal the effects of a combination of the identified factors. From the result analysis, the effects of each factor were revealed. From this study, faster working pace resulted in a higher LBD injury risk. As the slope angle increases from 0° to 15°, and then 30°, a decrease in LBD risk was detected. The facing side working condition posed extra pressure on the lower back due to a twisting angle. These findings might be helpful to develop specific guidelines and prevention training for tackling the LBD risk among roofers. The existing study did show a significant effect of the selected factors on the changes of the response variables, which indicated an influence on LBD risk. Some of the findings contradicted people’s common sense. For example, people tend to believe that it is risky on steep roofs and poses more injury risk to the trunk. But through the laboratory study, a relief in pressure on the back was observed for a larger slope. It is worth noting that similar guidelines exist; That is, to avoid working on the floor/inclination degree, when possible, raise the work height by using a workbench (CPWR 2015).

However, there is still room that could be further improved both in the experiment design and post analysis. 1) The twisting angle of the trunk is not captured in this experiment, which is expected to differentiate side and uphill posture better. 2) Only the trunk muscle is studied and used for the risk analysis. However, the ankle and knee are also prone to WMSD risks due to heavy use in two roofing postures. 3) As in a dynamic experiment, the duration of a single trial is short, which could add difficulty to reflecting the difference of factor levels by EMG. (4) Currently, the sample size is relatively low. In the future, an expanded experiment involving more subjects with a diverse distribution in age, stature, body fat percentage, etc. would be carried out.

Abstract: Hurricanes can significantly influence urban populations. The understanding of human movements in urban areas plays a key role in improving our disaster response, evacuation, and relief plans. However, there is a lack of research on human mobility perturbation under the influence of hurricanes. Furthermore, limited simulation studies have had access to empirical human travel data in urban areas during natural disasters. In this paper we examine human mobility during the approaching and strike of hurricanes. Inspired by animal movements in a fragmented habitat, we examined human movements in New York City and its adjacent areas during the striking of Hurricane Sandy. We found that while the urban travels within New York City did not experience strong perturbation, the movements crossing the boundaries of the city decreased dramatically during Hurricane Sandy. Based on the patterns observed, we also proposed a framework for a data-driven agent-based GIS model to simulate human movements during hurricanes. The model simulates human mobility patterns in three different scenarios: (1) the imposition of evacuation zones; (2) the occurrence of flooding; (3) and the abrupt failure of certain infrastructures. The research effort aims to inform policy-makers and support decision-making under different emergency situations that can arise during hurricanes.

1 INTRODUCTION

Natural disasters severely disrupt human society and cause significant damage to buildings and infrastructure. UNISDR (2013) reported that from 2002 to 2012, natural disasters caused 1.2 million deaths, influenced 2.9 billion people, and resulted in a total of 1.7 trillion dollars of economic loss. It is predicted that the numbers will increase due to on-going climate change. Humans are facing an ever pressing challenge to remain resilient during natural disasters.

Governments, especially those in large urban areas and population centers, have developed different coping mechanisms to fight natural disasters. Disaster response and evacuation plans are particularly prevalent. These plans evaluate possible risks brought by different disasters and attempt to control and minimize the consequences. However, the effectiveness of these top-down plans is often questioned due
to their lack of sufficient understanding and consideration of human behaviors (Chakraborty, Tobin, and Montz 2005, Drabek 2000, Wolshot and Marchive III 2007). Take New Yorkers’ actions during Hurricane Sandy as an example. While 71 percent of the New Yorkers living in evacuation areas were aware of the mandatory order to evacuate, more than 50 percent of them stayed nonetheless (Schuerman 2013). Regretfully, many of the fatalities occurred in the evacuation areas (CDC 2013). Even the people who evacuated were not entirely safe. Data from FEMA (US Federal Emergency Management Agency) show that the flooding areas in NYC during Hurricane Sandy were 15 percent larger than the evacuation areas, putting people who stayed in some of the assumed safe areas in severe threat (Rosenzweig and Solecki 2014). It is critical that we better understand human mobility during natural disasters to increase the percentage of the population that heeds the evacuation orders and to adjust that mobility dynamically when predicted evacuation areas change in unpredictable ways during a natural disaster. In short, we need to do a more effective job at getting impacted urban populations to safety.

Existing research has already pointed out that human mobility plays a key role in disaster evacuations (Pan et al. 2007, Schneider et al. 2011). On one hand, human mobility determines the effectiveness of evacuations. As Pan et al. (2007) pointed out, overcrowding and car crashing during emergency situations can cause incidents and thus injuries and loss of lives. Take the snow storm that pummeled Atlanta in December 2013 as an example. Alarmed by the approach of the severe snow storm, City of Atlanta officials issued a blizzard warning and advised people to leave school and work early. Without foreseeing such consequences of such a warning, many people crammed onto the roads and highways at the same time causing a city-scale traffic jam. People were still stuck on the roads or forced to abandon their vehicles to seek shelter when the snow storm arrived (Beasley 2014). Without a deeper understanding of human movements during natural disasters, the same situation is bound to occur again.

Human mobility also has an impact on the effectiveness of information communications during emergencies. When a region’s communications infrastructure is damaged by a natural disaster, human mobility effectively determines the bandwidth of emergency information networks and thus the speed and width of information diffusion. Natural disasters could possibly damage and/or destroy communication infrastructures and in that case, human movements would determine the width of temporary communication networks built on portable devices (Chaintreau et al. 2007, Feeley, Hutchinson, and Ray 2004, Kleinberg 2007). Furthermore, deep understanding and accurate prediction of human mobility can potentially save lives. In the case of Hurricane Sandy, if it had been possible to identify vulnerable individuals and provide them with detailed instructions, their lives might have been spared. The critical roles of human mobility related to all three of these aspects call for in-depth investigations to build our understanding of how best to work with real-world human behaviors in disaster situations (Wang and Taylor 2014). All these three aspects, namely effective evacuation, reliable communication, and accurate locating, are indispensable to disaster management in emergency situations.

Despite the critical importance of human mobility, studies of human mobility perturbation under the influence of natural disasters are limited. Current studies and models explicitly or implicitly assume that human movements happen in a continuous space without considering constraints and/or gaps. Such an assumption may not hold true during the occurrence of natural disasters. Many situations can cause gaps in space, such as road blocks, traffic jams, evacuation zones, and so on. These gaps can force people to change their routine movement trajectories.

This paper focuses on space constraints imposed by natural disasters, examining their influences on human mobility. While no research has studied this phenomenon in urban and built environments to the best of our knowledge, the problem has gained attention in natural environments. Inspired by these existing studies, this study focuses on discovering whether space constraints in urban environments have effects on urban dwellers similar to the effects of habitat gaps to animals. If so, we explore if it is possible to predict human movements better during the occurrences of natural disasters. The objectives of this research is to (1) understand human mobility perturbation under the influence of hurricanes, (2) explore how geographical constraints during natural disasters can influence human mobility by examining a case study in New York City, and (3) propose an agent-based model to integrate empirical data and simulate human mobility in emergencies and extreme events.
2 BACKGROUND

Researchers have attempted to describe animal movement patterns for over one hundred years. Pearson (1905) first proposed a mathematical model to capture human and animal movements. This model stated that an individual moves consistently where each movement has a set distance, but a randomly different angle from its previous movements. Such a model is called a random walk model. Later on, Lévy modified the model and made the distances of steps follow a heavy-tailed probability distribution such as a power-law (Mandelbrot 1983). This model was called a Lévy flight. Research has shown that the movements of many types of animals follow Lévy flight patterns (Bartumeus 2007, Benhamou 2007, Viswanathan et al. 1996).

Lévy flights observed in animal movements have inspired studies in human mobility. Brockmann et al. (Brockmann, Hufnagel, and Geisel 2006) was an early researcher that studied human mobility using a large quantity of empirical data. Using the travel distances of 464,670 one-hundred-dollar bills, the study confirmed that human mobility follows the Lévy flight model. The truncated power-law distribution governs human mobility, and the exponent value was found to be around 1.59. Such findings have been supported by multiple subsequent studies with exponent values ranging from 1.59 to 1.88 (Brockmann, Hufnagel, and Geisel 2006, Cheng et al. 2011, González, Hidalgo, and Barabási 2008, Havetka et al. 2013).

Undoubtedly an important discovery, Lévy flight patterns may not always be the best model to describe animal movements. An assumption of Lévy flights, though it may not be explicitly pointed out by researchers, is that animal movements happen in a continuous space without any constraints. In reality, animals’ habitats and foraging spaces always have boundaries. It is also evident that human activities have imposed more constraints and limitations to animal spaces. All of these constraints can make the Lévy flight pattern an inappropriate model to describe animal movements.

One example where human activity influences animal movement is habitat fragmentation. Habitat fragmentation is the process where a large habitat is transformed into several smaller patches. These patches become isolated from each other, and the total area of these patches is always smaller than that of the original habitat (Wilcove, McLellan, and Dobson 1986). Habitat fragmentation was observed to be associated with different types of long-term effects such as population reduction and extinction, edge effects, and reduced gene flows (Wolff, Schauer, and Edge 1997). Research has shown that habitat fragmentation can dramatically change animal movements as a short-term effect (Diffendorfer, Gaines, and Holt 1995). Laurence et al. (2004) studied how roads and human clearing influenced birds’ movements. They found while there were no physical constraints that prevented birds from flying near or crossing the roads built inside of forests, birds avoided doing so due to edge and gap avoidances. In fact, comparing two areas of the same size, one in a forest and one crossed by a road, the number of movements reduced by 50% in the latter case.

While mainly observed in animals, similar fragmentation can happen in human societies as well. As mentioned before, such fragmentations are particularly common during the occurrence of natural disasters. Different situations, such as road blocks, traffic jams, evacuation zones, disaster damaged areas, etc., can fragment urban spaces. In these emergency situations, urban dwellers may find it difficult to cross these gaps and be forced to reduce their activities to a smaller area, and/or be denied to the primary locations they visit in ordinary days. All of these can cause constraints to human movements.

Inspired by habitat fragmentation and its influence on animal movements, this study examines whether this phenomenon in built environments has a similar influence on human movements. Using a case study of Hurricane Sandy, the research attempts to discover whether evacuation zones separated New York City from its adjacent areas. Though not as effective as expected, the mandatory evacuation areas forced many New Yorkers to leave the area and prohibited people from going back or passing by it. Technically, it separated New York City from the adjacent land. We examined if such separations influenced movements crossing the gaps. Such understanding will not only reveal a critical pattern of human mobility perturbation under the influence of natural disasters, but also potentially improve our ability to predict human movements in similar situations.
3 METHODOLOGY

We collected human movement data from New York City and its adjacent areas during Hurricane Sandy. The data was then analyzed to identify any perturbation caused by habitat fragmentation.

3.1 Data Collection

Human mobility data were collected from Twitter. We used Twitter’s open API and created a continuous connection between a computer in our research lab and a streaming endpoint at a Twitter server. The connection continuously downloaded tweets in real-time. Each public tweet was collected if the tweet had both geolocation information, also known as being geo-tagged, and if the coordinates were within 74°15'W to 73°40'W longitude and 40°30'N to 40°57'N latitude, the range of coordinates that contains the studied area. The data collection started around 4pm on October 29th and lasted for 12 days. Every tweet included: the text information, the tweet’s ID, the name and ID of the user who posted the tweet, the time stamp for when it was posted, and its coordinate location. More details about the data collection process can be found in Wang and Taylor (2015).

3.2 Data Analysis

We analyzed NYC data and determined both the total displacements and the crossing displacements during and after Hurricane Sandy. A displacement is the distance between two consecutive locations of the same user. A crossing displacement occurs when the starting point of a displacement is within NYC with its corresponding end point located outside of NYC, or vice versa. The distance was calculated using the Haversine formula shown in Equation 1 (Robusto 1957):

\[
d = 2r \times \sin^{-1}\left(\sqrt{\sin^2\left(\frac{\phi_2 - \phi_1}{2}\right) + \cos \phi_1 \cos \phi_2 \sin^2\left(\frac{\phi_2 - \phi_1}{2}\right)}\right)
\]

[1]

Where \( r \) is the earth’s radius, which approximately equals to 6,367,000 meters, \( \phi \) is the latitude, and \( \varphi \) is the longitude.

![Geographical data from New York City](image_url)

Figure 1: Geographical data from New York City
We used ArcGIS and its associated Python package arcpy to conduct our analysis. The grey area in Figure 1 shows the shapefile of NYC. Each black point was a geographical coordinate retrieved from a geo-tagged tweet. The red shaded areas are the mandatory evacuation zones. The accuracy of each location is 3 to 8 meters depending on the geo-tagging devices. To minimize the possible errors caused by both the shapefile and devices, we created a buffer of 200 meters around the original shapefile (thick blue outlined areas in Figure 1). A crossing displacement needs to have one point inside the original shapefile, and the other point outside of the buffered shapefile.

4 RESULTS

Table 1 shows the total displacements and crossing displacements for each day data was collected. We found no significant changes in the total displacements during the strike of Hurricane Sandy. In fact, the total displacements increased by 19% during the first 24-hours after the landfall of Hurricane Sandy. However, the crossing displacements were dramatically reduced, and the reduction was up to 50%.

The crossing displacements gradually recovered to its steady state level. The phenomenon reflected the infrastructural situations in New York City. Hurricane Sandy caused flooding in several tunnels and a widespread power outage. Most public transportation systems did not resume partial or full scheduled service until 36 to 72 hours after Hurricane Sandy struck (Kaufman et al. 2012), and over 1 million people in the city were still without power until 2pm Nov. 2 (McGeeham 2012).

The geographical analysis highlighted the impact of habitat fragmentation on human mobility. Figure 2 shows that crossing displacements usually radiate from the lower Manhattan area to other places. During this emergency, areas surrounding the lower Manhattan area became evacuation zones and separated Manhattan from New Jersey. Comparing the three panels in Figure 2, the separation significantly reduced human mobility from crossing New York City to its adjacent areas.

5 FUTURE STUDY

Research has shown that agent-based simulations play a key role in the study of human mobility during an emergency situation (González, Hidalgo, and Barabási 2008). The analytical results and large scale data of human movements enable the possibility to build an agent-based model to simulate human mobility during the occurrences of hurricanes and typhoons. Therefore, we propose an agent-based GIS model structured by three levels: an individual level, an aggregate level and an environment level (Figure 124-5).
3). On the individual level, an agent represents a person in NYC. The analytical results from the human movement data will be used to create algorithms that govern each agent’s attributes, decision-making, behaviors, and interactions with other agents. Each agent will have its own individual center of movement, radius of gyration, trajectory, primary visiting locations, traveling routes, etc. An agent will also have their own preference to deal with the risk presented by environmental changes, i.e. a hurricane approaching and striking. On the aggregate level, we will simulate the aggregate properties and patterns from all of the agents. Following a pattern-oriented modeling approach (Grimm et al. 2005), distributions found from human displacements, shifting of movement centers, radius of gyration, and social degree will be used to govern the aggregate properties in the model. Lastly, on the environment level, GIS data of NYC’s urban setting and road system will serve as the context for agents’ movements and behaviors.

Figure 2: Geographical distribution of crossing displacements
Computational experiments will be conducted to test three scenarios using the agent-based GIS model. These three scenarios are: (1) the imposition of evacuation orders, (2) the occurrences of flooding, and (3) the abrupt failure of infrastructure that cause certain road blockage. In each scenario, we will test how human movements perturb and how human mobility patterns differ in various scenarios. The results will support the decision-making of policymakers for different emergency situations.

6 CONCLUSION

Natural disasters can significantly influence human activities and impose constraints on human mobility. One such influence is caused by habitat fragmentation. When natural disasters occur, they often force people to stay away from certain land areas due to present or potential damages. Even small gaps in the human habitat can cause significant perturbation in routine urban travels. While habitat fragmentation has not been examined in human movements, it has gained much attention in animal movements (Laurance, Stouffer, and Laurance 2004). Research has examined how habitat fragmentation can influence movement patterns from different animals (Diffendorfer, Gaines, and Holt 1995).

Inspired by these studies, this study examined whether such a phenomenon could be observed in human mobility. Using Hurricane Sandy as a case study, we retrieved human mobility data and analyzed the crossing displacements around the New York City area. We found that evacuation zones caused habitat fragmentation and substantially influenced human movements across these gaps. Crossing displacements reduced to approximately half the amount observed in normal states. The influence of habitat fragmentation gradually diminished when the city recovered from the hurricane.

The study confirmed that habitat fragmentation can significantly influence human mobility. To predict human mobility during natural disasters, the urban constraint is a key factor that needs to be considered. Therefore, we proposed the framework of an agent-based GIS model. The model incorporates urban fragmentation and can simulate human mobility in different scenarios. The model will help us explore the impact of habitat fragmentation in urban areas to improve our understanding of human mobility patterns under the influence of hurricanes.

Abstract: Construction dust emission has become an outstanding issue in the construction industry. As a key content of green construction, governments around the world have the responsibility of mitigating the adverse effects of dust emission on the environment. However, little has been known of how governments can sharpen their efforts in this area. Using literature survey and content analysis, this study aims to identify the main roles of governments in construction dust control. Considerable policies were collected for analysis. It is found that governments have three characters in the dust control, namely opinion leaders, policy makers and technical supporters. As policy makers, governmental measures for dust emission control span widely, which include technology, economy, management and organizational governance. The results shed some lights on the measurement of governmental policies in the dust control.

1 INTRODUCTION

The construction industry plays a vital role in a socio-economic entity. However, it has become the targets of environmentalists and sociologists. One of the main reasons is that the construction industry has become a key consumer of energy and a major pollutant of the physical environment (Wallis 2012, Wang 2014). Basically, construction activities including land excavation, concrete construction, demolition activities, roadwork and building decoration generate a great deal of environmental pollution such as dust, noise, garbage and solid waste (Shen et al. 2010). Of all these pollutants, dust emission poses considerable threats on human health and local environments and it has attracted closer attention in recent years (Bergdahl et al. 2004).

Dust emission on construction sites enforces frontline workers and local people more vulnerable to suffer from clinical health problems or other potentially longer-term health problems (Steenland et al. 2001). Silica dust, wood dust, demolition dust and other construction dust involving gypsum, limestone, marble and dolomite are the four main types of construction dust on construction sites (Partanen et al. 1995). There is widespread concern about the over exposure of construction workers to respirable crystalline silica, which is a major constituent of dust emission (Flanagan et al. 2010). Previous studies suggested that approximately 60% workers employed in the construction industry were possibly exposed to silica in 2009 in Netherlands (Lumens and Spee 2001), and the exposure levels of silica exceed occupational exposure limits (OELs) in works such as drilling, blasting, screening, grinding, crushing and earth-moving which involve silica-containing material or equipment that creates particles (Nij et al. 2003).
Construction dust has also been found as a main reason for severe diseases including silicosis, bronchitis, obstruction of trachea, occupational asthma as well as the decline in pulmonary function (Chisholm 1999). As revealed in a cohort mortality study of industrial sand workers, there is a causal relationship between lung cancer and crystalline silica exposure (Nget al. 1987, Steenland et al. 2001). Other hazard substances of construction dust like wood dust and demolition dust also presenting a risk of disease such as occupational asthma and Chronic Obstructive Pulmonary Disease (COPD). COPD is predominantly caused by smoking; however exposure to harmful dusts can also bring on the onset of COPD even if the person does not smoke (Bergdahl et al. 2004).

Particulate matter, also known as PM, is a complex mixture of extremely small particles and liquid droplets including acids, organic chemicals, metals, and soil or dust particles (Zhao et al. 2006). As for the environmental impact, growing size of construction activities have enhanced the level of PM10 and PM2.5 (particulate matter with aerodynamic diameters less than 10 um and 2.5 um) in cities. Researchers have found that high death rates of asthma, heart disease, and other ailments are attributed to all PM components (Lumens and Spee 2001, Zhang 2006). Major cities in the world such as London, New Delhi and Mexico and many cities in China have suffered from high levels of particulate pollution over the past two decades. In fact, a series of environmental impacts caused by construction activities have been worse off. Early in 1989, in appreciating account energy efficiency and emission reduction, the Chartered Institute of Building report (CIB 1989) identified four areas for improving environmental management on construction sites - (i) Efficient use of energy and natural resources; (ii) Carefully selecting environmentally friendly building materials and the control of toxic chemicals and dangerous wastes; (iii) Pollution control, clean technologies, recycling and waste management, and (iv) Environmental education via intensive training. In line with these principles, fugitive dust, as a major source of pollutants emission on construction site, is due to bear responsibilities for all negative influences.

Detailed planning and effective construction management are necessary to reduce the adverse impact of dust emission on the surrounding environment, the current mayor of London pointed out (Johnson 2014). As a key member of social regulator, governmental authorities ought to review and assess the situation of dust emission in the territory. This is the same case in many developing countries. In China, governmental efforts to control dust emission are gradually unfolded (Tanget al. 2013, Ye et al. 2013). Nowadays, governments worldwide are attempting to make due response to this challenge. However, what is the role of governments in this domain? How can they do effectively? Such questions have not yet been addressed clearly. Therefore, this study aims to investigate governmental policies on construction dust control with the intention of answering these two questions.

2 RESEARCH METHODS

The main method adopted in the study is literature review and content analysis. The research starts with identifying the roles of governments in the practices of construction dust control. Progress in promulgating dust control policies has been made worldwide including Asia, North America, and Europe. Relevant polices and regulatory documents of these regions were collected for analysis and comparison. As one of the largest developing countries, China is still in an important period of strategic opportunities for construction and will build at such an unprecedented speed and scale. Finally, the case of China was adopted analyze governmental measures introduced in surveyed policies.

3 ROLE OF GOVERNMENT IN CONSTRUCTION DUST CONTROL

Government plays a key role in practicing construction dust control. As the main point of green construction, fugitive dust controlling need for governmental intervention especially in the early stage. The limitation of people’s rational recognition and self-consciousness combined with the failed formation of evaluation criterion and behavioral patterns backed up by common goals further at this stage underline the necessity of making effective activities though correct induction of government. The effectiveness of construction dust control depends on a systematic program that involves a number of main bodies including governmental authorities at various levels and relevant parties like the owner, construction and supervision organization. As the owners of public works, governmental authorities bear responsibilities of
reducing dust emissions of their own projects; On the other hand, they play a role as social regulators in monitoring dust emissions in the local construction industry. While stakeholders in construction are largely profit-oriented, the actions taken by governments should be driven by a desire to improve social and environmental benefits. Institution-related drivers for government to improve both social and environmental benefits include affecting the behavior of individuals and firms, providing institutional guarantee and supporting and promoting technological innovation (Fraser 2013, Sharratt and Auvermann 2014).

3.1 Opinion Leaders
Prior to the formation of public willingness to pay for environmental protection, inducing and promoting practices for construction dust by affecting the behavior of individuals and firms is necessary. Individuals maximize temporary advantages, which is short-signed, while companies respond to costs and profits, which are their primary drivers (Witzke and Urfei 2001, Franzen and Vogl 2013). However, in construction, whether each stakeholder acknowledges and accepts the idea of environmentally friendly “Dust-free” and then makes it a lasting habit is more essential. Therefore, the great importance of government’s propaganda and guidance becomes to emerge; they pose a direct impact on public recognition and awareness and then form an industrial development pattern featuring the interaction between governments and enterprises (Wang and Ye 2010). American was the ultimate practitioner of this role, popularizing preventive and treatment knowledge of construction dust with the united efforts of Occupational Safety and Health Administration (OSHA) and Non-government organization (NGOs).

3.2 Policy Makers
The most fundamental function of government is to provide institution guarantee for various social undertakings, achieved by means of rules and regulations. As mentioned above, practices of construction dust monitoring place responsibility on all stakeholders; it is harder to correctly identify responsibilities of each stakeholders and that explains why regulatory gaps and overlapping responsibilities are most likely to occur. The governmental function of instituting policy support and improving supervisory mechanisms is necessary in this sense. In many countries, law of environmental protection, as the foundation law, stated the requirements of taking necessary measures to monitor dust emission. However, the most specific regulations were mostly promulgated by local governments of city or county level. Providing tools and practical guidance according to the general policies issued by central governments, local governments actually play a dual role.

3.3 Technical Supporters
Dust control needs technical support. Practices for suppressing dust emission in construction are quite miscellaneous but can be classified into several distinct categories, including suppression by water infusion or wet cutting methods, dilution by ventilation system, mitigation by water sprays and scrubbers, and isolation by personal respiratory (Nijet al. 2003). In the process of renovation which is difficult for dry sweeping, studies suggested the use of a central vacuum system as a control measure for construction renovation sites (Lehtinen et al. 1996). Commonly used infrastructures like vacuum cleaner, local exhaust system (LEV) and windbreaks hedge are developed by firms, whilst they must bear all risk and pressure during the process of technological innovation. It is government who provide a strong backstop for stimulating and supporting innovations through actions including providing basic infrastructures and platforms for communication, collaboration, and knowledge sharing (Patanakul and Pinto 2014).

4 POLICIES TO MONITOR CONSTRUCTION DUST EMISSION

4.1 A Review on Relevant Policies

As policy makers, governments are responsible for provide institutional guarantee for suppressing on-site dust t. The policy and supervising framework that support the construction dust management served well in many regions of the world. It has gradually sustained massive decrease of construction dust contamination especially silica-oriented cases and, in doing so, has accelerate the global process of sustainable construction in parallel. America, whose policy system of dust monitoring is more developed comparatively, is exampled. Since relevant policies, rules are mostly formulated by local authorities of states, counties, districts and boroughs in the U.S, they varies evidently and present diversification as well. Taking Yakima Washington for example, the policy "Construction Dust Control Policy of the Yakima Regional Clean Air Agency", which was promulgated in August 9, 2012, aims to reduce fugitive dust emissions with an emphasis on prevention rather than mitigation (Pruitt 2012). And Clark county focus on license application and emission targets instead of specific control measures, which makes on-site managers feel easy to further strength their supervision and inspection on dust discharge through quantitative evaluation. In addition, other governmental agencies like OSHA and Health and Safety Executive(HSE)in U.K also take their efforts. This paper provides a review on these policies promulgated by various authorities. The policy data gained from the relevant sources are mainly about laws and regulations, administrative rules and governmental plan. And these sources are approached by visiting the official websites, as see the Table 1 for more information.

4.2 Governmental Measures for Construction Dust Control in China

Nationwide the legal demand for improvements in emission control of construction dust in China have been tightened severely in the past decades (Pilarczyket al. 2013). In practice, however, the legalization started lately and it did not gained inadequate attention at that time. Until the year 2000, the Chinese
government promulgated the third version of “Law of the People's Republic of China on the Prevention and Control of Atmospheric Pollution”. In this law, a dust-free view is addressed, and then firstly added contents related to construction dust monitoring (mentioned in paragraph 2 of article 43). Pattern of “Central coordination, local implementation” on monitoring construction dust is thus laid in China. Subsequently, in 2004, the ministry of construction issued a series of standards on construction site including some compulsory rules that shall be strictly enforced like enclosure construction and road hardening. After that, local governments have commenced to promote dust controlling practices, more practical standards and specifications were elaborated.

Capital cities function as centers of politics, economy, military and culture in different regions. By investigating related policies of 32 capital cities in mainland China, it showed that 26 cities including Beijing, Hangzhou and Shanghai have launched special scheme of prevention of dust pollution on construction site. More specific information about these regulations is described in Table 2.

Using the method of content analysis, measures included in those policies (including 26 policies issued by governments of city level and standards mentioned before) above were extracted. The primary mission of content analysis is to make inferences by objectively and systematically identifying specified characteristics of messages (Holsti 1969). In current study, two steps under this method were followed, namely (i) identifying “construction dust” per regulatory document; (ii) identifying related dust control methods involved per regulatory document. By eliminating contents which are general, superficial and
untargeted, and then consolidating provisions that are similar, 30 measures were recognized as described in Table 3.

</tbody>
</table>

Since these measures seem quite different from each other, they can be divided into five important aspects:

- TECHNOLOGY—Measures directly taken by construction enterprises on site (13 measures);
- ECONOMY—Instruments to steer stakeholders’ behaviours by using economic factors influential to the cost-effective (4 measures);
- SUPERVISION—Methods by which various subjects monitor stakeholders to standardize their behaviours during the process of following the legal requirements (4 measures);
- ORGANIZATION—Measures that are conducted to analyze organizational factors in the process of dust management in order to establish the internal accountability system and improve management and operation mechanism (3 measures);
- ASSESSMENT—Measures acting as an instrument to restrict and regulate the activity of individuals, enterprises even governments by making their performance being linked to related evaluation system (6 measures);

5 CONCLUDING REMARKS

The successful control of construction dust has been highly concerned in the domain of green construction. Server air pollution combined with more potential health hazards caused by construction fugitive dust has triggered the governmental alarm. Governments, as owner of public works, should endeavour to reduce dust emissions of their own projects; and have more responsibilities as leaders and supporters of sustainable strategy. In this study, three main role of government played in practices of construction dust management were recognized and analyzed. As policy makers, it is found that governments around the globe should make due response to provide institutional guarantee. By taking China as example, it is found that specific governmental measures suitable to control dust emission varies from one sector to another, including technology, economy, organization, supervision to assessment, which provides guidelines for other countries to formulate policies. However, which
measures governments are more interested in and what measures are major and effective have not explored explicitly. The research findings can pave some ways for future studies on effectiveness of governmental policies on construction dust control.

VERTICAL DELIVERY CHALLENGES FOR HIGH-RISE BUILDING CONSTRUCTION

Yufeng Wei¹, ², Andre Pinheiro³, David Pedraza¹, Bowen Wu¹ and Brenda McCabe¹

³ Department of Civil Engineering, Fumec University, Brazil

Abstract: As buildings continue to be designed much taller than before, the increasing height of buildings produces problems of vertical delivery in efficiency, safety and cost. To address these challenges, researchers and engineers are applying new technologies and management strategies to improve vertical transportation of resources. This paper discusses state-of-the-art solutions to problems and successful examples of implementation in three selected areas: temporary hoists, concrete pumps, and tower cranes.

1 INTRODUCTION

The vertical delivery of materials and labour on construction sites is mainly achieved using temporary hoists, tower cranes and concrete pumping systems. However, the increasing number of high-rise building projects worldwide has introduced new challenges in vertical delivery (Chang et al. 2011). As the height of buildings grows, the efficiency of vertical transportation drops exponentially, thus affecting the safety, cost and overall schedule of projects. In particular, those sites in spatially-constrained urban areas are limited in the number of equipment that can be installed on site. This paper introduces the development of technology and management methods to enhance the safety and efficiency of on-site vertical delivery.

First, construction temporary hoists are the main method of transporting labour. Unlike materials that can be lifted during the night, workers only can be transported at the time of executing their assigned tasks (Moonseo 2013). Therefore, a significant amount of unproductive time is spent being transported to their designated floors, particularly in high-rise buildings. To counter this issue, current research introduces several methods to support decision making regarding hoist planning and operation. A case study and simulation experiments will show how operational strategies can improve the productivity of a construction hoist and reduce worker delays, which can significantly improve the productivity of labour.

Second, concrete is a common building material that is used throughout a project. Traditional methods of delivering concrete by crane and bucket are constrained by the limited number of cranes and weather conditions. The use of concrete pumps and an innovative method to reduce costs and guarantee constant flow will be highlighted.

Finally, tower cranes are used to lift and/or move heavy materials and large pieces of building components, and can be a big challenge in terms of safety. Special challenges for the use of tower cranes in tall buildings will be discussed.
2 CONSTRUCTION TEMPORARY HOIST

A construction temporary hoist, also known as a temporary elevator, construction elevator, or construction lift, is commonly used in building construction projects to lift materials and labour. For most building projects, hoists are leased or rented by the general contractor. Unlike a permanent elevator, temporary hoists are operated manually by an on-board operator, allowing direction changes or stops at any time according to the operator (Hwang 2009).

Hoists are commonly have single or double cages (1 or 2 cages per tower respectively) with a capacity varying from 25 to 35 people per cage (Chang-Yeon 2009). Capacity is reduced when materials and tools are carried with workers. The growing height of a building, limited number of hoists, and reduced capacity can make workers' movement between floors inefficient, resulting in a significant amount of time wasted waiting for hoists each day. For example, during the peak of construction at the Korea Convention and Exhibition Center in Seoul, South Korea, it took approximately 130 minutes to lift 1200 construction workers to their designated working floors (Moonseo 2013).

Hoist operations are also affected by weather and local regulations, which may restrict hours of operation. Therefore, optimized planning and operation of construction hoists is needed to reduce worker waiting time and improve overall schedule performance. Furthermore, since workers typically begin work simultaneously every morning, the biggest challenge of hoist operation optimization is to solve peak-hour congestion.

2.1 Construction Temporary Hoist Operation Optimization

Vertical transportation of construction workers and materials can be viewed as a cyclic operation, making it suitable for analysis and optimization using discrete event simulation (Ioannou and Martinez 1996; AbouRizk 2010). For the past decade, simulation techniques have proved effective in the development of improved lifting plans (Ahn 2004). The introduction of genetic algorithms to these models (Shin et al. 2010), lead to optimal lifting plans that minimized worker waiting times.

Strategies used in the elevator industry, such as zoning (Newell 1998), can be applied to minimize worker transit time in high-rise construction (Moonseo 2013). Zoning is used to divide buildings into groups of continuous vertical floors. These groups form zones that can be reached only by specifically assigned hoists. In this way, the number of stops each hoist has to make is reduced, and the total time to deliver a workforce is reduced. The challenge with this method is determining the optimal zoning configuration based on continuously changing conditions, including lift demand, floor demand, and number of floors. To solve these issues, a computer simulation incorporated with artificial intelligent and dynamic lifting demand was developed (Moonseo 2013). A case study in Korea shows that the application of zoning can significantly reduce the total lifting time by 40% (300 workers and the completed building height is 240 m).

Another, less restrictive way to reduce lifting times for sites with multiple hosts is to coordinate the hoists by optimizing the stops for each hoist when calls come for a pick up. The scenario of taking workers from the ground floor to their designated floors can be simplified to a travelling salesman problem (Cho 2013), which can be mathematically solved by a branch and bond algorithm. Combined with discrete event simulation, the hoist route becomes the objective of the optimization function. This method has been shown to improve the efficiency of hoist operations (Cho 2013).

Another alternative for dealing with peak hour congestion is to apply staggered arrivals to the workers' daily schedule. Staggered arrivals have been studied in transportation and elevator planning for office buildings (Kamleh 2014) to reduce the queue during morning peak hours. This concept achieves lower overall waiting times. While it is hard to manage arrival times of workers and visitors using elevators in operating office towers, construction sites may have more flexibility. Project managers can arrange staggered work hours to reduce the congestion at the start of the day.
2.2 Construction Temporary Hoist Alternatives

Because the elevator mechanical room is installed at the top of the building, the installation of the elevators happens after the building has been topped off and the roof has been completed and waterproofed. Due to recent developments in elevator technologies, elevators can be used at the early stages of construction by installing mechanical rooms that climb with the construction, eventually becoming the permanent elevator system. These jump lifts provide an alternative to exterior hoists for labour movement with several advantages: the elevators are up to 5 times faster than hoists and are unhindered during extreme weather. However, they are not typically designed to carry the weight of most construction materials, tools and equipment, and they are expensive. As far as the authors have been able to find, the first use of a jump lift in North America is currently underway at One Bloor in Toronto, Canada.

As hoists become the bottleneck of labour transportation during peak hours for high-rise building construction, a smarter and more efficient lifting plan is required to improve hoist productivity. Recent advances in elevator technologies are taking some of the pressure off hoists, allowing them to focus on material and heavier loads.

3 CONCRETE PUMPING SYSTEM

The majority of tall buildings under construction in Canada are concrete. The significant increase in the use of concrete in tall building construction is attributed to improvements in concrete technology including strength, admixtures, pumping, construction techniques and structural systems (Rizk 2010). To accommodate tight construction schedules, hydraulic concrete pumping has developed as a fast and economical method of transporting concrete due to its reduction in labour requirements and the ability to deliver continuous concrete pours (Mechtcherine et al. 2014). The traditional crane and bucket method of delivering concrete is limited by the availability of cranes, the effects of heavy winds, and its inability to deliver a continuous flow of concrete. Pumping methods aim to address these limitations.

3.1 Factors Affecting Concrete Pumping

Concrete pumping for construction purposes is directly related to two major factors, concrete composition and the mechanical characteristics of the pumping equipment. Concrete mix composition affects the properties of fresh concrete such as bleeding, segregation, viscosity, cohesion and compactness (Ngo et al. 2012). These properties have a significant impact on the pumpability of the concrete and the formation of a boundary layer (also referred to as lubrication layer), which forms at the interface between the concrete and the pipe (Choi et al. 2014). This lubrication layer is crucial to reducing the shear stress between the concrete flow and pipe wall to achieve the lower pressures necessary for pumping (Mechtcherine 2014).

Construction concrete is made of cement, water, aggregates, chemical additives and mineral admixtures. The concrete pump applies pressure through a pipe that is made from abrasion resistant material, and drives the concrete through the pipe. The cement paste deforms into the lubricating layer against the internal wall of the pipe. During pumping, this layer surrounds the “plug” along the center of the pipe that is made up of coarse aggregates and cement paste (Mechtcherine 2014). It is important for there to be enough mortar content in the fresh mix to form a lubrication layer throughout the length of the pipe, but that the mix composition remains homogeneous without segregation of the concrete constituents (see Figure 1).

The formation and effectiveness of the lubrication layer is highly dependent on the concrete mix. Another direct effect of the rheology of fresh concrete is the transmission of forces within the concrete plug. For the given equipment, adjusting the concrete mix can achieve lower necessary pumping pressures. Furthermore, using high pumping pressures can alter the properties of fresh concrete. For example, increased pumping pressures can lower air content, which increases the concrete’s plastic viscosity, leading to potential blockages. The challenge that engineers face is to find an optimal concrete mix to
reduce pumping pressure without negatively impacting other functions. There are various ways of optimizing the mix to achieve this (Ngo et al. cited 2012).

- Increasing the water to cement ratio (w/c) of the concrete makes the concrete flow more easily.
- If maintaining the w/c is necessary, increasing the paste volume while maintaining the w/c can achieve similar but less effective results.
- Similarly, a fine sand (0.5 mm) content of up to 10% has a very small effect on the plastic viscosity of the concrete yet improves the concrete’s slump. Beyond a 10% fine sand content however, the viscous constant begins increasing in a linear fashion.

A superplasticizer dosage of approximately 0.4%, which results in a slump of 21cm, produces a linear decrease in the viscous constant. Beyond this dosage, however, superplasticizers have no additional effect on the viscous constant.

![Figure 1 Schematic View of Plug Flow of Concrete during Pumping (Mechtcherine 2014)](image)

3.2 Emerging Solutions

To determine the required pumping pressures of concrete, standard tests such as the slump test or flow table test are used. The results from these tests are used as important inputs for estimation. The issue with this conventional way of determining pumping pressures is that monographs are often unable to account for extreme values of specific parameters, such as long pipe lengths or large spreads (Mechtcherine et al. 2014). More importantly, the concrete mix ratio which has a great influence on concrete attributes is ignored. While the traditional test is a good indicator of the yield stress of the concrete, it is a very poor descriptor of the plastic viscosity, which plays a major role in determining the pumping pressure required. Although concrete testing devices such as rheometers and viscometers can better estimate the palpability of concrete, their complexity and lack of mobility make them unpopular for on-site testing of concrete (Mechtcherine et al. 2014). To better describe the pumpability of concrete with a device that can be implemented in the field, the Sliding Pipe Rheometer (Sliper) was developed (Mechtcherine 2014). The crucial difference Sliper has compared to regular rheometers is its very close adaption to real pumping processes as well as its relatively simple and robust setup.

To further improve the pumping of concrete, testing in which electromagnetic currents are externally applied onto the pipe has been conducted (Choi 2014). This eases the formation of the lubrication layer, contributing to lower pumping pressures and increased flows. The electromagnetic field allows water to move more freely in the mix, and to form a thicker, more efficient lubricating layer. As a result of water's natural polarity, water molecules are typically attracted to each other and form clusters of approximately 100 water molecules at normal temperatures, reaching a thermodynamic equilibrium state between the association and dissociation of molecules in the cluster (Choi 2014). The application of the electromagnetic field allows the molecules to break off into single molecules or smaller clusters, which results in higher activity in the water and facilitates the formation of the lubricating layer. Using a special electronic called control device fluid liner, it was found that the optimal frequency range of the magnetic field was between 80 Hz and 1.1 kHz dependent on the composition of the mixture (Choi 2014). When these magnetic fields were applied, the pressure necessary to achieve pumping conditions was reduced by nearly 30% regardless of the concrete design mix. At equal pressures, pumping with an electromagnetic field resulted in a 15% increase in concrete flow through the pipe.

The reduction in pumping pressure makes it possible to use less powerful pumps, thereby reducing costs and improving the construction of tall buildings by facilitating concrete delivery. Although the magnetic
field was only applied to a 20 m length of pipe, pressure measurements along 1000 m of pipe
downstream showed an approximately linear relationship. This implies that the lubrication layer is
preserved through the piping during the pumping process (Choi 2014). This can be a major benefit for the
transport of concrete in tall building construction.

3.3 Summary

Concrete is a common building material in tall building construction. Advances in concrete mix design and
the implementation of new technologies, such as the application of an electromagnetic field, can help
reduce costs and improve overall process efficiency.

4 TOWER CRANES

Tower cranes are used on construction sites to lift materials or heavy building components. For those
sites located in urban areas, crane activities are confined, and any accident can lead to serious
consequence to workers and pedestrians. The use of tower cranes during tall building construction is
even more challenging because the increasing height adds problems of visibility, wind load and safety
issues for the operator.

4.1 Visibility Problems

Increased height often comes with visibility problems due to congested construction sites, the location of
the crane cab, and intensified weather conditions. Limited visibility forces the operator to rely on radio
communications when they are unable to see the load or the crew providing hand signals. In these cases,
communication, responses, and productivity become slower. Typical visibility problems include blind lifts,
sight distance, and poor weather.

- Blind lifts occur when crane operators experience partial obstruction of the loading or unloading
  working zone or the travel path (Shapira and Lyachin 2009). In these cases, the reliance on signals
  and radio communications to guide the lift becomes necessary, but it brings an increased risk of
  misunderstandings and accidents.
- Tower crane operators enjoy a bird’s eye view of the construction site, which contributes to good sight
  coverage of the site. However, as the height of the tower crane increases with the building, the
  operator’s perspective of the loading and working zone becomes nearly vertical, thereby losing some
  depth perception. Additionally, the operator’s ability to distinguish details decreases with the distance
  to the target. Long sight distances and vertical sight angles lead to difficulty in precise lifts or
  placements, which forces operators to depend on signals and increases the risk of accidents (Shapira
  et al. 2008).
- Poor visibility due to lighting or weather is an important contributor to crane problems. Operators
  sometimes have to work during dawn, dusk, night, or in direct or reflected sun glare (Shapira et al.
  2008). These circumstances reduce their ability to distinguish their target from the surrounding visual
  noise. This can cause eye fatigue and visual images to be blurred. Weather-related visibility problems
  may also result from heavily overcast skies, rain, snow, fog or dust. Visibility works both ways as
  operators may be challenged to see the loads that they are lifting, while others are challenged to see
  the tower crane. For example, in 2013, a helicopter hit a tower crane atop a 235m building that was
  under construction in central London, UK (BBC 2013).

Recent research has made progress in developing 3D and 4D simulation tools to optimize tower crane
and other equipment layout to reduce obstacles for operators during construction (Al-Hussein et al. 2006).
However, planning strategies have limitations in real-time management. New technologies have been
deployed on cranes to monitor their operations using wireless sensors and GPS (Kim et al. 2003). Proper
training of operators by increasing their situational awareness of construction site layouts has proven
effective in reducing accidents (Cheng and Teizer 2014).
4.2 Wind Loading Effect

Working at heights is also associated with higher wind speeds. Wind speeds may be represented using the power law, shown in Equation 1 (Sen et al. 2012), where $Z$ is the elevation, $V$ is the wind velocity ($V_2 > V_1$), and $n$ is the exponent that represents local climatology, topography, surface roughness, environmental conditions and weather stability.

$$\left(\frac{Z_1}{Z_2}\right)^n = \left(\frac{V_1}{V_2}\right)$$

Using average winter wind speeds for downtown Toronto shown in Table 1 (Environment Canada 2003) as the reference speeds for $Z_1=30m$ and $Z_2=80m$, an exponent of $n=0.34$ was calculated. This is a reasonably good fit with the general estimate of $n=0.4$ for a city area with tall buildings (Sen et al. 2012). With those two exponents, the average winter wind speed at 150m above ground level, or approximately 50 storeys, can be extrapolated using the power law as being between 8.0 and 8.8 m/s, almost double the speed at 30m. At wind speeds greater than average, there is a significant danger in underestimating the impact of doubling the apparent wind at ground level when lifting large loads up a tall building.

<table>
<thead>
<tr>
<th>Building height above ground level (m)</th>

<tr>
<td>150</td>
<td>8.0-8.8</td>
</tr>
</tbody>
</table>

Operation guidelines (not regulations) for tower cranes often cite 13m/s (30 miles per hour) as a maximum wind speed for crane operations, with warnings that operations may cease at 9m/s if conditions warrant (Worksafe BC 2015). This may be in consideration of the changes in wind speed with height that may not be obvious on the ground. Although the tower crane is designed to withstand much higher wind speeds while out-of-service, in-service wind speeds are lower because of the effect the wind has not only on the crane itself, but also on the load that it is lifting. Therefore, high wind speeds can increase the frequency in which cranes are out-of-service. Since heavy components such as glass curtain walls or concrete beams are primarily transported by tower cranes, their serviceability directly affects the overall schedule.

The wind can exert a significant load on the crane structure itself (Watson 2004) depending on the direction of the wind relative to the jib and on the size, weight, and proportions of the item being lifted. Formwork, for example, may impose forces well in excess of its weight if the load is moved by the wind from its expected position directly below the jib block. If the wind is from the side, then the displacement causes side loading of the jib, something for which it may not be designed to withstand. If the wind load is from behind, the movement can increase the load radius beyond the end of the jib and significantly reduce its capacity (Watson 2004). Additionally, high winds can cause movement of the load and directly strike workers or pedestrians. A moving load can also cause equipment or materials to fall when struck by the load and result in injuries. In 2008 in downtown Toronto, the cable from a derrick crane on the top of a topped out but not yet complete 51 storey building was caught in winds from a winter storm and broke windows between the 30th and 40th floors of the tower, showering glass at ground level (Reinhart 2008). The increased length of the crane’s tower and jib highly increase the complexity of its structure, making structural analysis more difficult, and causing more problems while installing and dissembling. Any malfunction of an element could cause the failure of whole structure, leading to a catastrophe.

Another potential hazard is the behavior or wind load on a tower crane when erected alongside a building (Mara 2010). The presence of the tower crane alongside the building significantly changes the aerodynamics of the building because the tower crane alters the geometric cross section of the building.
Based on a wind tunnel study (Mara 2009; Mara 2010), two recommendations were made to minimize wind loading effects on tower cranes.

- First, the location of tower cranes shall be restricted to the middle portion of a building face to reduce torsion forces on the crane. When tower cranes are placed near the center of building face, the wind load on the crane will match that of the building. As the cranes approach the edge of the building, the mean and fluctuation values of torsion forces significantly increase.
- Second, the tower cranes should be located along the leeward face of the building to reduce the wind loading due to the shielding effect provided by the building.

4.3 Safety Management

The main causes of tower crane accidents are carelessness, negligence or misjudgment of participants, inadequate training, sub-contracting operators, and pressure from tight schedules (Tam et al. 2011). Carelessness is often cited in conjunction with other factors, such as working too close to a high-voltage line or being struck by a moving load (McCann 2009). Therefore, safety management and safety culture on site are crucial for the decrease of accident rates related to tower cranes. The following factors influence on-site safety performance.

- The length of work shift for tower crane operators usually extend beyond normal working hours because materials are often delivered before and after work hours. Hence, the crane operators are typically the first to arrive and the last to leave. Further, due to the time and effort required for operators to get into the crane cab, managers tend to minimize shift changes. The long, repetitive, and monotonous work may cause the crane operator to lose focus and alertness. With the increase of both physical and mental fatigue, the chances of accidents increase as well (Shapira and Lyachin 2009).
- Operator aids includes crane monitoring and the information received from signalers and crews. Communications between operators and signalers are usually achieved by radio or similar technologies, where the instructions from a signaler plays an important role. Hence, signaler shall be trained to properly instruct crane operations. Crane safety monitoring systems include digital-display load indicators, 2D/3D crane operation graphic displays, GPS based weather and wind warning systems, anti-collision and zoning systems for sites with overlapping cranes, and video cameras that enable the operator follow the review of loading (Peurifoy 2002; Shapira et al. 2008, 2009). These new technologies often compensate for human fallibility and prevents accidents (Neitzel et al. 2001).
- Human resource management helps to ensure that the operator has the characteristics required to ensure a safe working environment. Objective measures of operator skills include formal training and certifications, accumulated experience and safety record (Shapire 2008).

To sum up, the chances of tower crane-related accidents significantly increases when safety management is deficient. Tower crane safety can be achieved through site-level and company-level actions. Site-level actions include training, preventive actions, monitoring, on-going inspections and balanced rewards and punishments (Ng et al. 2005). Safety for company-level management are usually measured by the allocation of resources, planning and scheduling, and strictly enforced inspection policies and procedures. (Shapira 2008).

5 CONCLUSION

Vertical delivery has a significant effect on the overall performance of the schedule for tall building construction projects. To address this challenge, technologies and management strategies are being developed to improve the efficiency and safety performance, while at the same time reducing the cost of vertical transportation on construction sites.

DECONSTRUCTION AND MAINTENANCE OF STEEL BRIDGE USING FATIGUE DATA AND BIM

Christian Wokem¹, ² and Jishnu Subedi¹
¹ Southern Alberta Institute of Technology, Canada
² christian.wokem@sait.ca

Abstract: Design for deconstruction is one of the emerging concepts for sustainability. For existing structures, the concept can be extended to optimize maintenance schedule for different components. Many existing steel bridges are at a stage in their lives where decisions need to be made to either continue in existing condition, to strengthen or to deconstruct them. This decision is highly dependent on the fatigue resistance of the steel connections which is a function of remaining structural strength, service load, expected future use and other environmental factors. Over the years a great deal of research work has been done in assessing the fatigue life of steel structures. This study utilizes these fatigue information to carry out a life cycle assessment of bridge elements and layer the system using BIM. As the BIM system will apply economic analysis for maintaining the bridge versus deconstructing and rebuilding of a new bridge, it will be instrumental to optimize the decision on any intervention in the bridge.

1 INTRODUCTION

A large number of steel bridges were constructed in the last 100 plus years and many of these bridges are still in operation. Many existing steel bridges are at a stage in their lives where decisions need to be made to either continue in existing condition, to strengthen them or to demolish them. The decision making process is dictated mainly by remaining serviceable life of the bridge. Fatigue is one of the key factors that need to be assessed in making decision about the bridges. The fatigue life, in turn, is a function of remaining structural strength, service loads, expected future use and other environmental factors. There exist many standards and approaches for bridge evaluation and one of the widely used approach is AASHTO (2011).

The construction and demolition industry accounts for 25-30 per cent and sometimes more than 50 per cent of the municipal solid waste in Canada (Yeheyis et al., 2012). Design for deconstruction is one of the emerging concepts for sustainability (Morgan and Stevenson, 2005; Shell et al. n.d.). As the structure, buildings, bridges and other infrastructure, constructed in the industrial boom of 20th century are coming to age, a comprehensive approach in assessing their remaining lifespan, function and re-usability is essential. Although the design for deconstruction has so far been limited to design of new buildings with view of optimizing deconstruction, the concept should be extended to sustainable use of existing infrastructure.

For existing structures, the concept of design for deconstruction should be extended to assess remaining life-span, optimize maintenance schedule for different components and increase function and life-span of the structures. Many existing steel bridges are at a stage in their lives where decisions need to be made...
to either continue in existing condition, to strengthen or to deconstruct them. This decision is highly
dependent on the fatigue resistance of the steel connections which is a function of remaining structural
strength, service load, expected future use and other environmental factors. Over the years a great deal
of research work has been done in assessing the fatigue life of steel structures. This study utilizes these
fatigue information to carry out a life cycle assessment of bridge elements and layer the system using
BIM.

A fatigue evaluation in bridges involves numbers of uncertainties and the practice, in general, has been to
assign a conservative fatigue life. The conservative consideration is reflected in the fact that “some
bridges with satisfactory service history are accordingly determined to have negative remaining fatigue
lives (NCHRP, 2012).” NCHRP (2012) mentions that “a number of factors may have contributed to this
conservatism: overestimated load distribution factors, unintended composite action ignored, the S-N
curve’s lower bound being used, etc.” However, not all cases of fatigue evaluation are believed to be
overly conservative. For example, truss or two-girder bridges carrying more than one lane of traffic may
have un-conservative fatigue life estimates because of the single lane loading prescribed in the MBE.
When multiple lanes are carried by the two trusses or girders, the fatigue life may be significantly
overestimated because possible simultaneous loads on other lanes are ignored (NCHRP, 2012).”

Maintenance and rehabilitation of the steel bridges require a comprehensive evaluation scheme for
decision making. Building information modelling (BIM) “is a digital representation of physical and
functional characteristics of a facility. A BIM is a shared knowledge resource for information about a
facility forming a reliable basis for decisions during its life-cycle; defined as existing from earliest
conception to demolition (NBIMS).” Overall scope of BIM, as outlined in NBIMS (2007), has three
categories: BIM as product for digital data representation, BIM as a collaborative process and BIM as a
facility lifecycle management tool. As BIM is gaining wider popularity in the construction industry,
extension of its application in evaluation, maintenance and rehabilitation of bridges will be instrumental to
support the decision making process. There already exist a number of such methods, schemes, tools and
approaches for this purpose; however, a comprehensive BIM approach is still not completely developed.

This paper presents a scheme of applying BIM in assessing fatigue life of steel bridges and applying that
information in BIM model to support decision making process. The system includes gathering field data,
applying the data for create drawings, develop finite element models from the drawings, assessing fatigue
life of the bridge and applying that information to make decision about status of the bridges.

2 INFORMATION MODELLING

The process used in the BIM is shown in the flow chart in Fig. 1. The first phase is the collection of data
from existing bridges, and then using this information an AutoCAD drawing is creating that is
representative of the bridge connection to be modeled. The AutoCAD drawing can be imported into a
finite element modeling software such as AutoDesk Simulation Mechanical. The model is loaded and the
necessary boundary conditions are applied and the stresses are obtained as the output from the finite
element analysis (FEA) software. The elastic stress concentration factor is then obtained by dividing the
maximum stress (in this case the maximum principal stress) by the nominal applied stress as used and
proposed by Wokem (2010) and Pilkey (1997), respectively. Using this information the fatigue life at any
instant of the bridge connection can be obtained and hence the remaining life of the bridge connection
knowing the load history of the bridge. Decision can be made based on the remaining fatigue life of the
connection whether to maintain or deconstruct the bridge. These decisions can be influenced by a lot of
factors such as how many connections are near to the end of their fatigue life within the same bridge, cost
of deconstruction, and importance of the bridge for traffic amongst others. The fatigue life of the
connections will give very useful information to guide this decision making process.
3 STEEL BRIDGE INFORMATION

For the purpose of this study, bridge samples constructed in early 20th century were considered. These bridges are constructed using riveted joints with or without staggered arrangement of the rivets (Fig 2 a, b).

Although presence of tack welds has significant effect in fatigue life of a riveted joint, the welds are not easily visible and their presence, strength and contribution cannot be easily ascertained. Furthermore, contribution of tack weld is to increase fatigue life resulting in conservative estimate of the remaining life. The effect of tack welds in this case is therefore not accounted for in this study. However, once the
presence of tack welding and its effect is ascertained, it is a simple process to include that in the BIM process discussed in this paper here.

4 NUMERICAL AND ANALYTICAL MODEL

The drawings of the bridge connection as shown in Fig. 2 a. and finite element model of the same the same connection are shown in Fig. 3. Drawing, in this study, has been accomplished using AutoCAD and the finite element modeling is done using Autodesk Simulation Mechanical.

![Figure 3: A typical rivet connection in a steel truss bridge is drawn in AutoCAD, exported to Autodesk Simulation Mechanical for FEA to obtain stress and strain information.](image)

4.1 Model geometry and the material properties

The typical angle connection of a bridge was modeled in AutoCAD. The equal leg angle connection had a dimension of 102 mm and a thickness for the angle was 12.7 mm. The gusset plate had a thickness of 12.7 mm. The analysis was elastic. The material properties used in the modeling was; Young's modulus of 200,000 MPa and a Poisson's ratio of 0.29. The rivets were modeled using the bolt command in the Autodesk Simulation Mechanical and a rivet diameter of 20 mm was used and a rivet head of 25 mm was specified for the simulation.

4.2 Finite element mesh

The angle and the gusset plate were modeled using a plate element. The rivet hole had a finer mesh size of 1 mm and the other parts of the connection detail were modeled with coarser mesh. The finer mesh was used around the rivet hole because the maximum stress is expected to occur in these holes rather than in any other part of the connection.
4.3 Load and boundary conditions

A stress of 200 MPa was applied to one end of the angle and the gusset plate. The gusset plate had the other end fixed. The leg of the angle that was not attached to the gusset plate was restrained from translating in the z-axis and the x-axis, and also there was no rotation about the y-axis in the leg. The angle leg attached to the gusset plate was not restrained at all.

4.4 Finite element analysis result

Fig. 4 shows the finite element analysis result for the bridge detail. A maximum principal stress of 706.51 MPa was obtained for an applied load of 200 MPa. The maximum principal stress occurred in the gusset plate and at the first hole closest to the point of application of the tensile stress in the detail. The results show that the first and the last holes had the highest stress concentration.

![FEA model showing location of maximum principal stress](image)

Figure 4: FEA model showing location of maximum principal stress

5 FATIGUE ANALYSIS

Autodesk Simulation Mechanical was used to obtain the maximum stresses and hence the stress concentration was obtained by dividing the maximum principal stress in the detail by a nominal applied stress, and fatigue strength of the typical connection type shown in the Fig. 3. The output from the finite element analysis and calculation of fatigue life as proposed in Bannantine et al. (1990) is shown below.

Calculations for the fatigue Life
Applied stress on the FEA = 200 MPa
Maximum Principal stress = 706.51 MPa (Obtained from FEA)
Maximum von Mises stress = 712.34 MPa (Obtained from FEA)
Ultimate strength of Steel = 400 MPa = Su
Kf = Max principal stress/gross section stress = 3.53
Assume notch sensitivity factor of q=1, therefore Kf = Kf = 3.53
For Steel (from Bannantine et al. 1990):
at 1000 cycles, S1000=0.9Su = 360 MPa
at 1000000 cycles S = 0.5 Su = 200MPa
Now accounting for the stress concentration from the FEA the new S-N curve becomes

<table>
<thead>
<tr>
<th>Fatigue Life, N (Cycles)</th>
<th>Stress, S (MPa)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1,000,000</td>
<td>56.66</td>
</tr>
<tr>
<td>1,000</td>
<td>101.98</td>
</tr>
</tbody>
</table>

Using the new S-N (from Table above) and the following equations (Bannantine et al. 1990) the fatigue life can be obtained:

\[ N = 10^{-c/b} S^{1/b} \]  
\[ C = \log \frac{s_{1000}}{s} \]  
\[ b = -0.333 \log \frac{s_{1000}}{s} \]  

A hypothetical case is shown below as an example to demonstrate fatigue life of a bridge. A bridge has the connection type modeled; the loading in the bridge was converted to an equivalent fully reversed stress of 70 MPa. What will be the life of the bridge at this time given that it is subjected to 1000 equivalent constant stress cycles per year?

**Solution**

From the equations above

\[ C = 2.264, \text{ and } b = -0.085 \]

Hence \( N = 8.48 \times 10^4 \) cycles

Therefore the bridge fatigue life is 84.8 years. The S-N curve for the detail is shown in Fig. 5. If the same bridge is subjected to an equivalent fully reversed stress of 69.02 MPa, then either by using Eq.1 or the S-N curve in Fig. 5, the fatigue life of that detail is 100 years given the same stress cycles per year of 1000.
6 BIM MODEL

Building information modelling (BIM) "is a digital representation of physical and functional characteristics of a facility. A BIM is a shared knowledge resource for information about a facility forming a reliable basis for decisions during its life-cycle; defined as existing from earliest conception to demolition (NBIMS)." In this paper a combination of picture representation, drawing and FEM tools (AutoCAD and AutoDesk Simulation Mechanical from AUTODESK) and spreadsheet (MS-Excel) is used to represent the data, to analyze the stresses and to evaluate the life-cycle of a typical rivet connection of a steel bridge. The schematic diagram is shown above in Fig. 3 and a screen capture from spreadsheet is shown below in Fig. 6.

<table>
<thead>

</table>

Figure 6: A schematic model showing hypothetical case of two typical bridge connections and calculation of remaining life from fatigue analysis. In this example, considering a hypothetical case in which the bridge has served 80 yrs of life, joint 1 has 4.8 yrs remaining life and joint 2 has 20 yrs remaining life. Joint 1 is critical needs immediate attention.

7 DISCUSSION AND CONCLUSION

As the structure, buildings, bridges and other infrastructure, constructed in the industrial boom of 20th century are coming to age, a comprehensive approach in assessing their remaining lifespan, function and re-usability is essential. Although the design for deconstruction has so far been limited to design of new buildings with view of optimizing deconstruction, the concept should be extended to sustainable use of existing infrastructure. BIM, which is not only data representation and storage system but also a life cycle management tool, needs to be extended to assess remaining life of infrastructure which will help in decision making of the continuing use of the infrastructure. In this paper a model is presented to analyze remaining fatigue life of bridge using drawing tools, Finite element analysis tools and spreadsheet application in assessing critical joints for bridges. The model can be further extended to include other factors such as serviceability condition, existing condition of infrastructure and functionality of the structures before making a final decision on how to optimize life-cycle of the infrastructure in question. In a bridge the is invariably going to be several connection details, and hence a BIM system is essential to track the connection type, the stress concentration, the fatigue life, and hence information on maintenance or deconstruction can be made in time.

Abstract: While significant investments have been made to advance energy auditing methods to reduce energy consumption in the residential sector, homeowners are still challenged to take action and realize energy savings on their utility bills. Key challenges facing homeowners in need of energy efficiency improvements were found to be: 1) lack of information, 2) lack of financing, and, 3) lack of skilled workforce (2009 CEQ report). Recent research examining home energy auditing has revealed significant process waste, including audits that do not lead to energy upgrades; distrust between auditors and homeowners; a tendency for audits to lead only to one time improvements as opposed to continuous improvement. In response, variable types of home energy audit practices and strategies are emerging, including standardization of training and rating programs, as well as alternative methods to lower the costs of audits through partial “assessments.” This research takes a value-oriented approach to study the energy audit process of residential homes, and seeks to elevate the effectiveness and efficiency of home energy assessments through process design. The objectives of this research are: 1) To characterize “on-site” value delivery during a 90 minute home energy assessment, 2) to present relationships between building trust and deliver value via a model, and 3) to explore how these trust-value relationships influence homeowners’ decision making to take action in a manner of home improvements. In addition to home energy audit sectors, elevation of value distribution and trust relationship in a productive process, not only enhance distributing characterized value during operation, but also increase identification of linkages between specific tasks and the accumulation of trust leading to action on behalf of participants in the design and construction industry.

1 INTRODUCTION

The purpose of a home energy assessment process is to identify and prioritize opportunities to improve energy efficiency in a manner that leads to action on behalf of the home occupant. Challenges facing the home energy assessment process include information barriers, available finances to invest in energy upgrades and trust relationship (Palmer, Walls, Gordon, & Gerarden, 2013). Past approaches in addressing these challenges have included homeowner outreach and education programs, weatherization training programs, and standardization of methods to characterize home energy assessment methods. Many of these approaches focused on the physical characteristics of homes, instead of occupants conditions. Opportunities exist to improve assessment processes, based on unique conditions in homes and homeowners, in a manner to generating value for both homeowners and energy efficiency service providers. Womack and Jones (J.P Womack & James, 2006) define value as: “a capability provided to a customer at the right time at an appropriate price, as defined in each case by the customer.” Unlike objective characters of products, the provision of services has a nature of intangibility. Customers often have little idea what to expect until they consume it, and typically perceive a service as a risk. Research into the exchange of value within service-focused industries has demonstrated that trust
helps raise consumer comfort in situations characterized by a high degree of risk, uncertainty, or lack of knowledge or information, during interactions between customers and service providers (Coulter & Coulter, 2002).

While significant research has been focused on standardizing the energy audit process, limited effort has been invested in subjective characters of service, such as trust cultivation during the audit process. Trust relationships are notable as a critical success factor in any service relationship (Coulter & Coulter, 2002). This research focuses on value distribution related to build trust relationship during home energy audit processes, as well as to indicate the relationships between invested effort in a manner of time spend in an audit process and the measurement of value- trust conversion involving in homeowners’ decision making system that leads to energy related home improvements. The specific objectives of this research are to: (1) Define and characterize the value dimensions and value adding processes of a home energy audit, (2) Construct a value conversion model with uniquely defined trust attributes that can be used to indicate value- trust conversions taking place during an in-house walkthrough inspection.

2 RESEARCH BACKGROUND

In the United States, the majority of residential housing is comprised of single family homes; and a large number of these homes were built prior to the development of energy codes. The U.S Energy Information Administration (EIA) states that the total energy consumption in the U.S, 2013 was 97.53 quads, or about 21.1% of the nation’s energy consumption came from the residential sector, followed by the transportation (27%), industrial (31.5%) and commercial (17.9%) sectors (EIA, 2013). In a study by the White House Council for Environmental Quality, key challenges facing homeowners in need of home energy efficiency improvements were found to be: 1) a lack of information, 2) a lack of financing, and, 3) a lack of skilled workforce to make home energy upgrades (2009 CEQ report). Since the time of this report, significant investments have been made to reduce energy consumption of the residential sector, including training of home energy auditors and weatherization workforce, as well as incentives and aid programs for home energy upgrades. While valuable opportunities, the role of the homeowner in making informed energy upgrade decisions is critical to the effectiveness of the outcomes.

The most well-known authorities in residential energy assessment are the Residential Energy Service Network (RESNET) and the Building Performance Institute (BPI). Both have developed assessment approaches and certification for professional auditors. However, the current energy audit approaches do not meet market demand, a survey of nearly 500 home energy auditors and contractors revealed that: 64% indicated that “homeowners lack an understanding about the information audits provided”; 50% stated that homeowners are “unaware that energy audits exist”; 74% stated that homeowners “cannot afford the upgrade that would be recommended”; 40% cited the high actual or perceived cost of audits; and close to 25% respondents believe the reason is due to a “lack of trust in the reliability and accuracy of an audit.” According to the research, almost 30% of survey participants stated that “half or more of their clients do not make any of the suggested improvements recommended in an audit.” (Palmer, Walls, Gordon, & Gerarden, 2013). Riley et al. (2012) state that notable inefficiencies of the home energy assessment process involving barrier categories, these include:

- **Process waste**: Wasted effort conducting audits that do not lead to upgrades, extensive diagnostics that do not provide value or are not understood by the customer
- **Information barriers**: Incoherent/confusing delivery of energy assessment information to homeowners, lack of understanding by homeowners on how to pursue improvements
- **Trust barriers**: Distrust due to poor communication, lack of understanding of customer behavior / choices by auditors, and infrequent or one-off approach to customer service

In an effort to reduce these barriers during a home energy audit, a value-oriented light-touch home energy assessment is introduced to enable flexibility, efficiency and effectiveness of in-house walkthrough. This approach emphasizes the execution of value adding processes that contribute to an efficient assessment process that maximizes the chance of action on the part of the homeowner.
3 THE OBJECTIVES OF THE NATIONAL ENERGY LEADERSHIP CORPS (NELC)

The National Energy Leadership Corps (NELC) is an education and research program aimed at the transformation of how homeowners think and act regarding energy decisions in their homes and other buildings, and provides the platform to examine the improvement of value delivery that is discussed in this research. The NELC program is designed based on expert input from home energy audit and weatherization programs, and research conducted on multiple approaches to engage homeowners in the delivery of low cost, meaningful, and scalable home energy assessments. The specific program objectives of the NELC are to:

1. Create a trusted network of 3rd party energy coaches who are capable of engaging homeowners in personalized home energy assessments;
2. Cultivate fundamental energy literacy for citizens through engagement of entry-level students and homeowners of all ages and demographics;
3. Enable scaled delivery of assessments at little to no cost to homeowners through the use of state-of-the-art practices and intelligent support tools; and,
4. Provide an on-ramp to credentials and careers in building energy efficiency and management.

These objectives are pursued through the development and deployment of curriculum, support tools and a supporting program infrastructure that enables instructors of multiple types of energy and sustainability-focused courses to integrate a student-led home energy assessment project into their curriculum. The program includes: (1). online learning modules that provide self-paced on-demand learning, (2) flipped classroom model to enable discussion and hands-on training in class, and (3) technical tools to facilitate data collection and report delivery, such as an I-pad application, energy efficiency measurement database, and web-based energy profile for homeowners to track utility usage and home improvements.

4 DECISION-MAKING AND VALUE DEFINITION

The implementation of energy upgrades reflects homeowners’ decision making processes. The study of value distribution in a home energy assessment can be pursued through decision theory and decision making processes involving a value-based approach. The decision theory methods contribute to increased accuracy in decision making by building a systematic structure into data gathering and analysis (Claudio et al. 2014). Two key elements to approaching a decision making process include: 1) Identify alternative options, 2) Determination of expected outcome on each option and the expression of values. With this approach, the decision makers are allowed to prioritizing from among a list of probable consequences (R. L. Keeney, 1971). A preferred decision is “the option whose expectation has the highest value” (Hazelrigg, 1998), which reduces the level of uncertainty by individuals in complex settings. Uncertainty can be stated as lack of understanding, incomplete information, lack of experience, or having no clear preference among several alternatives (Claudio et al., 2011b). “Value adding process” is a term referring to a set of activities which transfer an input into an output that is has increased value. Carol Sanford expands the term of value adding process as an ongoing value creation for stakeholders. The creation of value depends on continual improvement on how well the process serves stakeholders (Sanford, C., 2011), including users, co-creators, the environment, community, and investors.

The complex nature of homes as systems, coupled with the unique settings of individual households, an approach to value distribution seeks to align value adding processes with the unique types of value needed to support decisions made by homeowners to implement home energy improvements. This research seeks to categorize value dimensions in a manner that allows customization for specific circumstances. Examples of unique circumstances that may inform assessment process design include: market intelligence about homes or homeowners, specific services being promoted by energy service professionals, and opportunities to implement regionally available weatherization assistance programs.

4.1 Effort and the Concept of Home Energy Assessment Efficiency

When considering value in a home energy assessment, it is worthwhile to consider the effort invested in an assessment and the initial concept of assessment efficiency. As described in Lean principles, the goal of an assessment should be to maximize Value Adding Processes while also expending the minimal
Effort to be needed to enable these processes. “Effort” is introduced as an investment that can be measured in a variety of ways, including time and money. In the case of this research, effort is measured in time, specifically time spent during the home energy assessment. Total assessment effort expended includes all of the time spent by auditors on the physical home energy assessment, which is expected to be approximately 90 minutes in the NELC program. It is inevitable that only some of this time and effort contributes to the generation of value adding processes, and that some of this time is wasted, such as time spent waiting or looking for a misplaced tool, whereas, there is time spent on necessary but non-value adding, such as travel time between zones of a home. The study and categorization of effort in time invested into a home energy assessment systematically elevates the benefits of customize the assessment process for homeowners individually, and highlights value conversion in the inspection system. The elimination of waste effort spending on unnecessary tasks is also more feasible. For example, an assessor spends less time evaluating recently replaced equipment and spends more time on tasks that are related to homeowners’ expressed concerns, as well as the selection and representation of recommendations of home improvements based on homeowners’ market segmentation and worldview. Equation 1 is created to express the transformation from Effort in time to value adding effort, non-value effort and wasted effort.

Equation 1: Effort equation of value and non-value adding processes

\[ T_{\text{effort}} = V_{\text{effort}} + NV_{\text{effort}} + W_{\text{effort}} \]

Total effort \((T_{\text{effort}})\) = time spent on assessment (minutes)

Value adding effort \((V_{\text{effort}})\) = time spent or invested on the generation of value (minutes)

Non-value effort \((NV_{\text{effort}})\) = time spent on necessary but non-value adding activities (minutes)

Wasted effort \((W_{\text{effort}})\) = time spent on unnecessary and non-value adding activities (minutes)

Building on this foundation, the concept of assessment efficiency is introduced as useful metric that can be described as Equation 2 below.

Equation 2: Definition of Assessment Efficiency

\[ \text{Assessment Efficiency} = \frac{V_{\text{effort}}}{T_{\text{effort}}} \text{ in a manner of time (minutes)} \]

While assessment efficiency can be calculated through the use of time, the variability of value adding processes with respect to their contribution to action on the part of homeowners is significant and often unmeasurable. This research emphasizes the development of improved understanding of value dimensions and value adding processes as an approach to improving the design of home assessment processes and practices. Definitions of value in home energy assessment and trust attributes are introduced below to help better define how value adding effort leads to the outcome of decision making.

4.2 Value Definition of Home Energy Assessment

“Value refers to any aspect of a potential product that could influence the likelihood that customers would purchase that product” (Ralph L. Keeney, 2004). In the exchange of “value” within client customer relationships, the service sector, such as those services provided by an energy auditor, are defined heavily by the level of trust the client has in the recommendation of the service provider. Different industries have unique definitions of “value”. Womack (Womack, 1996) in their presentation of Lean theory define value as: “a capability provided to a customer at the right time at an appropriate price, as defined in each case by the customer.” Neap (Neap & Celik, 1999) also defined value as the “fair equivalent in service or commodities that an owner/buyer receives in exchange for money.”

To categorize value, this research adopts the value definition cited by John Kelly (Kelly, Male, & Graham, 2004), in the book of “Value Management of Construction Projects”, that value can be categorized into two dimensions - “objective value” and “subjective value”. **Objective value** refers to a measure of the
input resources used to create a physical component, object or service, such as units of cost, mechanical-related effort, information and resources. Examples of objective value creation in a home energy assessment include the gathering and exchange of information about the conditions of a home, and priorities of homeowners. **Subjective value** refers to the desire to obtain or retain an item, or how much the owners/buyers are prepared to pay for prestige, appearance, aesthetic, judicial, religious or moral reasons (Neap & Celik, 1999). In a home energy assessment, subjective value may take the form of the trust developed between the homeowners and the service provider, and is created through the means and methods delivering an audit. Subjective value strongly related to service providers’ personalities and delivery style, such as the approach to communicating with homeowners, how well they explain issues, and the demonstration of respect.

The concept of decision making and identifying the objectives of home energy assessments is a critical approach to defining value delivery. The initial objectives of a home energy audit are to: 1) inspect house conditions to assess opportunities to improve home safety, health and efficiency, and, 2) develop trust relationship with homeowners. Figure 1 illustrates the integrated concepts of invested value in an assessment, objectives of value of home energy audit, and value dimension as an initial framework of value model. Terms of Value of exchange ($V_{\text{exchange}}$) and Value of trust ($V_{\text{trust}}$) are introduced to define the objectives of the audit with its associated value dimensions. In layers of value categories in a home energy assessment including invested effort categories of Value adding effort ($V_{\text{effort}}$), Non-value effort ($NV_{\text{effort}}$), and Wasted effort ($W_{\text{effort}}$), the objectives of value, and dimensions of value.

![Diagram showing the initial framework of value model](image)

**Figure 1**: initial framework of value model: Layers of value types of home energy audit. Value adding processes ($V_{\text{effort}}$) yields instances of value transitions ($V_{\text{exchange}}$ or $V_{\text{trust}}$).

Value adding processes in home energy assessments take many forms, but can be classified based on objectives of value and dimensions of value, and the number of instances they take place during an assessment. Through observations of assessments over time, over sixty unique instances of value adding processes have been identified with corresponded categories of Vexchange, and Vtrust. In each case, the value adding processes are linked to a discreet task or transaction during a home energy assessment in which Vexchange, and/or Vtrust can be clearly identified. A deeper exploration of the types of value adding processes that take place during assessment and how they contribute to the generation of trust make up the remainder of this paper. Table 1 presents two examples of value adding processes that can be uniquely identified, corresponding descriptions of how value is generated, and the categorization of objectives of value ($V_{\text{exchange}}$ or $V_{\text{trust}}$) and dimensions of value (subjective or objective).

4.3 Trust Attributes of home energy assessment

The home energy audit is performed as a type of service in the construction industry. Customers have an inherent need to trust in their service provider to deliver the desired service outcome. Trust is one of the key predictors of future commitments between customer and service providers (Coulter & Coulter, 2002). Trust generally is viewed as an essential ingredient for a successful relationship. Trust is defined as “a willingness to rely on an exchange partner in whom has confidence” (Garbarino & Johnson, 1999). Research has demonstrated that reduction of risk, uncertainty, and/or share with knowledge/information on the part of interaction facilitate to establish trust relationships between participants (Coulter & Coulter, 2002). Seven trust attributes have been introduced from service literature to represent trust characteristics: competence, customization, reliability, promptness, similarity, empathy, and politeness. The additional attribute of open and effective communication is also adopted as a trust attribute to directly address the need for information exchange between energy service providers and homeowners. The first four of these characteristics pertain to the auditors’ ability to deliver their service and are referred to as “offer-related” trust attributes. The latter four pertain to the auditors’ personal characteristics or manner of delivery, and are referred to as “person-related” trust attributes (Coulter & Coulter, 2002). Definitions and examples of offer-related and person-related trust attributes as interpreted for a home energy assessment are presented in Tables 2a and 2b respectively.

Table 2a: Definitions and examples of trust attributes in a home energy audit

<td>Use direct and clear language to explain issues to homeowners and take steps to verify understanding</td>
</tr>
</tbody>
</table>

†Based on the study of adoption barriers in home energy efficiency, "open and effective communication" is added in this research to detect the understanding and transparency of a conversation.

4.4 Trust -Value Conversion Model

Trust attributes described in Table 2a and 2b are used to evaluate individual tasks in an in-house walkthrough inspection in a manner of time. Discreet inspection tasks are classified based on the value dimensions: objective and subjective value. The value is aggregated based on the objectives of value that contribute either gathering information of home conditions (Vexchange) and the building of trust relationships with homeowners through caring homeowners’ concerns, priority and preference (Vtrust). The objective value categorized trust attributes(Competence, Customization, Reliability and Promptness) are used to demonstrate the value of inspecting house condition, and the subjective value categorized trust attributes( Similarity, Empathy, Politeness and Open and efficient communication) are mainly used to evaluate auditors’ personality and the quality of delivery assessment service.

Be more specifically, the objective value is evaluated as trust attributes are identified through house inspection and data collection, which mainly focuses on various home systems, such as: attic, appliance, cooling, heating, lighting, renewable energy, water heating, building envelop and house upgrade. Subjective value is used to characterize assessors’ methods delivering the assessment; such as communication skills, worldview techniques to learn homeowners’ priorities and concerns, and the assessors’ general behavior to interaction with homeowners during the assessment. Worldview refers to the study by the Shelton Group in which distinct market segments of home energy clients are categorized (in percentage of home energy clients) into four types: True believer (23.5%), Cautious Conservatives (22%), Concerned Parents (31%) and Working Class Realists (23.5%). Intrinsic and extrinsic motivations of each type of worldview are stated in table 3 (UtilityPulse program, Shelton group, 2013).

Table 3: Worldview†: Intrinsic and extrinsic motivations of each type of worldview (UtilityPulse program, Shelton group, 2013).

<table>
<thead>
<tr>
<th>Type of Worldview (% of home energy clients)</th>
<th>Characteristics and qualities</th>
</tr>
</thead>
<tbody>
<tr>
<td>True believer (23.5%)</td>
<td>Intrinsic – Protect environment live responsibility</td>

<tr>
<td></td>
<td>Extrinsic – lower bills, payback/ ROI</td>
</tr>
<tr>
<td>Working Class Realists (23.5%)</td>
<td>Extrinsic – lower bills, payback/ ROI</td>
</tr>
</tbody>
</table>
To integrate the processes of home energy assessments, there are various tasks required to complete in an in-house walkthrough assessment. Assessment tasks are categorized based on energy systems and locations in a home, and their corresponding trust conversions, which enables linkages to be made between invested effort and types of value contributions to actual home energy implementation.

In summary, categories of tasks used in this research represent groups of upgrades that are related and have common energy efficiency measures including: attic, appliance, cooling, heating, lighting, renewable energy, water heating, envelope, and living upgrades. Living upgrades refer to tasks that identify potential improvements to the health, safety and comfort of the home, and are included for two reasons. First, many of these conditions are related to energy efficiency measures and can provide added incentive to pursue energy upgrades. Secondly, the effort to identify health and safety issues in homes provides an opportunity to demonstrate credibility and empathy and as a result, help to build trust between homeowners and assessment provider. Additionally, three approaches of value distribution related to assessors are identified as communication skills, the ability to identify and respect variable worldviews, and professionalism. Figure 2 illustrates a comprehensive architecture of typical tasks of an assessment and the manners in which the assessment is performed are related to value dimensions and trust attributes. In this framework, the overall value generated through a home energy assessment (HEA) walkthrough is characterized by (1) the Objective value generated by information-gathering tasks and which lead to the generation of service-related trust attributes, and (2) Subjective value generated by the interactions between assessors and homeowners and which lead to the generation of people-related trust attributes.

![Diagram](image)

**Figure 2**: Trust-value conversion model - the categorized tasks of an assessment walkthrough with corresponded trust attributes and value dimension.

The evaluation of a home assessment with respect to the value distribution can be achieved through observing tasks performance and measuring the tasks performance according to the value dimensions and associated trust attributes. Table 4 provides an example of series of tasks of exterior walkthrough; tasks are categorized into related task system, trust attributes and value as a pilot study. The further
study will be spanned through calculating time spent in individual task and homeowners’ feedback of assessment service.

5 IMPLICATIONS

Energy retrofit projects for homes and buildings have significant potential to reduce energy waste, advance energy independence, and enable job-creating design and construction projects across sectors of the design and construction marketplace. Improved characterization of value exchange and the development of trust with clients will help lead to the design of more effective energy assessment delivery methods by helping to elevate the need to combine effective information gathering with the generation of business relationships between homeowners. These concepts also apply to energy assessment and auditing procedures for commercial buildings, where similar opportunities exist.

6 CONCLUSIONS AND THE NEXT STEPS

This research seeks to improve the home energy assessment process design through a value-oriented approach. The methodology presented here links value theory to the home energy assessment process via introducing the dimensions of objective and subjective value, and value objectives and trust attributes of home energy assessment. Currently, this research is focused on the design of a follow-up survey and feedback tool that will verify the value-trust model. By doing so, the expected contribution of this research are: (1) process of value distribution and the trust cultivation can be studied in more detail; (2) the design of assessment processes that target assessment efficiency; and (3) the facilitation of homeowners’ decision are aligned with homeowners’ interest and ability to act. Furthermore, this research proposes a feasible approach to analyze and measure continuous in-field activities in a quantitative manner, which leads to more possibilities to manage production/ service processes based on clients’ demands, as well as elevate customization with effectiveness and efficiency in the A/C/E industry.

Abstract: Panelized construction offers benefits to the construction industry including energy savings and reductions in carbon emissions and waste. This research addresses the sustainability of panelized residential construction during the framing phase, which consists of panel fabrication in the plant, transportation to the site, and on-site assembly. This study is conducted in collaboration with Landmark Building Solutions (LBS), a panel manufacturer in Edmonton, Canada. Two tasks with respect to assessing the sustainability of panelized construction are carried out in this research: (1) The positive impact of panelized construction on the construction schedule is evaluated by utilizing archived schedule data. In this task, the cycle time of framing for panelized construction is investigated; the results are compared with those of conventional stick-built construction, and the impact of framing cycle time on on-site winter heating is addressed. (2) The benefits of panelized construction are measured in terms of construction waste reduction by quantifying the recyclable and non-recyclable waste. The results are compared with those of the stick-built method, and the impact on embodied emissions in material waste is addressed. The primary data source is archives of the industry partner, including accounting records and construction records. A literature review and comparison are carried out to provide the necessary context for achieving the research objective. The preliminary results support the sustainability of panelized construction compared with the conventional stick-built method.

1 INTRODUCTION

Off-site construction has received wide attention due to benefits such as accelerated schedule, improved quality, decreased material waste, and sustainability in terms of energy savings and emission reductions. This research aims to evaluate the sustainability of panelized construction in terms of construction cycle time (operational carbon emissions from the construction process) and construction waste (embodied carbon emissions of materials). The carbon emissions are neutrally indexed in order to evaluate construction sustainability. Construction carbon emissions associated with construction, it should be noted, comprise operational emissions from the construction process and embodied emissions of materials. Operational emissions refer to the emissions from construction activities, while embodied emissions are indirect/upstream emissions associated with the building materials used, such as manufacturing of the equipment used in production or transportation of raw materials. In specific, these include emissions from the following: (1) extraction of raw materials; (2) raw material transportation to material processing plant; (3) building material manufacturing in plant; (4) building material transportation...
to the site; (5) construction on site; (6) operation and maintenance; and (7) demolishing, disposal, or recycling (Inui et al., 2011). The entire process is known as “Cradle-to-Grave”, and the corresponding emissions are referred to as “Cradle-to-Grave” emissions, among which those phases from raw material extraction to material leaving the manufacturing plant are specified as “Cradle-to-Gate”, including emissions from stages 1 to 3. “Cradle-to-Gate” is the domain most commonly used, and the one used in this study.

Li et al. (2014) quantified and compared the direct (construction operation) and indirect (embodied) emissions from panelized and stick-built construction, and concluded that the use of the panelized construction method reduces overall emissions by 42.76% compared to the stick-built method. They also found that on-site winter heating accounts for 34% and 50% of the measured emissions for the panelized and stick-built methods, respectively. The key aspect of panelized construction that leads to reduced emissions from on-site winter heating is the reduced cycle time of construction. Panelized construction is also proven to reduce wood waste from construction. Mah (2011) investigated the waste generated from the framing of residential buildings, and found that an average of 1,400 kg of waste is generated from the framing of a single-family home using the stick-built method, among which 89% is wood waste. Monahan and Powell (2011) investigated panelized timber frame construction, and found that there was a 34% reduction in embodied carbon when compared to traditional construction methods. In this research, to further investigate the benefits of panelized construction, the construction cycle time and generated waste associated with panelized construction are studied and compared with those associated with the stick-built method.

This research uses a case study to investigate differences in operational (direct) energy and emissions between the two methods with regard to winter heating. This case study is unique in that it reveals differences between the two methods specifically in a cold weather climate. Further investigation leads to a greater understanding of the differences in methods with respect to winter heating and waste, using environmental metrics such as embodied energy and embodied emissions as the indices. Embodied energy and emissions are summations of all the energy and emissions related to all materials, transportation, and construction up to the framing stage, i.e., the energy expended and emissions emitted from the upstream of the framing stage along the value chain.

2 RESEARCH OBJECTIVE

The aim of this research is to address the sustainability of panelized residential construction in the framing phase in terms of construction cycle time and construction waste. The research objective encompasses the following two tasks:

1. Evaluate the benefit of panelized construction in terms of construction schedule: In cold regions, on-site winter heating is a primary contributor to energy consumption and carbon emissions. Construction cycle time, in turn, is the determining factor for on-site winter heating duration. In order to assess the benefits of panelized construction, the average framing cycle time of panelized construction is evaluated based on archived construction records, the results are compared with those of stick-built construction, and the impact of framing cycle time on on-site winter heating is addressed using operational (direct) and embodied energy and emissions.

2. Measure the benefit of panelized construction on construction waste: Material waste is another important factor influencing the sustainability of construction. In this study, the waste generated with the state-of-the-art technology is categorized into recyclable and non-recyclable and then quantified. The results are compared with those of the stick-built method and the impact on material embodied energy and emissions is addressed.

To achieve the research objective, the required data is obtained from: (1) the industry partner’s operation records for 2013, including accounting and construction records, and (2) construction schedule records for January, 2011 to April, 2013. A literature review and comparison are also carried out.
3 CONSTRUCTION CYCLE TIME

Corresponding to the manner in which the current state-of-the-art technology is utilized, the milestones in the residential construction schedule are date to field, framing start, siding start, drywall boarding, finishing stage 1, and possession date. Based on the construction schedule records for January, 2011 to April, 2013, the cycle times of panelized and stick-built construction are given in Table 1, Figure 1, and Figure 2.

The cycle time comparison between panelized and stick-built is graphically represented in Figure 3. Regarding construction schedule, the main difference between panelized and stick-built construction, which has to do with the construction technology used, is the span from framing start to siding start; other schedule differences are primarily determined by the business process and coordination of residential construction and are not specifically tied to either panelized or stick-built construction. Regarding the identified span during which there is a notable difference between the two construction methods, panelized construction is associated with a 47% reduction in duration from framing start to siding start compared with stick-built, as shown in Figure 3.
Construction cycle time has a major impact on on-site winter heating in cold regions. In cold regions, winter heating accounts for the largest portion of energy consumption and carbon emissions during the framing phase. On-site propane heaters operate 24 hours a day, 7 days a week, and are refilled by a 5-ton truck every 3 days on average in winter. The heating season in Alberta is about 6 months in duration, i.e., winter heating is occurring 50% of the time. However, the nature of panelized construction shifts many outdoor construction activities to a more efficiently heated indoor environment, which markedly reduces the use of on-site winter heaters. As well, panelized construction reduces on-site assembly cycle time, thereby reducing winter heating time.

The common practice within the residential construction sector is to install a 100,000 Btu propane heater in the basement once the foundation has been backfilled. The hourly propane consumption is calculated as Equation 1, and the diesel consumption of the truck carrying out the propane refill is assumed to be 20 L per instance.

\[ P_h = 100,000 \times \frac{CC}{HV} \approx 4.17 \text{ (L/hr)} \]

Where: \( P_h \) is hourly propane consumption (L/hr); \( CC \) is converting coefficient from BTU to MJ, 0.0010551; \( HV \) is heat value of propane, 25.3 MJ/L (Natural Resources Canada, 2010);

Based on the above calculation, the assumption regarding propane tank refilling, and the recorded cycle time, propane and diesel consumption per house is calculated for panelized and stick-built construction as shown in Table 2. Furthermore, to measure the impact of using the panelized construction method on winter heating, (as a result of improving the productivity of the process and reducing the idle time between framing and the downstream construction activities), the winter heating period for the purpose of comparison is defined as the span from framing start to siding start. The propane and diesel used for winter heating entails: (a) operational energy and emissions, which can be calculated using Equations (2) and (3), and (b) embodied energy and emissions, which can be calculated by means of Equations (4) and (5).
Where:

\[ E = F \times HV_F \]

\[ \text{CO}_2 = F \times EF_F \]

Where: \( E \) is operation energy (MJ); \( \text{CO}_2 \) is \( \text{CO}_2 \) emissions (kg); \( F \) is the amount of Fuel (L); \( HV_F \) is heat value of fuel: the \( HV \) of propane is 25.3 \( MJ/L \) (Natural Resources Canada, 2010), and the \( HV \) of diesel is 38.68 \( MJ/L \) (National Energy Board, 2015); \( EF \) is the operational emission factor of fuel: the \( EF \) of propane is 1.51 kg \( \text{CO}_2/L \) and the \( EF \) of diesel is 2.663 kg \( \text{CO}_2/L \) (Environment Canada, 2013).

\[ EE = F \times EF_F \]

\[ E\text{CO}_2 = F \times EEF_F \]

Where: \( EE \) is embodied energy (MJ); \( F \) is fuel consumption (L); \( EF \) is the embodied energy factor: the \( EF \) of propane is 26.44 \( MJ/L \), and the \( EF \) of diesel is 45.7 \( MJ/L \), \( E\text{CO}_2 \) is embodied \( \text{CO}_2 \) emissions (kg); \( EEF_F \) is the embodied emission factor of fuel: the \( EEF_F \) of propane is 0.22 kg \( \text{CO}_2/L \) and the \( EEF_F \) of diesel is 0.57 kg \( \text{CO}_2/L \) (Energetics, 2013).

The operational energy and emissions of winter heating calculated based on the above methodology are shown in Table 2, and the embodied energy and emissions are shown in Table 3.

4 CONSTRUCTION WASTE

Construction waste is another important metric of construction sustainability. Based on the assumption that the net materials used in a house are the same for both the panelized and stick-built methods, the waste difference determines the difference in embodied emissions of materials between panelized and stick-built methods. The wood waste of panelized construction consists of waste generated in the plant
and waste generated on site. The on-site waste accounts for only a small proportion (0.036 in this case) of the overall waste for panelized construction, so only the wood waste generated is considered in this research. To measure the sustainability of panelized construction, the waste generated is collected by reviewing accounting records, as shown in Table 4; Figure 4 shows the amounts of wastes shipped out from the manufacturing facility in 2013.

The nature of panel fabrication in a plant provides the opportunity to optimize material usage and reduce material waste. Furthermore, several measures to reduce waste were implemented in 2012. Currently, all lumber and engineered wood for framing is precut by computer numerical control (CNC) saws, which have the ability to optimize cutting for multiple panels. As a result, the waste in the plant is less than with the stick-built method. The waste generated under the current approach is illustrated in Figure 5 to Figure 8.
Usually the floor joists are cut from 60-ft standard length I-Joists, which are purchased directly from manufacturers; accordingly, more than 70% of the total wood product waste generated in the plant is I-joist cut-offs. In the case of the stick-built method, I-Joists are precut by the material supplier before they are shipped to the site, and the waste in houseware is not included in the scope of the stick-built method; to be consistent for panelized and stick-built methods, it is therefore necessary to deduct the corresponding amount of waste associated with this process at the supplier’s warehouse from the waste calculated for panelized construction. Table 4 shows the adjusted waste amounts of the panelized construction method and associated embodied GHG emissions.

To compare panelized with the stick-built method, the waste generated from stick-built construction is ascertained through a literature review. It is found that the construction of a single-family home in North America typically produces between two and four tons of wastes on site (NAHB Research Center, 1996; Laquatra 2005). Mah (2011) conducted an empirical study of construction wastes has been undertaken to investigate the mass and volume of waste generated during the new home construction process. His study noted that typically in stick-built construction there are three waste pick-ups, with the first pick-up coming after the completion of framing. The study included an on-site audit of the first waste pick-ups of five single-family homes under construction. On average, over 1,400 kg of total waste (wood and non-wood) had been generated at a single-family house construction site by the time framing had been completed. Almost 89% of this waste was either dimensional lumber or engineered wood products. The results of Mah’s study are consistent with those of similar studies that have been conducted around North America. Therefore, the results from Mah (2011) that on average 536 kg of lumber waste and 710 kg of engineered wood waste are generated in the framing of one house are used in this research for the purpose of comparison of between the stick-built and panelized approaches.

To evaluate the impact of reduced waste on the sustainability of construction, the amount of waste is used to calculate the embodied energy and emissions of materials using Equation (6) and Equation (7). The results are shown in Tables 4 and 5.

\[ [6] EW = W \times E_W \]

Where: \( EW \) is embodied energy of waste (MJ); \( W \) is the mass of waste (kg); and \( E_W \) is the embodied energy factor of wood product: 10 MJ/kg for dimensional lumber and 15 MJ/kg for engineered wood (Geoff Hammond & Craig Jones, 2011).

\[ [7] ECO_2 = W \times EEF_W \]

Where: \( ECO_2 \) is embodied CO\(_2\) emissions (kg); \( W \) is the mass of waste (kg); \( EEF_W \) is the embodied emission factor of wood product: 0.341 kg CO\(_2\)/kg for dimensional lumber (Meil, 2000), and 0.576 kg CO\(_2\)/kg for engineered wood (Forintek Canada Corp., 1993).

5 CONCLUSION AND LIMITATIONS

This study has demonstrated that utilization of a panelized method enhances the sustainability of construction. In particular, this study has investigated the impact of cycle time savings and waste reduction resulting from panelized construction. Based on the operational data, the framing cycle time of panelized construction has been calculated, and the impact on winter heating has been evaluated. The waste generated by panelized construction has been quantified and compared with that of stick-built construction, and the impact on embodied emissions has been evaluated. The results in Table 6 and Figure 9 show that the overall energy intensity, including operational and embodied, is reduced by 202.378 MJ/ft² using the panelized construction method, which represents a 67.77% reduction compared to the stick-built method. Table 7 and Figure 10 show that the overall emission intensity is reduced by 1.758 kg/ft² using the panelized construction method, which translates to a 49.1% reduction compared to the stick-built method. Compared with stick-built construction, panelized construction as a sustainable construction method is demonstrated empirically to reduce energy usage and CO₂ emissions.

This research entails the following limitations: (1) due to the data accessibility, the data on stick-built construction waste was obtained from published research collaborated with the same industry partner, while others was archived from the industry partner’s records for this research; (2) Winter heating is a crucial issue in Canada; however, in other countries and regions, there may not exist the same issue.

LIFE CYCLE ANALYSIS OF STRUCTURAL STEEL REUSE USING THE ECONOMIC INPUT-OUTPUT METHOD

Abstract: Reuse of structural steel is not a new concept in civil engineering. However, even though members, and assemblies of members, have been reused for decades, reuse of steel is not a widely implemented practice. Approximately 90\% of demolished steel is recycled and only 10\% of that steel is reused in its current state. The structural steel reuse that does occur is due to the reuse of very large members or from specialty projects. The reason for these low levels of reuse is because the cost of reusing structural steel is too high. Unfortunately, many decision makers are coming to this conclusion without a comprehensive knowledge of the true cost of reuse and recycling. In order to fully understand the additional costs, or savings, associated with steel reuse, a life cycle analysis needs to be incorporated into an economic analysis. In this study, the economic input-output method was used to perform a life cycle analysis of structural steel reuse as it compares to current practices. The economic input-output method provides the benefit of being able to facilitate a quick analysis but is limited by only being able to perform a generalized analysis across the entire industry. The analysis was performed for several metrics, which can be grouped into four categories: greenhouse gases, energy usage, water usage, and hazardous waste generation. Results from the analysis show that there is a significant decrease, upwards of 65\%, for the calculated metrics across each category for reuse. In order to remedy the limitations of the economic input-output method, it is recommended to perform a similar analysis using a process model approach.

1 INTRODUCTION

Steel reuse shows great promise to become a more “environmentally friendly” alternative to creating new steel from virgin resources and recycled scrap steel. Current practices result in only about 10\% of steel being reused as opposed to the nearly 90\% of steel that is recycled, but it is believed that this could increase by up to 150\% if economic conditions were to change, technological advances were to be utilized, or externalities affecting life cycle cost were considered (Gorgolewski, 2006 and Ness et al., 2014). The impact of a product, process or activity is not only limited to economic impact; there are also environmental impacts and social impacts. Life cycle analysis is a tool used to assess the entire impact of a product, process or activity throughout its entire life cycle. This analysis is a necessary step in the decision making phase of any project. The complete impact of a decision throughout its entire economic life cycle needs to be quantitatively understood in order to properly and knowledgeably make a
comparison between proposed alternatives. Performing a life cycle analysis is the only way to truly understand a decision’s full impact, but there are several ways to do this.

2 BACKGROUND

Before being able to quantify the environmental benefits of reusing structural steel, the metrics for assessing environmental impact must be established. These metrics often include carbon footprint, water footprint, and energy use. It is important to note that these metrics need to be determined for the entire life cycle of the process or component and are based on direct and, sometimes more importantly, indirect impacts. A more detailed list of life cycle impacts can be seen in the work of Reijnders (1995), where the focus was on limiting resource use, minimizing pollution, and preserving nature.

2.1 Carbon Footprint

According to Wiedmann and Minx (2008), “… carbon footprint is a measure of the exclusive total amount of carbon dioxide that is directly and indirectly caused by an activity or is accumulated over the life stages of a product.” This definition of carbon footprint does not include any of the other carbon based pollutants or greenhouse gases, such as methane. Wiedmann and Minx argue that this definition is ideal in spite of its limited scope due to its high level of clarity. When selecting a metric for environmental impact it is important that this metric be of significant contribution, clearly defined, and relatively simple to calculate, especially when implementing practices to reduce environmental impact.

2.2 Water Footprint

The industrial sector consumes large volumes of water, but can also pollute even greater volumes downstream (WWAP, 2009). The idea of a ‘water footprint’ associated with each product and process was introduced by Hoekstra (2003) as a very similar concept to ‘virtual water’, originally coined by Allan (1997). Virtual water is the water consumed by the production of every product. It was used in a proposed solution to countries with water shortages by allowing those countries to export their water needs. A water footprint takes this concept a step further by including the water consumed during the entire life cycle of the process or product, rather than just during its production.

2.3 Energy Use

Based on the work by Dincer (1999), energy use is a suitable metric for environmental impact because of the wide range of problems that can be associated with it. Increases in energy use can be correlated to acid rain, ozone depletion, global warming, air pollution, forest destruction, and the production of radioactive materials. This is because many of the bi-products of energy creation have negative effects on the environment. Acid rain is a result of excessive amounts of sulfur dioxide (SO2), nitric oxide (NO), and nitrogen dioxide (NO2) being emitted into the atmosphere, which are all released during the combustion of fossil fuels. Ozone depletion is mostly due to chlorofluorocarbons (CFCs), which are used in air conditioning and refrigeration units but NO and NO2 also contribute. Other gases produced during energy production, including carbon dioxide (CO2), methane (CH4), nitrous oxide (N2O), ozone (O3), and peroxyacetylnitrate, are major contributors to the greenhouse gas effect and global warming.

2.4 The Economic Input-Output Method

The economic input-output (EIO) method for life cycle assessment (EIO-LCA) aims to simplify the process of performing a life cycle assessment without having to limit its scope (i.e. exclude minor products and processes). The EIO method takes an aggregate view of a process or product and determines its life cycle impact based on the resulting inputs and outputs into various industry sectors (Hendrickson, Lave, & Matthews, 2006). For example, in order to construct a reinforced concrete building, a certain quantity of steel reinforcing bars will be required. This steel would represent an output from the steel industry and an input to the construction industry.
The EIO method works by first selecting a product or process to be assessed for its life cycle impact. Next, the entire life cycle requirements for the supply chain of this product or process are determined. These supply chain requirements include everything from extracting raw materials to producing the final product. Once the life cycle supply chain has been established, the discharges associated with each activity in the supply chain are summed and the total life cycle impact is presented. Depending on the desired life cycle analysis output, the aforementioned discharges can be economic activity, environmental, social, etc. (Hendrickson, Lave, & Matthews, 2006).

In order for the EIO method to be feasible, the economy needs to be divided into a limited number of distinct sectors. Each sector also needs to have established and quantified relationships with each of the other sectors. This relationship identifies that amount of inputs required from each sector in order to produce one unit of output for the specified sector. Fortunately, these relationships exist because of the work proposed and carried out by Leontief (1970). The discharges per unit of output from each sector are also required in order to convert the supply chain outputs to a specific type of impact, such as environmental impact. For the specific case of environmental impact, these relationships have already been established (Lave et al. 1995, Hendrickson et al. 1998).

The limitations of the input-output method result mostly from uncertainty as outlined by Lenzen (2001) who listed seven types: (1) source data uncertainty, (2) import assumption uncertainty, (3) estimation uncertainty for capital flow, (4) proportionality assumption uncertainty, (5) aggregation uncertainty, (6) allocation uncertainty, and (7) gate-to-grave truncation error. The data used in the input-output method is collected from national surveys and while errors can be estimated, they cannot be quantitatively known. This results in source data uncertainty. The uncertainty from imports arises because the data associated with foreign goods does not necessarily follow that of their domestic counterparts but the foreign data is not necessarily known. Worst-case errors are typically used to adjust imports but this is a simplified approximation. If capital flow tables do not exist, they must be constructed from capital expenditure from varied sources. This is an approximation and, as a result, a source of uncertainty. The proportionality assumption states that there is a linear relationship between the inputs and outputs and that price is uniform across the economy (Hendrickson et al. 2006 & Lenzen 2001). This means that doubling the output will require doubled input from each input and that the cost of electricity is the same whether being purchased by the steel industry or the fabrics industry. Aggregation leads to uncertainty because multiple producers are combined into a single industry without any way of differentiating between them. The final uncertainty associated with the input-output method is the uncertainty that results from the truncation of the gate-to-grave portion of the life cycle. The EIO method only accounts for the production discharges and neglects any operation, maintenance and end-of-life processes.

3 METHODOLOGY

The life cycle analysis performed in this study was undertaken using the economic input-output life cycle assessment (EIO-LCA) tool, developed by the Green Design Institute at Carnegie Mellon University (CMUGDI, 2008). As discussed previously, the EIO-LCA employs an aggregate overview of the life cycle impacts of a sector of industry based on the desired economic output from that sector. This includes the impacts of other sectors providing inputs to the sector of interest. The methodology for this comparison can be defined by three steps (Figure 1): (1) determining a point of reference, (2) defining appropriate sectors and activities, and (3) equating and comparing equivalent economic activities.
Figure 1: Overview of life cycle analysis methodology

The first step in performing a life cycle analysis is determining a point of reference for the comparison. A life cycle analysis serves very little purpose unless the results are compared with results for another, equivalent alternative. For this study, a particular mass of steel was used as a reference. The exact value for the mass of steel is not important because of the linear nature of the EIO-LCA. Another important consideration for the reference point is where along the supply chain the steel is located. The steel could be located, for example, in the ingot phase, the pre-fabrication phase as an individual member, or the post-fabrication phase, as a member ready for delivery to site. For the purposes of this study, the point of reference was selected as the pre-fabrication phase (PoR1 in Figure 2). This means that the steel has been formed into a standard steel section but has not yet been incorporated into a design or structural assembly, thus no end connections or other such details have been applied. A post fabrication phase point of reference (PoR2 in Figure 2) would also be interesting and may be the subject of a future LCA.

Figure 2: Modified process model for reuse with the life cycle analysis point of reference

The second step of performing the life cycle analysis was to identify the relevant sectors that should be used in the EIO-LCA. The data set used for the analysis was the USA 2002 Benchmark (CMUGDI 2008). This is comprised of 428 different sectors and contains the cradle-to-gate interactions required to produce outputs from each of these sectors. Cradle-to-gate means that the life cycle analysis is only complete to the point where the desired output is produced, for example when a steel ingot is produced at the
The production of new steel components was assumed to come from the “iron, steel pipe and tube manufacturing from purchased steel” sector. This is responsible for the production of welded and rolled structural steel shapes (CMUGDI, 2008). The production of reused steel components was assumed to come from economic activity in the demolition industry. Unfortunately, demolition is not a sector included in the USA 2002 Benchmark data so construction of nonresidential manufacturing structures was selected as a surrogate. It is reasonable to consider construction and deconstruction as equivalent processes performed in an opposite manner. Many of the activities in this sector would be present in the removal of structural steel from buildings at the end of their service life. The main difference is that the deconstruction processes also includes activities for steel and cement manufacturing. The activity in these sectors would be present for the case of construction activity but would likely be absent from reuse activities. An adjustment was made to the impacts of the nonresidential manufacturing structures sector by removing the impacts that result from steel and cement manufacturing. With these sectors removed, the impact results will be more representative of reuse activities. For example, Table 1 displays the five highest total energy using sectors required to produce economic output from the “nonresidential manufacturing structures” sector. It is reasonable to presume that a large majority of the energy usage from “Iron and steel mills” would not be required, and can therefore be disregarded, if the structural steel is being reused.

Table 1: Highest energy users from the “nonresidential manufacturing structures” sector

<table>
<thead>
<tr>
<th>Sector Name</th>
<th>Total Energy Usage (TJ)*</th>
</tr>
</thead>
<tbody>
<tr>
<td>Nonresidential manufacturing structures</td>
<td>2.39</td>

<td>Petroleum refineries</td>
<td>0.26</td>
</tr>
<tr>
<td>Truck transportation</td>
<td>0.14</td>
</tr>
</tbody>
</table>

*values are reported per $1,000,000 of economic output

The final step was to determine the economic output from each sector required to achieve the desired mass of steel as specified in the first step. In order for a meaningful comparison to be made, the end production of each process needs to be the same. This means that the mass of steel that results from current practices and reuse need to be the same. Unfortunately the EIO-LCA method uses economic activity as the scale defining parameter for the analysis so equivalent economic activities for each production method needed to be calculated. The conversion values used in this study can be found in Table 2.

Table 2: Mass to economic activity conversion rates

<table>
<thead>

</tr>
</thead>
<tbody>
<tr>
<td>Current Practices</td>
<td>$3.64 / kg</td>
</tr>
<tr>
<td>Reuse</td>
<td>$4.93 / kg</td>
</tr>
</tbody>
</table>

The current practices conversion rate of $3.64 / kg was selected based on the average material price of structural steel sections ranging from 200 mm to 350 mm in depth. The unit prices for these sections were obtained from RSMeans (2009). The reuse conversion rate was selected as $4.93 / kg. This value was based on the average construction cost per unit mass of various industrial steel framing structures. Following similar logic to the selection of the sectors from USA 2002 Benchmark data, the cost of constructing a particular mass of steel is equivalent to deconstructing that same mass. These unit prices were also obtained from RSMeans (2009). Neither price was adjusted for inflation or changes in market value. The accuracy of this study would be increased if current prices were used, but this was deemed unnecessary for this investigation. Together, these values create a new steel to reused steel price ratio of 1:1.35. This comparison is based on the assumption that the steel is in a pre-fabrication state, as
previously stated. It is expected that reused structural steel closer to the installation stage of the supply chain (PoR2 in Figure 2) would result in a more favourable price ratio.

4 RESULTS

The metrics for the previously described comparison were divided into five distinct groups: conventional air pollutants (Figure 3), greenhouse gases (Figure 4), energy consumption (Figure 5), water usage (Figure 6a), and hazardous waste production (Figure 6b). The reported results are based on $1,000,000 of new steel production. A description of each metric can be found in Table 3.

</table>

Figure 3 through Figure 6 show that, typically, the analysis for structural steel reuse results in significant life cycle impact reduction. Only four out of the 19 metrics investigated resulted in a significantly increased impact due to the reuse process. Table 4 quantifies the comparison of each metric as the percent reduction that results from applying reuse processes as opposed to current practices. Although a benefit is not demonstrated in all metrics of this study, a generalized decrease in the environmental impact can be seen as a result of reuse. The total mass of conventional air pollutants was reduced by 0.25 t, or 1%, the total mass of greenhouse gases in CO₂ equivalent was reduced by over 1500 t, or 75%, and the total energy usage was reduced by over 17 TJ, or 69%.

5 DISCUSSION AND CONCLUSIONS

The economic input-output life cycle analysis results show a clear indication that reuse has the potential to provide significant benefits over current practices. Steel reuse exhibited superior results in nearly every presented metric, given the parameters of this study. When the results are generalized, a 75% reduction in greenhouse gases and a 69% reduction in energy use is expected for steel reuse.
The external costs associated with construction decisions, such as material source, are not often considered in current decision making practices. These costs are not considered because they are not accurately understood and they are not associated with direct costs to the decision maker. Introducing direct costs to the decision maker, through carbon credits for example, would encourage practices that incorporate a broader, societal cost into their decision making process. This work makes progress towards achieving accurate quantification of the societal cost of reuse practices but more work is still required.

6 FUTURE WORK

One of the main drawbacks of the EIO-LCA method is its aggregate scale. This prevents the specific processes, such as the reuse process, from being examined directly. As a result, a number of assumptions and simplifications needed to be made. These assumptions and simplifications may have an impact on the results. As such, these results should only be treated as preliminary.

A more detailed analysis is essential for accurately quantifying the benefits or costs of reusing structural steel. For this analysis, it is recommended to replace the aggregate approach used by the economic input-output method, with a more detailed approach, such as the process model approach.

It is also worth investigating how the externalities identified in this EIO-LCA could be monetized, such as carbon credits, so that the opportunity cost to society of not reusing steel could be understand and could influence future reuse decisions.

Abstract: This paper contemplates the development of a single high-level productivity metric for Alberta capital projects in order to represent overall improvement over time. The Industry Leaders Roundtable would use this metric to challenge the status quo, and formulate "out of the box" thinking to improve Alberta Megaproject productivity. The measure would be most relevant for the owner; however, owners and industry need to be supportive to make it successful. For this purpose, the proposed study includes comparisons with data held by the Construction Industry Institute (CII) such as COAA (Construction Owner’s Association of Alberta) and CII Performance Assessment Database. This paper establishes selection criteria for input/output variables for the high-level productivity metrics based on the comprehensive review of existing productivity metrics and create a high-level productivity metric. Data are collected from COAA and CII Performance Assessment Database. Descriptive and statistical inferential analyses are conducted for comparison of high-level project productivity between Alberta and U.S. capital projects. The results of this study are anticipated to provide a single high-level productivity metrics with informative quantitative analyses for Alberta projects.

1 INTRODUCTION

Construction industry has been a significant role in Alberta’s as well as Canada’s economy. In 2013, the construction sector represents 10.9% of $338.2 billion (CND) of total gross domestic product in Alberta (Alberta Government, 2015). Over the two decades, the construction industry in Alberta increases from $4.5 billion (CND) to $36.8 billion (CND). Especially, oil sands industry is a big portion of the construction sector in Alberta and more than $102 Billion (CDN) was spent on construction and operation capital necessary to develop oil sands resources (COAA, 2009). While the size of construction industry increases, the productivity performance and improvement in Alberta’s construction industry have been declining. This decline in Alberta is consistent with the decline of construction productivity in North America region over the past three decades (Jergeas, 2009).

For improving performance of construction productivity, academic researchers and industry practitioners have tried to provide effective productivity measurements. In usual, construction labor productivity is measured in actual work-hours per installed quantity. This measurement has been widely adopted in existing productivity studies (Yi and Chan, 2014). However, this productivity measurement focused on micro-level measurement for construction productivity depending on disciplines and workers. In spite of outstanding contributions from the previous studies, a high-level project productivity measurement has been demanding to capture overall improvement of project productivity for capital projects over time. The
Industry Leaders Roundtable in Alberta seeks a comprehensive measurement of high-level project productivity to challenge the status quo, and formulate “out of the box” thinking to improve Alberta capital project productivity.

This paper contemplates and presents possible measurement of high-level project productivity for Alberta capital projects. This paper aims to identify the most appropriate single, high-level project productivity metric for Alberta’s capital projects in order to gauge overall status and trends across the industry based on pros and cons of each measurement. This paper also compares Alberta capital projects’ project productivity with those of U.S. capital projects as a benchmark.

2 RESEARCH BACKGROUND

2.1 COAA-CII Performance Assessment Initiative

As the principal industry association for capital projects in Alberta, the Construction Owners Association of Alberta (COAA) strives to provide leadership to enable its owner members to be successful in their drive for safe, effective and productive project execution. Since 2005, COAA and CII have had a collaborative partnership for the purpose of benchmarking capital projects in Alberta. Building on the collective expertise of COAA and CII, the COAA Benchmarking program has provided a comprehensive performance assessment system comprised of a customized questionnaire, a dedicated database, and a suite of individualized reports for each company submitting project data as shown in Figure 1. This program was funded by COAA with assistance from Alberta Finance and Enterprise, a component of the provincial government of Alberta, and operated by University of Calgary Performance Assessment Lab.

Since 2005, the collective effort of COAA and CII has focused on exploring the performance and productivity concerning the execution of capital projects in Alberta. This collaboration was premised on the extensive experience of CII in researching and benchmarking industrial facilities in the United States and around the world. Extending CII’s reach into Alberta permitted tremendous understanding of the performance of these projects, especially when compared with similar projects in the United States. In the line of this efforts, this study develops a high-level project productivity metric for Alberta capital projects.
2.2 Macro-Economic Level Workforce Productivity

Statistics Canada, Canada’s national statistical agency, measures labor productivity as an economic indicator across the world, which is calculated by real gross domestic product per hour worked. Real gross domestic product (GDP) (or real value-added) is a chained Fisher quantity index of GDP at basic prices. According to the definitions from the Statistic Canada (Statistic Canada, 2015), the number of hours worked in all jobs is the number of all jobs times the annual average hours worked in all jobs. According to the retained definition, hours worked means the total number of hours that a person spends working, whether paid or not. The hours worked generally includes regular and overtime hours, breaks, travel time, training in the workplace and time lost in brief work stoppages where workers remain at their posts. On the other hand, time lost due to strikes, lockouts, annual vacation, public holidays, sick leave, maternity leave or leave for personal needs are not included in total hours worked. Statistic Canada has adopted this measure to calculate workforce productivity as well as international economic organizations and other countries. Figure 2 was created using annual labor productivity by province and industry that Statistics Canada announced (Statistics Canada, 2015).

![Labor Productivity in Construction](chart.png)

**Figure 2: Labor Productivity in Construction Sector (2007-2013)*

*Courtesy by Statistic Canada (2015)

Figure 2 indicates that the labor productivity trend in the construction sector over the past seven years since global economic recession. During the pre-recession (2007-2009), the labor productivity in the construction sector had declined in both Alberta and Canada. After recession, Alberta’s labor productivity in construction sector has been increasing 20.7% from 2009 to 2013 while the labor productivity in Canada tends to be steady during the same period. In 2013, Alberta’s labor productivity in the construction sector was 1.3 times than overall labor productivity in Canada. This remarkable improvement of the labor productivity in Alberta’s construction sector is consistent with the economic development in Alberta’s economy over the last years.

This labor productivity, which is announced by the government, is representing national and regional economic indicator and is used as a fundamental data when the government develops an economic policies and makes capital investment decisions. However, this indicator has a limitation not to show project-level productivity that can be used for improving performance of owners and contractors. Thus, this paper contemplates the measurement of high-level project productivity metrics that can be applied to individual capital projects.

239-3
3 METHODOLOGY

3.1 High-Level Project Productivity Metrics

To develop high-level project productivity measurement, the reasonable input and output need to be defined to meet the purpose of measurement. This study adopts two approaches for exploring high-level productivity measurement in Alberta capital projects.

First, a quantity-based approach is applied which aggregates construction productivity in major construction disciplines including concrete, structure steel, piping, equipment, electrical, insulation, and instrumentation. Construction productivity of each discipline is measured based on actual work-hours per installed quantity. When using this manner, lower productivity values indicate better productivity performance. Using this quantity-based approach, the CII developed project-level engineering and construction productivity metrics to measure high-level project productivity of capital projects. This approach was applied to measure project-level productivity through standardization and aggregation of productivity metrics of engineering and construction disciplines (Liao, 2012; Chanmeka, 2012). Similarly, the project-level construction productivity metric was calculated through the following procedures:

- Transformation: For calculating project-level productivity metric, the productivity data first needs to be assessed on normality of the distribution because the standardization is conducted based on the assumption of normal distribution of the data. This study checked the normality and skewedness on the distribution of productivity values and applied natural log transformation to transform the skewed productivity data for standardization.

- Standardization: The transformed productivity values of the disciplines were standardized to z-score which standard score which means the number of standard deviations. In practice, the absolute value of this metric represents the distance between the productivity value of one project and the population mean of the productivity values in units of the standards deviation. A value is negative when the productivity is below the average, positive when above.

\[
z_i = \frac{p_{ij} - \mu_i}{\sigma_i}
\]

where: \(z_i\) = z score of \(i^{th}\) construction discipline’s productivity; \(p_{ij}\) = the transformed productivity metric value of \(i^{th}\) construction discipline’s \(j^{th}\) project; \(\mu_i\) = mean value of the transformed productivity metric value of \(i^{th}\) construction discipline; \(\sigma_i\) = standard deviation of the transformed productivity metric value of \(i^{th}\) construction discipline.

- Aggregation: Through the standardization of the productivity values, the variability of productivity values in different disciplines was neutralized and calibrated in the same scale suitable for aggregation. The standardized productivity values of construction disciplines are aggregated using work-hours as the weights because work-hours is usually considered as a common parameter amongst different disciplines (Liao, 2012). The standardized productivity values in different disciplines are aggregated using the following equation:

\[
\text{Project Level Productivity Metric} = \frac{\sum_{i=1}^{n}(WH_i \times z_i)}{\sum_{i=1}^{n}WH_i}
\]
where: \( z_i \) = \( z \) score of \( i^{th} \) construction discipline’s productivity; \( WH_i \) = work hours of the \( i^{th} \) construction discipline.

Second, a cost-based approach is also used which considers costs for construction activities as an output. Total site work-hours is considered as hours worked in construction field. All costs have been normalized in terms of currency, location, and time. The normalized cost are value in 2013 Chicago. Similarly, this approach is applied to high-level productivity measurement. The following costs were considered as output.

- The total constructed cost includes all costs, direct and indirect, inherent in converting a design plan for material and equipment into a project ready for start-up or commissioning, but not in production operation; the sum of field labor, supervision, administration, tools, field office expense, materials, equipment, and subcontracts. Therefore, this study uses sum of procurement and construction cost as total constructed cost.
- The construction phase cost includes the costs of construction activities from commencement of foundation or driving piles to mechanical completion. The costs include construction project management, construction labor, and also equipment and supplies costs that are used to support construction operations and removed after commissioning. The CII defined construction direct and indirect costs for detail of typical cost elements in construction phase.
- The equipment cost is the total cost of major equipment. The major equipment is commonly used interchangeably with engineered equipment. It is generally defined as tagged/numbered process or mechanical equipment including drivers.

When using this cost-based approach, larger productivity values indicate better productivity performance because the costs indicate amount of construction works that have been done as output. For calculating cost-based productivity metrics, the following simple equation is applied.

\[
\text{Project Productivity Metric} = \frac{\text{Cost for construction activities}}{\text{Work-hours}}
\]

In addition to that, the ratio of construction phase cost to procurement cost is also considered as a high-level productivity metric. This metric indicates that how much construction cost is larger than procurement cost considering major equipment and large modularization. If major equipment or modularization is larger, the value of this metric would be smaller.

Based on these two approaches for measuring high-level project productivity, this study investigates the following five candidate as high-level project productivity measurement.

1. Project Level Construction Productivity
2. Total Constructed Cost/Total Site Work-hours
3. (Total Constructed Cost – Equipment Cost)/Total Site Work-hours
4. Construction Phase Cost/Total Site Work-hours
5. Construction Phase Cost/Procurement Cost

### 3.2 Data Sources and Collection

This paper uses the data extracted from CII Performance Assessment Database and COAA Major Project Benchmarking Database. The CII Performance Assessment has collected capital projects data into its database through the collaboration with more than 130 industrial partners including leading construction owners and contractors around world. As of 2014, CII Performance Assessment Database suppressed 2,300 projects in its database, exceeding over $300 Billion (USD) of cumulative capital project investment since 1995 (CII, 2014).

By 2014, 60 Alberta capital project data has been collected in the COAA Major Project Benchmarking system which mainly consisted of oil sands projects including oil sands SAGD, oil sands upgrading, oil sands mining/extraction, oil and gas exploration, pipeline, and so on. The project data were extracted in
the databases if the middle point of construction phase of the projects was 2001 and later conducted in United States and Alberta.

3.3 Analysis Methods

Once the high-level project productivity measurements are determined, this study calculates each project productivity metric and compares its mean between Alberta and U.S. projects. To compare the mean of high-level productivity metrics and their distributions between two regions. An independent sample t-test was applied to project productivity comparisons. The independent sample t-test is a parametric test and two-sample test. This analytic method tests if the means between two groups are same or not. Thus, this study applied the independent sample t-test to test if the mean value of project productivity between Alberta and U.S capital project during the given period at 0.05 significant level. If a p-value of the t-test is less than 0.05, the result indicates the mean value of two groups are significantly different. Using this statistical analysis, this paper presents comparing means of project productivity between Alberta and U.S. capital projects.

4 HIGH-LEVEL PROJECT PRODUCTIVITY BENCHMARKS

4.1 Quantity-based High-Level Project Productivity

As a quantity-based high-level project productivity, the project-level construction productivity developed by CII was applied to comparison of project productivity between Alberta and U.S. capital projects. The value of the project-level construction productivity metric indicates that smaller productivity value indicates better productivity performance. In this study, the zero (0) value indicates the mean of productivity values of capital projects built in North America region.

![CII Project Level Construction Productivity](Image)

Figure 3: Project-Level Construction Productivity Trends (2001-2011)

Figure 3 shows the comparison of the results of project-level construction productivity of Alberta and U.S. projects. The average of project level construction productivity in Alberta projects was 0.30 while that was -0.03 in U.S. projects. The 0.3 of the mean values of Alberta projects indicates 0.3 standard deviation above the mean of North America’s construction productivity. On the other hand, the average of U.S.
projects is -0.03 that indicates the average of construction productivity of U.S. projects is below the mean of North America’s productivity. As the results from the t-test, there was a significant difference in the project level construction productivity for Alberta projects (Mean=0.30, SD=0.69) and U.S. project (Mean=-0.03, SD=0.66) at the 0.05 significant level (p = 0.021). This result indicates that Alberta projects’ construction productivity was above the average of capital projects’ construction productivity in North America. Also, the average of Alberta projects’ construction productivity was statistically significantly worse than that of U.S. projects.

4.2 Cost-based High-Level Project Productivity

High-level project productivity values measured by cost-based metrics were compared between Alberta and U.S. projects as can be seen in Figure 4. The value of the productivity metric developed based on cost-based approach indicates that larger productivity value indicates better productivity performance. That is, the larger value indicates that more amount of construction works has been done during one hour.

![Image of box plots showing cost-based high-level project productivity](image)

Figure 4: Cost-based High-Level Project Productivity

- **Total Constructed Cost/Total Site Work-hours**: The project productivity metric “Total Constructed Cost/Total Site Work-hours” means that the sum of procurement and construction cost per one hour worked in a capital project. The mean value of the project productivity of Alberta projects was US $215.58 per hour while that of U.S. projects was US $221.98 per hour. Thus, the U.S. projects’ productivity was slightly better than that of Alberta projects but the t-test results shows that there was no significant difference between Alberta and U.S. projects (p-value=0.793).
• (Total Constructed Cost – Equipment Cost)/Total Site Work-hours: The project productivity metric “(Total Constructed Cost–Equipment Cost)/Total Site Work-hours” means that the total constructed cost excluding major equipment cost per one hour worked in a capital project. The mean value of the project productivity of Alberta projects was US $157.47 per hour while that of U.S. projects was US $157.21 per hour. Thus, the Alberta projects’ productivity was slightly better than that of U.S. projects but the t-test results shows that there was no significant difference between Alberta and U.S. projects (p-value=0.989).

• Construction Phase Cost/Total Site Work-hours: The project productivity metric “Construction Phase Cost/Total Site Work-hours” means that the amount of construction phase cost per one hour worked in a capital project. The mean value of the project productivity of Alberta projects was US $161.75 per hour while that of U.S. projects was US $174.28 per hour. Thus, the U.S. projects’ productivity was slightly better than that of Alberta projects but the t-test results shows that there was no significant different between Alberta and U.S. projects (p-value=0.526).

• Construction Phase Cost/Procurement Cost: The project productivity metric “Construction Phase Cost/Procurement Cost” means that the ratio of construction phase cost to procurement cost for a capital project. The mean value of the project productivity of Alberta projects was 2.99 while that of U.S. projects was US 2.94. The value of Alberta projects (2.99) means that the construction phase cost is about three times more than procurement cost. The larger metric value indicate that the project spent smaller amount of procurement cost including equipment cost compared to other projects. Alberta project procures engineered modules Thus, the Alberta projects’ productivity was slightly better than that of U.S. projects but the t-test results shows that there was no significant different between Alberta and U.S. projects (p-value=0.793).

5 CONCLUSIONS AND PATH FORWARD

This study contemplates a high-level project productivity metrics that can be used for achieving stable planning and engineering to provide the baseline estimates of planned performance. Five measurements for high-level project productivity were developed and investigated through comparison between Alberta and U.S. projects. These metrics can be used to fill the gap between country- and industry-level labor productivity calculated by government and activity- and discipline-level productivity. As the results from the t-test analysis of the productivity between Alberta and U.S. projects, Alberta projects’ project productivity tends to be lower than that of U.S. projects and can be more improved. The relatively lower productivity of Alberta’s capital projects, especially large oil and gas construction projects causes various factors such as the apparent management deficiency in management scope, time, quality, cost, productivity tools, scaffold, equipment, materials, and lack of leadership, and others (Jergeas, 2009).

For capturing high-level project productivity, the measurement requires to be easily understandable and accepted as a measure of macro-efficiency of construction execution, dis-aggregatable to figure out causes, and practical to tract and record. Based on these requirements against high-level project productivity metric, only project-level construction project productivity metric developed at CII can be dis-aggregatable. So, it can be used for the high-level productivity measurement for Alberta capital projects. However, the high level productivity measurement needs to more elaborated and improved for capturing impact of off-site costs and module costs that are very significant component of capital projects. Although the COAA-CII collective efforts lead about 60 Alberta’s projects in the COAA Large Major Benchmarking System, the number of the submitted projects is not enough to create time series trend over the time with statistical significance. Therefore, the more data collection of Alberta’s projects may be required to develop better productivity measurements.

Abstract: Assessing the quality of information in building information models (BIM) at the time of project handover is critical for owners. Lack of quality information in delivered BIMs can cause significant issues in using BIM for facility management purposes, potentially limiting or preventing their use in building operations. Our studies of numerous BIM projects and deliverables have found that most BIMs created for design and construction today contain significant quality issues including inaccurate, incomplete, or unnecessary information. To make these models useful for building operations requires significant adjustment to the models, which can be very time-consuming and costly. This paper describes different types of quality issues identified through numerous case studies of BIM projects and categorizes them according to different model perspectives (entity, model, and user level) and relevant facility management perspectives (assets, MEP systems, and spaces). We identify the different characteristics of each type of quality issue and then systematically analyze relevant literature in the AEC and computer science domains to put these issues in context. This analysis highlights the ambiguity in characterizing information quality issues in a BIM and demonstrates the need for a comprehensive and consistent formalization of BIM quality.

1 INTRODUCTION

Assessing the information quality (IQ) of building information models (BIM) for facility management (FM) purposes is a critical and challenging task for owners at the time of project handover. Lack of IQ in delivered BIM could have costly consequences for owners, including: manual adjustments to correct and complete the models; laser-scanning of (a part of) the building and related post processing efforts; and delays in the start of FM systems. Currently, researchers and owner organizations have different perspectives about the IQ of BIM, which consequently lead to different approaches to its assessment. Although organizations like U.S. General Services Administration (GSA) and British Standards Institution (BSI) have developed approaches to enforce BIM requirements throughout the project handover (BSI 2014, GSA 2011), such approaches are mainly based on generic checks and do not cover all required IQ characteristics for FM needs. For proper BIM-IQ assessment, it is necessary for owners to have a clear understanding about “what” are the potential quality issues, “which” IQ characteristics are relevant, and “how” to assess them.

The objective of this paper is to contribute to the development of a comprehensive and consistent representation of BIM quality for owners. Through numerous case studies of BIM projects and interviews with FM personnel, we describe different types of quality issues and categorize them according to
different model perspectives (entity, model, and user level) and relevant facility management perspectives (assets, MEP systems, and spaces) in section 2. In section 3, we identify the different characteristics of each type of quality issue and then systematically analyze relevant literature in the AEC and computer science domains. This analysis highlights the ambiguity in characterizing information quality issues in a BIM, demonstrating the need for a comprehensive and consistent formalization of BIM quality for owners.

2 BIM QUALITY ANALYSIS FRAMEWORK FOR FM

The motivation of this study has its roots in numerous case studies of BIM project deliverables and interviews with various FM personnel. In order to systematically analyze the different types of BIM quality issues, we developed an analysis framework considering different FM categories and model analysis perspectives (Table 1). Generally, FM information management systems (IMS) require information related to three essential terms: assets, MEP systems, and spaces. Although MEP systems may be considered a compilation of different assets, there are still differences between asset related and MEP system related IQ issues. Therefore, we divided the observed IQ issues accordingly in terms of assets, MEP systems, and spaces. Furthermore, the BIM-IQ issues can be categorized into different types from different analysis perspectives of model consumption. We determine these perspectives as: 1) entity level, which focuses on the smallest information pieces in a model; 2) model level, which considers the entire BIM as one information package; and 3) user level, which analyzes the information system from the model user’s perspective.

The analysis methodology below follows the structure of this framework. Specifically, we go through each issue type to analyze them systematically in correspondence with the related FM category. As the first step of the systematic analysis, we briefly describe each issue type by giving specific examples from a case study project. This description includes the IQ characteristics that are affected as well as their relevance for FM. In the next analysis step, we discuss the relevant literature for each type of quality issue. This includes the terms used by researchers to address these issues, the general topic that they discuss and their proposed approaches for preventing (IQ assurance) or identifying (IQ assessment) such issues. Finally, we evaluate these different perspectives and discuss the potential research gaps for each issue type.

3 TYPES OF QUALITY ISSUES AND RELEVANT LITERATURE

This section presents a systematic analysis of each type of BIM quality issue from the BIM-IQ analysis framework introduced above in Table 1. In this analysis, we start with the entity level perspective and discuss the issue types related to assets, MEP systems, and spaces, and then continue with the model and user level perspectives.
3.1 Information Incompleteness (Entity Level)

Incomplete Assets: Assessing the information completeness of assets means to check if all necessary equipment are represented in BIM. This step is related to the identification of available MEP systems in the building and their completeness assessment (Table 2). Therefore, it is necessary to identify which systems are in the models first and then check which major assets these systems must have. There are two reasons for considering only the major assets and not all of them in this assessment. First, when the available BIM is not representing the as-built situation, like in our case studies, then many assets and details are missing in the available model. As a result, the modeling of the entire missing assets will require a huge amount of effort. Second, an FM-IMS does not necessarily require detailed information for all assets. According to our interviews with FM experts, the fact is that it is not reasonable from a time and resource point of view to consider all single assets in such FM-IMS. Hence, as for information completeness, the models have to contain at least the major assets completely. For this purpose, it is necessary to check the existence of major assets, their quantity and their necessary attributes. For example, Table 2 shows a missing expansion tank in the MEP BIM of our case study project.

Table 1 shows that although different researchers discuss such IQ issues in different contexts (“General Discussion Topic”), most of them address this issue type as “information completeness.” However, only a few of them propose specific methods for assessment or assurance of this IQ characteristic. For instance, in (Becerik-Gerber et al. 2011), the authors propose a list of required information for FM that should be captured in BIM during design and construction. This generic list requires information for assets’ description (like type, serial number, criticality, and status), attributes (like weight, power, and energy consumption), manufacturer (like serial, model, and part numbers) as well as the location of the assets (like building, floor, and space). A more comprehensive list of assets can be found in OmniClass Table 21.
(2006). This list follows an object-oriented approach and so provides a hierarchy for each asset type that can have up to seven levels. The examples above and the similar references (GSA 2011, Kulusjärvi 2012, National Institute of Building Sciences 2007, SBCA 2013) show that the main focus of the AEC researchers regarding to the information completeness is on the IQ assurance by using one of the introduced methods above. However, significant issues remain in terms of how to deal with the incomplete models, how to incorporate such checklists and hierarchies and integrate them into the owner’s requirements and how to assess them in a given BIM.

**Incomplete MEP Systems:** It is necessary for FM-IMS to define MEP systems completely in the mechanical BIM (GSA 2011, Kulusjärvi 2012, SBCA 2013, USC 2012). However, our analysis of BIM projects demonstrates that MEP systems are frequently defined inaccurately and incompletely in the mechanical BIM as in our case study (Table 3). This type of IQ issue is very similar to the incompleteness of assets with the difference that in this case one should investigate the entire components of a system or a sub-system.

</tbody>
</table>

The information about systems is especially significant for intelligent troubleshooting processes where one does not exactly know which equipment is not working properly as well as for better understanding the consequences when an asset is broken. The completeness check for MEP systems should include the identification of assets without a specific system as well as systems that miss a major asset as a member (either the major asset is not modeled or it is not assigned to the system). As shown in Table 3, even though this IQ issue type and its consequences for the projects are not explicitly discussed in detail among AEC researchers yet, there are few (but important) references that propose IQ assurance approaches to avoid incompleteness in the MEP system definitions. Nevertheless, there is a research demand for evaluation of the assurance methods, and for the assessment of the required system attributes and the relevant system components (assets).

**Incomplete Spaces:** In addition to assets and systems, spaces play also a crucial role in an FM-IMS. The representation of spaces in a BIM can support FM personnel particularly for what-if analyses, decision-making sessions, and routing the service components (Akcamete et al. 2010, Becerik-Gerber et al. 2011, Nepal et al. 2012). However, incomplete space information makes such processes more difficult. Researchers treat incompleteness of spaces in BIMs as an obvious issue that should be addressed. Therefore, this issue type has not been discussed as a separate topic yet and its assessment is usually included together with other building entities as a part of general checks, as in (Kulusjärvi 2012, LACCD BIMS 2010, National Institute of Building Sciences 2007, SBCA 2013, USC 2012).
3.2 Value Inaccuracy (Entity Level)

**Inaccurate Values for Asset Attributes:** In a desired BIM for FM, it is significant that the major assets are defined accurately. That means that the modeled assets must have the required attributes with precise values, their type must be correct and they need to be represented in the model with the correct size. In addition, the asset names must be clear, meaningful and not redundant. Inaccuracies in the attribute values is a very common IQ issue that we also recognized in our observations (Table 4).

### Table 4: Inaccurate definition of modeled assets

### Example

[Image of example: Figure 3: Example of inaccurate information for heat pump #03]

---

Reviewing related literature shows that when AEC researchers discuss the quality of BIMs, they strongly connect it to the accuracy aspect of the IQ and mainly use this term to address IQ characteristics related to the modeled “values”. However, much of the reviewed literature either does not specifically describe their interpretation of this term in more detail, as in (Du et al. 2014, GSA 2011, Kasprzak et al., National Institute of Building Sciences 2007), or the literature describes it in different ways. For example, (Berard 2012) refers to accuracy through different terms like information “precision”, “unambiguity” and “level of detail.” Du et al. (2014) define information accuracy as the degree to which the BIM models precisely reflect the physical real world conditions of a project. (Kulusjärvi 2012) address the accuracy aspect of IQ through the term “correctness.” These examples highlight a certain degree of ambiguity among AEC researchers when they discuss the quality values in a model. In contrast to the AEC researchers, the CS researchers organize these aspects in a different way. For example, (Lee et al. 2002) assign all value-related IQ aspects to the “intrinsic” IQ category. This category covers aspects like correctness,
unambiguous, consistency, precision, reliability, etc. which match mostly with the different interpretations of accuracy in the AEC domain. Nevertheless, there is still a great potential for unambiguous analysis of each of these aspects. In addition, Table 4 shows that the researcher mainly focus on using checklist for accuracy assurance and assessment methods. However, using checklists is a very generic approach and leaves room for different interpretations.

**Inaccurate Values for System Definitions:** In contrast to the completeness of MEP systems, the accuracy of system definitions has not been discussed explicitly in the AEC literature yet. The main reason is that such systems can be considered as a composition of different assets (as system components) and so the value accuracy of asset’ attributes can result in a certain level of accuracy for the related system. Thus, the values of important system attributes can be calculated as summations of related asset attributes, as for system flow, total pressure, electricity voltage, medium type, etc. Therefore, most of the BIM authoring tools offer automated calculations for system attributes. Nevertheless, there are system attributes that describe specifically a system without a direct connection to the system components (Figure 5), like system names, types, classifications, and related documents (specs, sequence of operation, etc.). Thus, this IQ issue type has a high potential for further research to identify the consequences of inaccurate system information for FM-IMSs.

**Inaccurate Values for Space Definitions:** Unlike incompleteness of spaces (and similar to other value inaccuracy issues discussed above), AEC researchers put emphasis on IQ of space definitions. Figure 5(a) in Table 5 shows an example from our case study where the space definition in BIM is inaccurate and incomplete. Figure 5(b) shows how building operation personnel keeps track of changes in the space arrangement with the help of printed PDF floor plans. The space related inaccuracies in the architectural BIM include spaces with incorrect utilization as well as spaces with different names from the actual space names in the building. A similar space related issue is the compliance of the room names with a required nomenclature by the owner. Such compliance is also documented in (Kulusjärvi 2012, LACCD BIMS 2010, National Institute of Building Sciences 2007, SBCA 2013, USC 2012).

</table>
3.3 Spatial Inaccuracy (Entity Level)

This IQ issue category is about the inaccuracies in placing the entities in a three-dimensional environment as in BIM. This group of issue types is significant because the spatial placement of entities brings the architectural and mechanical information hierarchies together.

**Inaccurate Asset Placement:** For facility operations, it is very important to find the related spaces for different assets (Asen et al. 2012). Becerik-Gerber et al. (2011) and Cotts et al. (2009) suggest facility managers ensure that the trade mechanics are familiar with equipment location. This highlights the significance of trades’ personal experiences with a facility where an intelligent FM-IMS is not available. Hence, using BIM could be a suitable alternative approach through accurate placements of assets in spaces. This requires both the accurate space definition as well as accurate asset placement in the space according to a spatial hierarchy. This placement is not only about identifying in which space is an asset located but also it is about determining where exactly this asset is placed in the assigned space.

</table>

Finding assets’ exact location is challenging in projects without an as-built model, as in our case study. The reasons are first, mechanical and architectural models are usually separate models and need to be merged and adjusted, and second, it is challenging to assign assets correctly within a wall or ceiling to a space in an automated way. For instance, the height of a room begins from the top of the floor to bottom of the ceiling. Therefore, the challenge is to find the correct space for the assets within the floors’ slab. Figure 6 in Table 6 shows an example of assets within a second floor slab that belong either to the upper space (like diffusers) or to the space below (like light fixtures). Inaccuracy in asset placement in BIMs is a significant issue for creating FM-IMSs. Reviewing related literature shows that this IQ issue type is only marginally addressed in few publications and general expectation is that modelers assure the accuracy of asset-space relation by using a list of certain generic measures. However, a clear IQ assessment approach in this connection is missing.

**Inaccurate Spatial Allocation of MEP Systems:** The relationship between MEP systems and spaces must include both the actual location of system components (assets) in the building as well as the served spaces by each MEP system. This is also emphasized in (Asen et al. 2012) where they describe such relationships as “spatial” for physical relation between assets/systems and spaces, and as “logical” for non-physically related assets/systems and spaces. The spatial relationship between MEP systems and spaces can be considered as a summation of space assignments for individual system components (assets). Thus, through an accurate system definition and correct placement of assets in spaces, this kind of issues can be avoided. The logical relation corresponds to the identification of which space(s) are served through a system (Table 7). This is significant for systems with a central role in a building, which usually serve spaces (mechanical zones) other than the location of their major assets.

Identification of served spaces is very relevant for FM (East et al. 2013, GSA 2011, Teicholz 2013, USC 2012), since such significant systems usually require frequent maintenance and the buildings operators need to know which building parts are affected when a system needs to be maintained. Automated identification of served spaces for MEP systems is more complicated than the location finding challenge above. Our review of related literature in Table 7 reveals that in the discussion about spatial allocation of MEP systems, researchers have been focused so far on the quality assessment measures for BIM mainly using COBie spreadsheets.

### 3.4 Model Incompatibility (Model Level)

Model incompatibility is about the model compliance with BIM standards and is an important IQ issue type from the model level perspective (Table 8). This issue type is about whether or not the information within the model is compatible with specific data structures. In other words, this issue type corresponds to the way the information is organized in BIM and it is related to all FM categories (assets, MEP systems and spaces). This is an important IQ characteristic, since the compliance with a standardized data structure, such as IFC, can shape the modeling process, facilitate information exchange between different BIM authoring tools and as a result can increase the quality of collaboration in a project (Kulusjärvi 2012, LACCD BIMS 2010). In addition to IFC standards, some literature propose the use of BIM exchange standards (like COBie) as alternative benchmarks for model compatibility assessments. For instance, the authors in (East et al. 2013, Kasprzak et al., Teicholz 2013, USC 2012) suggest to perform compatibility checks with COBie standard worksheets as a quality control approach. Moreover, the authors in (USC 2012) propose the compatibility checks with EcoDomus as an alternative to COBie for IQ control purposes. Our literature review results that AEC researchers have comprehensively researched model compatibility with BIM standards (Table 8). However, they address it through very different terms. For example, the authors in (Kasprzak et al.) describe it as “Data & Process Standardization” and propose that the modeled information should be in compliance with specific standards, like the internal standards of the Office of Physical Plant (OPP) at the Pennsylvania State University. This approach is similar to the “Quality Control” checks that the authors in (Messner and Kreider 2013) demand as a part of owner requirements. (Schuette and Rotthowe 1998) address the validation of an information system as the “Language Adequacy” of the model. This emphasizes the importance of this IQ aspect, i.e., the information structure as the “grammar” for organizing data, for the researchers before the BIM era. An alternative approach to check the validation of model data structure is to analyze the warnings that specific BIM artifacts report as described in (Du et al. 2014, USC 2012). An extensive analysis about the warning messages in BIM artefacts is given in (Lee et al. 2015). They divide these warnings into three categories: annotation, information and geometry warnings. The interesting point about such researches is that they do not only propose approaches for assessing IQ issues but also provide analyses to identify the reason of those warnings, which makes this type of researches more valuable.

4 CONCLUSION

In this paper, we present a novel division of typical IQ issues in BIM for FM into six categories. The information incompleteness and the value inaccuracy have been the subject of many research works, especially in connection with real objects (like assets). Nevertheless, there is still a great research demand for studying different accuracy aspects like value precision and correctness. As for spatial inaccuracy issues, whereas spaces as location of assets have been subject of several studies, there is a demand for future research about the relation between assets/MEP systems and served spaces, which is an essential aspect from FM perspective. System related issues are issues in the semantic of a model. To prevent such issues, researchers propose different instructions and checklist. Nevertheless, an automated method for identification and correction of such issues is a potential subject for future works. IQ issues related to the model incompatibility and uncoordinated information are well-studied fields by AEC researchers. Therefore, it is necessary that the owners deploy these studies to create suitable BIM-IQ strategies and assure the quality of required information for operation phase in the early phases of the project. This research shows the need for further studies on BIM quality and for automated IQ assessment approaches especially at the time of project handover to owners.

AN AUTOMATED MODEL FOR SELECTING THE OPTIMUM MOBILE CRANE MODEL AND ON-SITE POSITION USING GENETIC ALGORITHMS

Tarek M. Zaki¹,², Osama Hosny¹ and Khaled Nassar¹
¹ The American University in Cairo, Egypt
² tarekzaki@aucegypt.edu

Abstract: Selecting both the optimum mobile crane model for a lift job and identifying collision-free position on site can result in productivity and safety improvements. Planning for lift operations is a task carried out by experienced lift engineers who examine each mobile crane’s lift-capacity specifications as provided by the cranes manufacturer to determine the most suitable mobile crane, configuration settings and a collision-free placing location. In this paper, an automated model was developed that follows a four-stepped algorithm process. First, is an algorithm that acquires the user defined lift requirements and calculates the required crane configuration settings using non-linear trigonometric equations. Second, is an algorithm that selects a crane model from the database of mobile crane models which mostly fits the calculated configuration in terms of crane safety and operation. Third, an algorithm that provides safety and clearance checks for the selected configuration. Finally, Genetic Algorithms are applied to optimize the process and to select the optimum crane model that has the safest configuration settings to use as well as its optimum placing location on site. The model was designed to generate a site layout plan as an output with a Cartesian coordinate system in order to assist the lift engineers in their planning for lift operations. The model was validated through its implementation on a working construction project in Cairo, Egypt. The outcomes highlighted the potential benefit of the model in assisting lift engineers in the planning of lift operations on construction sites and demonstrated its essential features.

1 INTRODUCTION

Heavy lifts planning require the selection of an appropriate type of crane that is capable of carrying, slewing and placing a load without endangering the safety of the crane and the ongoing site operations. In general, mobile cranes are more suitable for typical infrequent heavy lifts such as placing mechanical equipment on building roofs, steel structure erection, etc. The task of selecting a mobile cranes and developing engineered-lift-studies is a crucial part in any heavy lift operation planning. This is due to the fact that, selecting the appropriate mobile crane for a specific lift contributes to the overall project’s productivity; thus, minimizing schedule delays and cost overruns (Hanna 1994). In practice, heavy lifts planning is prepared by experienced lift engineers. Their task is to (1) determine the most adequate crane configuration settings that can safely carry the required load and (2) identify the most appropriate placing location on site that is collision-free with all the nearby structures. A typical mobile crane’s specification has a number of charts including: model geometry and dimensions, lift-capacity charts and boom length range charts. Lift engineers use these charts to determine the best configuration in terms of: operating radius, operating boom angle to ground and the boom length extension which correspond to the weight of the object required to be lifted. Unfortunately, heavy lifts planning is a manual human-based calculation.
which is prone to errors and requires some interpolation and guesswork between charts. Moreover, it does not guarantee the selection of the best mobile crane for the job and its most appropriate onsite location. However, the mobile crane selection and location problem is not new, previous studies have tackled this problem from different perspectives as will be discussed in the next section.

2 PREVIOUS STUDIES

2.1 Mobile Crane Selection

A number of studies have focused on automating the mobile crane selection process by developing models and algorithms that determine the best configuration settings required to safely lift a given load. Al-Hussein et al. (2001) developed a systematic approach algorithm for selecting mobile cranes and calculating the spatial clearances for their locations on construction sites. The work focused more on the development and processing of the algorithm for any type of mobile crane problem. The algorithm was coded with MS-Visual basic and supported by a previously developed crane database named “D-Crane” (Al-Hussein et al. 2000) which was designed to replace the lift-capacity charts for each crane model and rigging accessories. The working principle for the algorithm is that a crane data is retrieved from D-Crane and is processed to determine the near optimum selection of configuration settings which are showed on a user interface.

Moselhi et al. (2004) developed a system that integrates the previously developed algorithms (Al-Hussein et al. 2000 and 2001) with graphics engine to produce 3D animations that act as a simulation tool for a lift planning task. The system demonstrated its capabilities as it assisted crane operators in avoiding potential accidents and reduced the time and cost associated with planning the lift operation on site.

Later in 2005, Al-Hussein et al. developed another algorithm which was not restricted to predefined configurations of cranes’ manufacturers, the objective was to eliminate the guesswork required by practitioners in relation to the limited information pertained in the lift-capacity charts. The developed algorithm continued the work of the previously developed algorithm (Al-Hussein et al. 2001) and provided the optimum crane configuration for a required lift as a range of minimum and maximum values of boom length and radii settings. The algorithm was also developed with MS-Visual basic and the optimization module used MS-Solver. The output of the algorithm was displayed as a 2D-elevation for the range of crane settings.

Wu et al. (2010) developed an algorithm for selecting mobile cranes that considers the lift capacity, geometric characteristics of the crane and the ground bearing pressure which was one of (Al-Hussein et al. 2005) limitations. The algorithm was incorporated in a 3D environment to simulate the crane operation. The crane selection module only covered crawler crane types. The path planning was not considered in the 3D simulation. The proposed algorithm was applied on a working construction project which demonstrated the usability and accuracy of the developed algorithm.

2.2 Workspace planning for the onsite locations of mobile cranes

Most of the previous studies discussed above were mainly concerned with the development of algorithms that automate the selection of the optimum mobile crane configuration settings. However, the collision free-paths and a crane’s workspace considerations in relation to the site plan was not tackled enough.

Tantisevi and Akinci (2009) have modeled the dynamic behavior of mobile cranes during operation in order to identify the possible spatial conflicts. The developed model generated the motion of mobile cranes during construction given some inputs including: building design, schedule, crane load-capacity specifications and information regarding the crane operation. The output of the model generated a 4D simulation of mobile cranes on construction sites that identified the possible spatial conflicts and determined the set of conflict-free site locations where a crane can be placed.

Safouhi et al. (2011) developed an algorithm to determine the optimal location for mobile cranes onsite using a mobile crane’s body working area by defining inside and outside boundary limits as restriction
areas for a crane’s operation. The outside boundary limit was defined as the access areas around permanent structures, while the inside boundary limit was defined as the areas which pertain the crane’s operation due to obstructions such as laydown areas, construction trailers, foundations, etc. The intersection between the inner boundary limit and the outer boundary limit was defined as the feasible area for the crane’s operation. The model used a 2D construction layout plan where facilities and the mobile crane are presented as \((x,y)\) Cartesian coordinates. The algorithm was validated via a case study; the output generated all the feasible locations for a crane to be placed with the ability to rotate 360˚ without its body colliding with any onsite obstruction.

After reviewing the previous works, some findings could be drawn: (1) the previously developed crane selection algorithms used mathematical optimization techniques which adopt differential equations to determine the maximum and minimum values, (2) the mobile cranes’ databases were mostly developed while the original specification charts supplied with each mobile crane model were not considered, (3) the crane’s workspace planning required simulation in a 3D environment to determine the spatial conflicts with the surrounding obstructions.

The objectives of this paper are to develop an automated model that uses the original lift-capacity charts supplied with the mobile cranes, optimize the selection, location and configuration settings of the mobile crane using Genetic Algorithms (GA) while considering the current site mobilization plan.

## 3 METHODOLOGY

A model was developed that is composed of a three components: Inputs, Engine and Outputs as shown in Figure 1. The Inputs component is a site layout plan module which includes coordinates for the site boundaries, the permanent facilities, the temporary facilities and the object required to be lifted. The Engine component, which is the core of the model, is composed of three concurrently working modules: crane’s database, geometry calculator and safety/clearance checks. Each module has its own built-in calculating algorithm and all modules are linked together. GA was used to determine the optimum output from each of the three modules while satisfying a set of constraints. Finally, the Output component generates the most suitable crane to be used, its configuration and the best onsite operating location that is conflict-free. The output is presented on a site layout plan. The developed model was coded on MS-Excel 2010 and was designed with a user interface to facilitate the user inputs and the output reports. GA was used in this model due to the combinatorial nature of the problem in hand. Moreover, GA tend to find global optima in complex spaces compared to traditional mathematical optimization, as presented in the previously developed models that may get stuck in local optima (David 1991).

The working principle of the proposed model is that, at first the site mobilization data which includes the site boundaries, temporary facilities and object to be lifted is input to the model in the form of Cartesian coordinates. At the same time, the Crane Database module generates a crane with all its specifications as placing coordinates as an initial solution to the GA engine. Second, the Geometry Calculator module determines the boom length and working radius that correspond to the required weight to be lifted using a set of non-linear trigonometric equations. The calculated length and radius then flow back to the selected crane’s lift-capacity charts following a search algorithm to select a built-in configuration of boom length, working radius and maximum weight for this setting. The selected configuration then passes to the Safety & Clearance Checks module where a checks algorithm determines any flaws with the selected configuration. If any of the check tests fail, the crane database module selects another crane model and new coordinate points to be the new initial solution for the model and starts over again. If the configuration passes all the check tests, an output report is generated which includes the selected crane model, its configuration, its placing location on site considering the previously input mobilization plan.

### 3.1 Module 1: Site Layout Plan

The site layout plan was modeled in 3-D space where all the facilities, the mobile crane and the object to be lifted were represented in the form of blocks, each defined by nine Cartesian \((x,y,z)\) coordinates as shown in Figure 2.
The site layout was considered to be static, which meant that all facilities were considered to be stationary and occupied spaces. In other words, each facility occupied 9 unique coordinate points in the 3-D space. Hence, the unoccupied grid points represent the domain of all possible coordinates where a mobile crane could be placed. To overcome the limitations of MS-Excel 3-D plots, the model was plotted on three 2-D plots that are interconnected and represent elevations for a 3-D site problem; namely: the (x-y) plan view, the east (y-z) view and the south (x-z) view as shown in Figure 3.

Each block on the plots was defined by its initial coordinates \((x_1, y_1, z_1)\) and its length, width and height. The remaining coordinate points were calculated based on the defined dimensions and the initial coordinates. For example, if L=3m, W=2m, H=3m and the initial coordinates were \((4,3,0)\) then the remaining coordinates shall be \((7,3,0), (7,5,0), (4,5,0), (7,3,3)\), etc.

The mobile crane was also defined as a block with 9 coordinates and with any initial position of \((x_1, y_1, 0)\). The boom was defined as straight line with a start and an end point. The start point was set to be \((x_p, y_p, H_c)\), where \((x_p, y_p)\) are the coordinate points for the crane's pivot and \(H_c\) is the height of the selected crane model from the database. The end point coordinates were set to be \((x_{wc}, y_{wc}, z)\), where \((x_{wc}, y_{wc})\) are the centroidal coordinates of the weight to be lifted.
Figure 3: Representation for the 3-D site problem in the form of three elevations

3.2 Module 2: Crane Database

A database for 10 mobile cranes models with different capacities and from different crane manufacturers such as DEMAG, LIEBHERR, etc, was built as an add-in MS-Excel workbook to the model. For each model a number of specifications were used including lift-capacity charts, crane dimensions, range charts and the crane model’s maximum parameters. Each crane model in the database was coded with a Search Routine Algorithm which acquires the calculated boom length, working radius, lift angle and the total weight to be lifted (which is equal to the rigging accessories weight and the lift weight) from “Module 3: Mobile Crane Settings Calculator” and searches for the best configuration from the lift-capacity charts. For example, assuming that the calculated boom length was 36m, the radius was 21m and the total weight was 12t; the algorithm searches the different databases to determine the best configuration, thus the result could be use Crane#1 named DEMAG AC (120) and selects the configuration that has a boom length = 36m and a radius = 22m where the maximum load for this setting is 13.5 as shown in Figure 4. The determined configuration is then used in both “Module 1: Site Layout Plan” and “Module 4: Clearance Checks”. In the event that the determined crane fails the clearance checks, the algorithm searches again for a different crane with a different configuration.

3.3 Module 3: Mobile Crane Settings Calculator

This module is the engine of the model where all the calculations are made. The algorithm used in this module was the Genetic Algorithms (GA) using Palisade (2009) Evolver™ v5.5 add-in for MS-Excel. Its function was to provide the optimum configuration settings in terms of: (1) the operating radius (R) which is defined as the distance between the centroid of the lift and the center of rotation of the crane, (2) the boom length (L) which is defined as the distance from the crane’s pivot to the centroid of the weight and (3) the lift angle (θ) which is defined to be the boom-to-ground operating angle. The determined configuration settings was then converted to coordinates and presented in “Module 1: Site Layout plan”. Demonstrations of the used variables in the model were represented on a mobile crane schematic diagram as shown in Figure 5.
Both the R and the L can be calculated based on Pythagoras theorem as shown in Equations 1 and 2. The total weight to be carried is the weight of the rigging accessories and the weight of the lift as shown in Equation 3.

[1] \( R = \text{sqrt} \left( (x_{(\text{crane})} - x_{(\text{weight})})^2 + (y_{(\text{crane})} - y_{(\text{weight})})^2 \right) \)

[2] \( L = \frac{(R + P2C)}{\text{Cos} \ \Theta} \)

[3] \( W_{\text{total}} = W_o + W_{\text{rig}} \)

It should be noted that the relation between the \( \Theta \) and the \( L \) and \( R \) are inversely proportional. Thus, \( \Theta \) is considered to be a variable in the model and has a minimum and maximum range as defined in the specifications of the selected mobile crane. Moreover, \( R \) is dependent on the crane initial coordinates and the crane operating orientation which is either over-side or over-front/rear.
The chromosome structure for the GA engine is composed of five genes (variables) as shown in Figure 6; namely: the lift angle (Θ), the initial crane coordinates (x1, y1, 0), the orientation (defined as 1=over-side and 2=over-front/rear) and the crane model number (C#) (number from 1 to 10) as imported from "Module 2: Cranes Database”.

\[
\begin{array}{cccc}
\Theta & x1 & y1 & Ort.
\end{array}
\begin{array}{c}
\text{C#}
\end{array}
\]

Figure 6: GA chromosome structure

Manufacturers recommend practitioners to base their calculations on the shorter working radii as much as possible whereas the outriggers have to be fully extended, since such setting provides stability during operation and reduces the chances of crane overturning.

Therefore, the model’s objective function was to obtain the minimum R that satisfies a set of constraints (Equations 6 to 8), where:

[6] \( R_{\text{min}} \leq R \leq R_{\text{max}} \), where \( R_{\text{min}} \) and \( R_{\text{max}} \) are defined in the lift-capacity chart of the crane selected

[7] \( L_{\text{min}} \leq L \leq L_{\text{max}} \), where \( L_{\text{min}} \) and \( L_{\text{max}} \) are defined in the lift-capacity chart of the crane selected

[8] \( \Theta_{\text{min}} \leq \Theta \leq \Theta_{\text{max}} \), where \( \Theta_{\text{min}} \) and \( \Theta_{\text{max}} \) are defined in the working range chart of the crane selected

3.4 Module 4: Clearance Checks

In addition to the above mentioned constraints, a number of clearance checks were also required to be satisfied for each selected crane; which include:

3.4.1 Carrying capacity check

The selected configuration settings from Module 2 that corresponds to the calculated L and R from module 3 have to satisfy the weight requirements including the object weight and the rigging weight as shown in Equation 9:

[9] \( W_{\text{configuration}} \geq W_{\text{lift+rig}} \)

3.4.2 Crane location is within the site

The calculated crane coordinates have to be within the defined site boundaries. Therefore, the outermost point for the site boundaries \((x_{3[\text{site}]}, y_{3[\text{site}]}, 0)\) has to be bigger that the calculated outermost point for the mobile crane \((x_{3[\text{crane}]}, y_{3[\text{crane}]}, 0)\) as per Equations 10 and 11.

[10] \( x_{3[\text{site}]} > x_{3[\text{crane}]} \)

[11] \( y_{3[\text{site}]} > y_{3[\text{crane}]} \)

3.4.3 Overlap between facilities

There has to be no overlap between the placing position of the mobile crane and the surrounding temporary or permanent facilities, which mean the unoccupied coordinates on the grid can only be assigned to the mobile crane. Also, the crane has to be positioned to have enough clearance spaces between its body and the facilities edge. Therefore, the minimum distance between the mobile crane and any facility can be calculated as the distance between their centroid coordinates, where:

[12] \( d = \sqrt{(x_{C[\text{crane}]} - x_{C[\text{facility}]��})^2 + (y_{C[\text{crane}]} - y_{C[\text{facility}]��})^2} \)

[13] \( \text{min} \; b_{\text{crane}}/2 + \text{min} \; b_{\text{facility}}/2 + 2” > d \)
Where “2**” in Equation 13 is an extra 1 meter allowance from each side of a facility and the crane as a common practice recommendation.

### 3.4.4 Boom to building collision

The operating angle should be sufficient enough to avoid any collisions with the building when planning a lift; therefore, this can be depicted using Equation 14 which requires that the clearance should be bigger than the maximum of either the centroid coordinates location of the weight to the edge of the building. In common practice, usually the minimum clearance is 1 meter from any of the building edges.

\[
\frac{Hr + Hw}{\tan \theta} > \max (\text{Abs}(x_{2(building)} - x_{C(weight)}) \text{ OR } \text{Abs}(y_{2(building)} - y_{C(weight)}))
\]

### 3.4.5 Weight to building intersection

The hook of the crane in the rigging element cannot intersect with the building as shown in Equation 15.

\[
L \sin \theta \geq (Hb - P2G) + Hr + Hw
\]

### 3.4.6 Boom to Weight Clearance

The rigging height has to be tall enough to avoid boom collision with the weight as shown in Equation 16.

\[
\frac{Hr}{\tan \theta} \geq b_{(weight)}/2
\]

### 4 CASE STUDY

The case considered herewith involved the placement of an Air Handling Unit (AHU) on top of an office building project located in Cairo, Egypt. The building was a 6-story high; the mobilization plan for the site was obtained from the Contractor and was input to the developed model. The site mobilization plan was composed of a number of facilities; including: Employer/Engineer’s offices, Contractor’s offices, storage/laydown areas, carpentry workshop and steel workshop. The Contractor’s fleet of owned mobile cranes were also considered and included a number of 4 all-terrain telescopic boom mobile cranes of different capacities. The site layout data was input through the model interface which is divided into 3 sections as shown in Figure 7. The first section is about the permanent facilities which require the user to define site boundaries (length and width), the dimensions and coordinates of the buildings being constructed. The model allows for three buildings to be placed in the layout; however, this case only uses one building; thus, the other input spaces were not used and are shown to be dimmed on the model interface. The second section is about the temporary facilities. The model allows the user to enter 6 temporary facilities; however, in this case only 5 were used. The last section is about the object to be lifted where the user is required to define the object’s dimension, coordinates and the weight in tons, which in this case is the AHU. The objective function was originally set to minimize the radius while satisfying the set of constraints as defined in the model engine. The GA initial solutions’ pool was set to be 100 solutions, the stopping time was set to 15 minutes, the crossover rate was set to 95% and the mutation rate was set to 5%. The model was required to run a number of times to validate its outputs.

### 5 RESULTS

Evolver™ was left to complete its 15 minutes run time, even though the solutions showed to have stopped converging after 10 minutes as shown in Figure 8. The algorithm selected crane model “DEMAG AC (665) 250t” to be used with the configuration of L= 53.6m that corresponds to R= 34m, θ=55.5°, the placing coordinates (43.4,4.6), the outriggers to be fully extended, the counter weight= 100t and the operating zones to be 360°. The outputs were presented in the form plan view, east elevation and south elevation, whereas the calculate parameters were represented on the mobile crane schematic diagram as shown in Figure 9. By further running the model extra number of times, it was concluded that for this optimum configuration, other two optimum placing coordinates could be used, which are: (75.3,27.8) or (60.4,7). By these results, the Contractor had the flexibility to select the onsite placing location for the
mobile crane from these 3 optimum locations (coordinates) in order to minimize any disruptions to the ongoing construction activities that may arise due to the mobile crane’s placing position and operation.

6 LIMITATIONS AND FUTURE IMPROVEMENTS

Although the proposed model demonstrated practicality, yet it had some limitations including: (1) the site layout module was designed to include only 6 temporary facilities and 3 permanent facilities. However, such limitation can be adjusted from the model engine itself, (2) the mobile crane database only considered the telescopic boom cranes without the allowance of an additional jib attachment, and (3) the mobile crane was considered to be a block diagram and the boom a straight line, more detailed variables may need to be included in the model calculations such as the soil bearing pressure, the wind load, etc.

7 CONCLUSION

The task of selecting a mobile cranes and developing engineered-lift-studies is a crucial part in any heavy lift operation planning. In practice, experienced lift engineers develop such studies manually and interpolate between the specifications charts to select the mobile crane to uses while estimating the corresponding onsite position. A model was developed to automate this process and provide the optimum crane selection and onsite position. The model was coded on MS-Excel and ran with GA using Evolver® add-in for excel. A case study for an ongoing construction project in Cairo, Egypt was presented to demonstrate the use of the developed model and illustrate its features. The outcomes demonstrated the
practicality of the model in selecting the optimum mobile crane from a predefined list of a contractor’s fleet of mobile cranes and determined the optimum configuration settings as well as a number of optimum onsite locations. The optimum configurations were exported in the form of a site layout plan.

QR-CODED CLASH-FREE DRAWINGS: AN INTEGRATED SYSTEM OF BIM AND AUGMENTED REALITY TO IMPROVE CONSTRUCTION PROJECT VISUALIZATION

Tarek M. Zaki\(^1,2\) and Cherif A. Khalil\(^1\)

\(^1\) The American University in Cairo, Egypt
\(^2\) tarekzaki@aucegypt.edu

Abstract: Design coordination problems are considered as one of the causes of driving project delays. The current normal practice in the Egyptian construction industry is highly dependent on using the traditional 2D CAD software to design and issue construction drawings. The main problem with 2D drawings is that they fail to properly visualize the design intent of the project, hence consuming project time in resolving design coordination problems and in some cases may lead to abortive works. Therefore, this research proposes a workflow that integrates both Building Information Modeling (BIM) and Augmented Reality (AR) using commercially available software to address these problems. The proposed workflow integrates the use of BIM in the design process to produce fully coordinated clash-free 3D models. Later, each exported 2D drawing from this model is imprinted with a unique Quick Response Code (QR-Code). An application reads the QR code using a smart device’s camera and then the clash-free model is displayed on its screen. Users can transform, manipulate or use section planes to easily visualize the design intent behind the produced drawings. A case study was conducted on a project originally designed using a BIM platform to test the applicability of the proposed workflow. Results demonstrated the potential features of integrating a system of BIM and AR to improve the visualization of the design intent after the production of 2D clash-free drawings and improve the design coordination/communication problems.

1 INTRODUCTION

Visual simulation has emerged from the field of computer science, providing planning and analysis tools for the engineering processes by creating dynamic virtual scenes; hence, providing environments where experimentation can be done without the committing real resources or endangering the operational safety. BIM represents the development and use of computer-generated n-dimensional models to simulate the planning, design, construction and operation of a building (Azhar et al. 2008), while AR is the superimposition of computer-generated images over a user’s interface of the real world. In other words, AR allows users to explore and navigate the real world with the virtual objects or models superimposed/blended inside the real view (Behzadan and Kamat 2006). The applications of BIM and AR promise a breakthrough in the way projects are designed, constructed and operated. Even though this technology has been around for some time, developing countries like Egypt are still not familiar with their powerful capabilities. The current on-going practice in the Egyptian construction industry uses 2D-CAD software to generate design and construction drawings. Unfortunately, a few numbers of firms deploy the use of BIM software in their early design stages and use very limited features. BIM is currently used only to (1) design the basic building form as a whole then layout views are generated on 2D-CAD drawings for
each building trade and (2) to export the 3D models to other software specialized in rendering for client presentations. On the other hand, the concept of AR is new and its applications are unexplored and even unknown to many Egyptian construction professionals.

Design coordination and visualization problems are considered to be of the major issues that negatively affect construction projects. Design problems generate seeds for variations and design changes which delay the progress of the works and in some cases may lead to abortive works. Although the design and construction teams do their best endeavors to produce coordinated drawings, failure to coordinate between the different parties and visualize the building components off the 2D CAD drawings remains a problem that needs to be tackled.

2 PREVIOUS STUDIES

BIM has been around for over two decades; however, it only started to become very popular by the beginning of this century as it showed serious potentials in developing and revolutionizing the design and construction processes in the Architecture, Engineering and Construction (AEC) industry. Previous studies have investigated how the use of BIM tools affect projects in all its stages.

Haymaker and Fischer (2001) reported statistics based on 32 major projects where BIM was adopted and the results show that the cost estimation accuracy increased by 3%, up to 7% reduction in the project time and up to 40% elimination of unbudgeted change. Later, a survey was conducted by Azhar et al. (2008) to track the productivity gain by the use of BIM in construction projects. Results showed that the productivity gain ranged from 20% to 30% more, in addition to reduction in Request for Information (RFI) and change orders by a factor of 10% or more.

Another survey was conducted by Becerik-Geber and Rice (2010) for the uses of BIM in the construction industry. The results of their survey concluded that the current top uses of BIM are visualization, clash detection and as-built models. BIM could also facilitate resolving coordination problems using clash detection engines. The 3D coordination process could start right after the model is created in order to detect geometric interferences and clearance interference.

Wu and Chiu (2010) proposed a workspace conflict detection and analysis system using Bentley Microstation software. They created a plugin extension to identify design, damage, safety and congestion conflicts on site. However, Gaungbin et al. (2011) conducted an experiment on 3 software: Autodesk Navisworks, Bentley Interference Manager and Solibri Model checker. The experiment concluded that Autodesk Navisworks’s clash detection module was the best among the rest of software.

Conclusions could be drawn from previous studies that adopting BIM throughout a project’s lifecycle has improved the ways projects were designed and constructed.

Concerning the use of AR in construction, few studies were conducted on the integration of BIM with AR in building design and construction. Wang and Dunston (2006) used AR as an assistant viewer for standard CAD drawings in order to perform a conflict detection tasks. They investigated the time and cost benefits realized when using AR vs using a standard approach (CAD) to solve the conflict in the drawings.

Shin and Dunston (2011) used AR to perform construction inspection tasks, more specifically inspecting a steel column using AR and compare it to the conventional inspection techniques. They developed an AR system composed of a backpack processor that includes a GPS and a helmet with built-in glasses that transposes the model on the glasses screen. The results of the experiment they conducted showed that the device they used to perform inspection satisfied standard tolerance and required faster and simpler setup, hence it was considered promising inspection tool.

Zollmann et al. (2014) discussed in details the technicalities behind transposing a 3D system in the physical environment, which permits monitoring and documenting the onsite construction project progress.
Gheisari et al. (2014) explored the use of BIM and AR for facilities management. The research highlighted the benefits realized to the facility management professionals when using BIM, and indicated that its integration with a handheld mobile augmented reality device (MAR), enhances the current practices for facility management.

After reviewing some of the previous studies conclusions can be drawn that: (1) BIM has proven to improve the ways projects are designed and constructed, (2) implementing AR required the use of electronic devices or tools in order to develop the required system and (3) the integration of BIM and AR in resolving design coordination issues was not tackled thoroughly in literature. Moreover, given the fact that construction projects in Egypt face delays and cost overruns mainly due to design and construction miscoordination, the objective of this paper is to introduce the Egyptian market to an approach considering the use of a BIM and AR in solving coordination problems since the early design stages. The proposed approach provides a simple and cost efficient visualization approach for the project team to tackle the design/shopdrawings complexity and hence increasing the productivity of the project team.

3 THE METHODOLOGY

In order to identify the major problems that negatively impact the progress of any construction project, a number of 40 expert interviews were conducted with industry professionals with experiences ranging from 10 to 20 years in the construction industry profession (including project managers, construction managers, design managers, design team leaders from different trades and site superintendents). The interviewees were required to identify the major problems that negatively affect construction projects. The results generated a number of identified problems which were sorted, grouped, compiled and presented as a percentage scale. For example, the “design complexity” problem (complex building geometries, sophisticated mechanical and electrical systems, etc.) was identified by 34 interviewer which resulted in 34/40 = 85%. All the interview results are presented in the form of a bar chart to give a visual presentation as shown in Figure 1.

![Figure 1: Compiled expert interviews results](image)

The interview results revealed that the design coordination is major a problem that negatively affect the progress of the construction project. This is due to the fact that, coordination between the different trades requires extensive engineering works, which delays the related construction work progress. The design complexity came in second place with a score of 85%. Some experts highlighted that complex designs are difficult to be visualized using the current 2D CAD drawings being used, which results in constructability problems. The communication problems came in third place with a score of 83%.

The results from the expert interviews were used to formulate a workflow that facilitates design management and resolves the coordination problems from the early project stages.
3.1 Proposed Workflow

A workflow approach was developed to demonstrate the systematic procedures that should be followed to assist in solving the design coordination problems and to produce AR-ready design drawings as shown in Figure 2. The developed workflow requires users to use any BIM software equipped with a clash detection module to resolve the coordination problems, as well as any AR software that can generate and read QR/Bar codes.

![Workflow Diagram]

Figure 2: Proposed Workflow
3.1.1 Clashes Identification and Reporting

The process starts by generating a multi-model by amending all the design trades’ models (Architecture, Structure, MEP and Civil). Then, the Design Manager or the BIM coordinator (the reviewer) starts reviewing the model and plans the interference tests. The Clash detective helps in identifying, inspecting and reporting interference clashes between the different design trades in a compiled 3D model. The main objective of clashes detection compared to the traditional design coordination practice is to eliminate the tedious and error-prone manual design review of multiple 2D drawings while reading all of the dispersed information to end up with a complete coordinated model. Typically, clash detection is an iterative process and is dependent on the reviewer’s experience in observing the clashes; thus, a batch of tests needs to be conducted in order to make sure that the model is clash free, such process could take days to complete or even months depending on the project complexity and the number of design trades involved.

After running the required tests, the clash results are generated and the reviewer could generate a clash report based on these results. Clash reports are very handy as they can define clashes in the model by their number, status, type, date found, clash point (coordinates of the clash in the model (x,y,z), item 1 ID and type, item 2 ID and type and the name of the test. The reviewer could then send this clash report by mail to the design team leader in order to fix the clashes in the report. Once the design leader and his team are done fixing the clashes, the reviewer refreshes the model on and checks if there are more clashes occurring. Clash testing runs until all clashes are resolved i.e. the model is almost clash free.

3.1.2 Model Walkthrough

Another step that should follow the clash detection process is the model walkthrough. A model walkthrough can be performed by generating a third-person avatar to walk inside the coordinated model. The main function of the model walkthrough after concluding the clash detection test is to spot the design errors or any further coordination problems by the reviewer’s visual inspection that the clash detection test fails to spot and require the reviewers’ visual inspection to be detected; hence, model walkthrough can be considered as complementary to the clashes identification process.

3.1.3 Imprinting Drawings with QR-Codes

The final step is to implement the AR part by creating unique QR-Codes and markers that resembles each drawing or sheet produced. Each marker should have a unique model attached to it. The purpose of the marker is to enable the end user to superimpose the design intent off the basic 2D drawing. In order to do that, for each construction drawing a QR-code is added; which when detected by a camera (smartphone/tablet camera) superimposes the 3D AR view off the drawing. The proposed position for each QR-Code is to be located within the drawing’s title block or below each drawing in its canvas. It is important to note that the superimposed model can also be a 4D model or a video that illustrates to the users how to construct or assemble the model in consideration. The superimposed AR model could be viewed from each drawing either using a smartphone or a tablet with AR-ready software that reads QR codes.

4 CASE STUDY

A case study was used to test the applicability of the proposed workflow. Three commercially available software were used; (1) Autodesk™ Revit™ 2013 was used to design the BIM, (2) Autodesk™ Navisworks™ Manage™ 2013 was used to review and resolve the design coordination problems and (3) AR-Media™ for Apple™ iPad™ was used for generating the unique QR-Codes and superimpose the models on the screen. The reason for selecting Autodesk products is due to their popularity in the Egyptian market, even though their full capabilities are not taken advantage of by most firms or professionals.

The case study was on an administrative building in a hospital project designed originally designed with Autodesk™ Revit™. The Administration building is a single story building that serves the hospital. The building is composed of administration offices, clerk cubicles space, large storage hall, a dining lounge,
kitchenette and mechanical room and a number of toilets. The building’s exterior is cased with concrete precast panels and lined with gypsum wall cladding from the inside; the partitioning is mainly insulated gypsum board along with some glass storefronts. The perspective view and the ground floor plan for the building are shown in Figure 3.

Figure 3: (Left) building perspective view, (Right) ground level layout

First each design discipline team leader exported their Revit models to the Navisworks™ file format and forwarded them to the reviewer (hereafter called the Design Manager [DM]) who compiled and generated a multi-model as shown in Figure 4. The different design disciplines that were used in this case study were: Architecture, Structure, Electrical, Plumbing, Firefighting and HVAC, which means that 6 BIMs were amended in one multi-model.

Figure 4: The multi-model on the Navisworks™ software interface

Second, the DM executed the clash detection module and specified the batch of tests that were required to be performed. Three clash tests were used in this case which were: (1) Arch vs HVAC, (2) Arch vs
Plumbing and (3) Arch vs Firefighting. The generated results showed that there were 18, 39 and 18 clashes respectively in each of the three defined tests. Selecting the clash number from the clash detection module determines its location and the two elements intersecting as shown in Figure 5. For example, in Clash [7] the DM found that the HVAC pipes were intersecting one of the storefront glass panels inside the model. The DM assigned this clash to the HVAC Piping Team leader with a comment saying “review the placing level of the pipes”.

Figure 5: An output from Arch vs HVAC test showing clash [7] for example where a HVAC pipe and a glass panel intersect

Next, all the resulted clashes from all tests were exported in the form of a clash report. In general, the DM can define all the required fields that are necessary to be shown in the report. In this case, the DM chose the following fields: a picture of the clash, a location of the clash (model coordinates), the clashing elements and the person assigned to resolve the clash as shown in the Figure 6.

Figure 6 - A sample clash report including comments to the assigned person to fix the clash

Since this building was considered to be not that complex and small in size, each of the design discipline trades were given 3 days as a review time to fix their clashes. The DM refreshed model after such review period and re-ran the tests again to review the pending, approved or newly identified clashes.

After almost resolving 95% of the clashes in the multi-model, the DM generated a third-person avatar and performed a walkthrough inside the model. After some time walking with the avatar inside the model and visually inspecting the all the model elements some problems were spotted. For example, it was noticed
that the dimensions of the men’s toilet door were incorrect (1.13 x 0.49m) as shown in Figure 7. Using the review and measurement tools, the problem was redlined and a snap shot was taken and sent to the Architecture design leader who was notified with the problem and was required to check if such door type was misplaced or the type itself was not correctly defined in the model. Other detected items included: misplaced lighting fixtures, some storefront doors were missing, floor finish was missed in toilets, etc.

![Figure 7: Redline on an error in the model when walkthrough was performed](image)

Once the model was clash free and all the files were coordinated with no/minimal problems, the DM notified all the design leaders from each discipline that their models were fully coordinated so that they could start generating the 2D drawings from the BIMs and the QR codes for each design drawing. The QR-Code’s position was proposed to be set within each of the produced 2D drawing’s title block as shown in Figure 8.

![Figure 8 - The proposed location of the QR code for the generated 2D drawing from the BIM](image)

Later during a constructability review session with the attendance of the project’s construction manager and each of the design team leaders, the 2D drawing for the building plan was selected to be used as a test for the system. The AR-Media™ application on iPad was launched, and when pointing the iPad’s camera towards the QR-code, the software automatically read the QR code and the respective model was superimposed on the iPad’s screen as shown in Figure 9. The team reviewed the superimposed model on the iPad’s screen, and implemented some of the manipulation features such as translation, rotation and scaling, cross sectioning, layers management and shadow testing to assess the design and the details for each assembly in the model.
5 RESULTS

The application of the proposed approach has demonstrated its effectiveness in design coordination and visualization in many ways. First for the design team, it assisted in resolving most of the design conflicts by testing the hard and soft interferences of the model elements from different trades using the clash detection module. The conflicts were easily communicated to each reviewer via the clash reports. The avatar walkthrough has also assisted in identifying some design problems that were difficult to be detected using the clash detection module; such as errors in the dimensions of the men’s toilet doors, the storefront partition for one of the spaces being misplaced in a wrong level, etc.). Although the time spent in resolving the coordination issues was longer compared to the traditional method, the proposed workflow has proven to be much more systematic and efficient. Having a fully coordinated model has facilitated the production of the shopdrawings from the model with minimal requirement for the extensive engineering works that are usually performed in the traditional design coordination process. Thus, applying clash detection from the early design stages helped in minimizing the design errors which usually propagate to changes in the drawings and could generate seeds for variations and claims during the construction phase of the project.

Second, the application of the AR has also improved the visualization of the design intent for the whole team. For instance, during the constructability session the construction manager identified some issues in the fixation details of the exterior precast wall casing. These issues were easily communicated to the design team leaders to propose other alternatives and to further elaborate on the design requirements. Clients easily communicated their requirements within the session which was made very clear to the project team. Thus, the application of AR has proven its effectiveness in visualizing the project intent from the 2D drawings and improved the communication between all the team members.

6 CONCLUSION

Design coordination problems are considered as one of the major causes driving project delays. The current normal practice in the Egyptian construction industry is dependent on using the traditional 2D CAD drawings that fail to visualize the design intent, hence consuming project time in resolving design coordination problems. The integration of BIM and AR technologies reveal promising results in tackling the design coordination and visualization problem. In this paper a systematic workflow was proposed that
integrates the use of BIM in the design process to produce fully coordinated clashes-free models and imprinted the generated 2D drawings with QR-Codes. A case study was conducted on a project originally designed using a BIM platform to test the applicability of the proposed workflow. The proposed workflow has shown a number of outcomes. Contractors could generate automatic shopdrawings from the BIM software used and therefore, minimize the number of technical personnel deployed to produce the shopdrawings on site (compared to the traditional approach when using CAD drawings) which shall help in minimizing the direct and indirect costs on the project. Similarly, the Engineer could minimize deploying technical personnel to review the shopdrawings and therefore, minimizing direct and overhead costs.

Applying AR to superimpose the 3D model of the construction drawing at hand provided an innovative approach for implementing AR in construction without being involved in complex coding or buying expensive software. Using a commercially available software makes the process much easier. The application of AR with the drawings helped to better understand the design intent behind the drawing. Consequently, the project team effectively communicated the design. To conclude, the proposed approach provides a simple and a cost efficient method for improved project visualization for the project’s team to tackle the design/shopdrawings complexity and hence increases the productivity of the project team.

ENERGY LOSS MODELING OF WATER MAIN BREAKS: A HYBRID
SYSTEM DYNAMICS-AGENT BASED MODELING APPROACH

Hamed Zamenian1,2, Dulcy M. Abraham1, and Kasey Faust1
1 Purdue University, Indiana, U.S.A.
2 hzamenia@purdue.edu

Abstract: According to the United States Government Accountability Office Energy-Water Nexus Report, the water pipeline infrastructure system is nearing the end of its service life. Up to 50 percent of water is lost, as evidenced by the 240,000 water main breaks that occur each year, estimated by the American Society of Civil Engineers (ASCE). Water loss in the distribution system leads to additional expenditures for extracting water from natural resources, treatment, pumping, and transporting water into the distribution pipeline network system. Minimizing water losses has the potential to curb the increase in operating costs throughout the distribution system. This paper describes a conceptual System of Systems (SoS) framework for estimating the energy footprint resulting from water main breaks that considers the full cycle of providing drinking water to customers. The paper focuses on the interactions between the water loss in the distribution system and the energy-intensive operational components of the water infrastructure. This paper contributes to the body of knowledge and practice by developing a methodology to quantify the impact of water main breaks on energy consumption and by creating a tool that assists the water utilities as decision-makers in their assessment of the effects of water main breaks on the satisfaction of customers and the revenue loss of water utilities.

1 INTRODUCTION

A 2013 study by the Center for Neighborhood Technology of the Great Lakes states revealed that 6.5 billion gallons of drinking water are lost annually from 63,000 leaking pipes in this region; enough water to meet the demand of 1.9 million consumers for a year (CNT 2013). Water losses cascade into energy loss due to the interdependencies of the infrastructure systems, and leads to additional energy expenditures for extracting water from natural resources and treating, pumping, and transporting water to the end users. Approximately four percent of all electricity generation in the U.S. is used to move and treat drinking water and wastewater (Electric Power Research Institute 2003). For example, the water sector in California consumes 19 percent of the state’s electricity per year (California Energy Commission 2005). Nationwide, the energy bill comprises 40 percent of operation cost for water utilities to provide a clean supply of drinking water for customers (WaterRF 2013). Therefore, minimizing water main breaks through an effective asset management program has the potential not only to reduce the operating and social costs associated with disruption of services to the communities, but also to reduce the energy and carbon footprint resulting from water main breaks.

This paper develops and demonstrates a framework for quantifying the energy footprint resulting from water main breaks that considers the full cycle of providing drinking water to customers. In this study, the energy footprint is a measure of total amount of energy loss in water distribution and supply systems resulted from water main breaks. This framework will investigate the impact of water main breaks on the water supply and distribution system, and assess the interdependencies of the water and energy sectors.
1 BACKGROUND

Extraction and conveyance of water requires a significant amount of energy to transport usable water for the treatment plant. For example, in Southern California, water agencies have to import water from the Colorado River Aqueduct, which requires 2000 kWh/h electricity for pumping (Nuding 2011). In water treatment facilities, the amount of energy used for the treatment process depends on the quality of the water received and the applicable quality standard required for drinking water. Drinking water quality regulations have become more stringent in recent years, requiring advanced water treatment processes, such as UV disinfection systems, which are energy-intensive. Drinking water is then pressurized and pumped through the pipeline distribution network for delivery, which requires additional energy. Figure 1 represents the energy consumption of water supply and distribution components.

Prior research in the water-energy nexus area that addressed the energy needs for water (e.g., American Water Works Association Research Foundation 2007; WaterRF 2011; EPA 2013; WaterRF 2013; U.S. Department of Energy 2014) focused on macro-level analysis of water and energy interactions, including the energy and water demands related to population growth, the development of technology to reduce the energy footprint of the water and wastewater treatment processes, the energy consumption during the rehabilitation and renewal processes, and the improvement of the energy optimization of pumping stations. Additional work has included the quantification of the energy loss of water pipes based on head loss, friction loss, and hydraulics equations (Pelli and Hitz 2000; Colombo and Karney 2002; Filion et al 2004). Cabrera et al. (2010) not only considered the effect of water leakage in distribution systems, but also assessed the energy audit from the resource (reservoir) to the end user. The Reynolds transport equation and integral energy equation were used to develop a mathematical model to evaluate the energy input/output for a water distribution system. These integral energy equations led to calculating the energy loss indicator using leakage; however, it measured only the energy loss in the closed loop of water distribution, not from the water supply systems (extracting and treatment). In addition, the current state of the literature is limited to macro-level analysis of water distribution and supply systems (in the delta level shown in Figure 2), and has not addressed the energy-intensive components of water distribution system in cases of main breaks.

2 METHODOLOGY

In order to better understand the complexity and boundary of the water infrastructure system, a multi-level hierarchical framework for water infrastructure system was developed using the System-of-Systems framework (see DeLaurentis and Callaway 2004), as shown in Figure 2. The alpha (α) level is the base level system and further decomposition does not take place in this context, the beta (β) level is collections of α-level systems, the gamma (γ) level is collections of β-level systems in a network, and the delta (δ) level is collections of γ-level systems. This bottoms-up assesses the interaction between entities in each level, as well as interdependences across levels.
Investigating the dependencies and interdependencies of a complex system requires a theoretical framework including three phases: definition, abstraction, and implementation (DeLaurentis and Callaway 2004). In the forthcoming paragraphs, a discussion on each of the three phases is provided to highlight the purpose of each phase as well as the processes and tasks conducted within each phase.

The first phase, namely definition, intends to ensure that the current problem fits within the overall system characteristics by defining the operational context, status quo, and barriers. In this study, the existing interactions between water and energy infrastructures are defined in order to improve water utilities’ capability by addressing the water and energy loss in water supply and distribution system. Barriers to the possible interactions between water and energy infrastructures can be counted as different managerial and operational dependencies and lack of appropriate communications.

The abstraction phase defines the key entities and their roles. Four main entities can be defined in this phase, which can be grouped under two entity-descriptors, specifically, explicit-implicit and endogenous-exogenous. The four entities that are addressed in this phase are: resources, stakeholders, drivers, and disruptors. Infrastructure resources are the physical entities which are managed, operated and maintained by utilities and acquired by end users. In this study, these resources include water pipes at the alpha level, and the water pipelines network and pumping stations, water treatment plants at the beta level. These resources have an impact on stakeholders. Stakeholders are those who are impacting or are impacted by decisions. Stakeholders include public/private agencies (i.e. water and energy utilities), and users (i.e., water consumers and utility managers). In this study, the drivers are the operation cost (such as energy, cost repair cost, etc.) and the level of service of water infrastructure. Drivers influence the decisions of utility companies to maintain the infrastructure to a certain level of performance. Disruptors are severe events that will reduce the efficiency of the system; in this case, water main break events.

The implementation phase builds upon the definition and abstraction phases. To assess the impact of water main breaks on water and energy infrastructure interdependencies, a number of mathematical models (see Cabrera et al. 2010) must be integrated. Due to the complexity of system, difficulty of integrating these mathematical models, and the level of uncertainty represented by this problem, system dynamic modeling was chosen for conducting the study and to uncover emergent patterns of system
behavior. System dynamics is a methodology that can be applied to analyze the behavior of complex systems with a series of stocks, flows, and feedback loops (Forrester 1991). In this research, the system dynamics component focuses on the interactions between the water loss in the distribution system and the energy-intensive operational components of the water infrastructure. The advantage of using system dynamics modeling to assess the interdependencies is that it allows explaining the endogenous structure of the system, from water main breaks and pipeline characteristics to pumping stations, water treatment, water extraction, and water conveyance, as well as how the different components of the system interact. The closed boundary of the system structure does not imply that the system is unaffected by outside events, such as, traffic load, external corrosion. However, the dynamic behavior is created by interactions within the boundary (Forrester 1999). Figure 3 identifies the boundaries of the system dynamics model and depicts the interactions between system components.

The research methodology was applied to water distribution system in U.S. City A to demonstrate the framework. City A is a Midwestern city with an approximate population of 853,000 in 2013 with an area of 372 square miles and water supply capacity of 79 million gallon per day (US Census 2014; CEG 2013). Water pipeline installation was initiated in 1848 with cast iron pipe (CIP) materials. According to the City GIS database, the current water pipes range in diameter from 0.75 inches to 60 inches. CIP comprises the majority of the installed materials, followed by ductile iron pipe (DIP), polyvinyl chloride (PVC) pipe, steel pipe, asbestos cement (AC), high density polyethylene (HDPE).

AnyLogic 7.0, an object-oriented program, is used to demonstrate the modeling and simulation of the water and energy footprint, as well as the modeling of the interdependent micro-behaviors of the agents toward water main breaks, water loss, and energy loss. The primary components of the system dynamics model include:

- **Stocks**, which represent the variables of the system that change or accumulate over time. Examples of stocks are number of water main breaks, amount of water loss, amount of energy loss, amount of revenue.
- **Flows** represent rates that produce changes in the value of the stocks. These elements introduce changes in the flows to and from the stocks. Examples of flows are frequencies of water main breaks, water loss rates, energy consumption rates.
- **Causal or feedback loops** that represent the dynamic behavior of a system and the causality relationship between the variables and determines the flow of resources from the stocks.

The relation between stock and flow in system dynamics modeling is defined by Equation 1 (Sterman 2001):

\[
\text{Stock} (t) = \int_{s}^{t} [\text{inflow} (s) - \text{outflow} (s)] ds
\]
Where, \( t_1 \) is the initial time, \( t_2 \) is the current time, and the difference between inflow and outflows is the flow rate.

The amount of water loss from water main breaks is based on the AWWA M36 Manual (AWWA 2009). The water loss equation is a function of number of breaks in distribution system, the average flow rates of leaks, duration of leaks, and the average pressure in distribution system, shown in Equation 2 as:

\[
[2] \text{Annual Loss (MG)} = (\text{BR} \times (\text{AFR} \times 60 \times 24 \times \text{TD} (\text{AP} + 70)^{0.5}) / 1,000,000)
\]

Where, MG is million gallons, BR is the number of annual breaks reported by agencies, AFR is the average leak flow rate at 70 psi (gpm), TD is the total duration is days (= awareness duration + repair duration), and AP is the average system pressure (psi).

2.1 Data Analysis

The model input, such as the number of breaks, flow rates, average system pressure, and response time to the water main breaks were retrieved from City A’s GIS database and from literature sources, including AWWA M36 manual, Water Research Foundation, and Environmental Protection Agency (WaterRF 2013; AWWA 2009; EPA 2009). The input variables are the characteristics of three common types of pipe materials, CIP, DIP, and PVC, and three categories of pipe diameters, 6” diameter, 12” diameter, and higher than 16” diameter. The model output variable includes the energy footprint of water main breaks based on the characteristics of the distribution and the main breaks. The average pressure is assumed to be 70 psi for entire water distribution system, based on the City A requirements. The average flow rate for water main breaks is estimated using the pipe diameter and the AWWA M36 Manual as shown in Table 1 (AWWA 2009). The total duration of water loss (awareness duration + repair duration) is retrieved from the GIS database of the City A.

The water loss from main breaks affects the water supply system in order to extract, transport, treat, and pump extra amount of water to customers. The energy rate for extracting water (ground water or surface water) depends on pump efficiency (WaterRF 2013). In this study, it is assumed that the source of water is surface water with the pumping efficiency of medium and production of 20 million gallons per day (MGD), based on the water production rates in City A. The estimated energy consumption of this source water pumping is 2,898 kW/day (WaterRF 2013). Equation 3 is used to calculate the energy consumption of extracting water from resources in the system dynamics model as flows.

\[
[3] \text{Energy Loss of Extracting & Conveyance} = \text{Initial Value} + \frac{d(Energy Loss of Extraction & Conveyance)}{dt}
\]

The amount of energy used for the water treatment process depends on quality of raw water and the quality standard required for drinking water. Drinking water quality regulations have become more stringent in recent years, requiring advanced water treatment processes, which are energy intensive (WaterRF 2013). The types of treatment plant needs to be considered for energy footprint analysis because traditional treatment plants energy consumption is different from advanced treatment plans. This study considered the conventional water treatment plant as a process of treating raw water through rapid mixing, flocculation, sedimentation, filtration, and chlorine stages with the approximate energy intensity of

¹ Time of identification of failure to repair of failure
25,605 Kwh/day (WaterRF 2013). Equation 4 is used to calculate the energy consumption of water treatment plant in the system dynamics model as follows:

\[ \text{Energy Loss of Water Treatment Plants} = \text{Initial Value} + \frac{d(Energy Loss of Water Treatment Plants)}{dt} \]

Energy consumption of pumping stations is a function of the flow, an assumed distribution system pressure head, and assumed pumping efficiency (a measure of pumping system efficiency). In the study, the average pressure of the distribution system is assumed to be 70psi and the efficiency of pump is considered as 65%, based on the commonly observed practice in the water industry (AWWA 2009). Based on these values, the approximate energy consumption of finished water pumping with the pumping efficiency of medium and production of 20 MGD is 21,563 kWh/day (WaterRF 2013). Equation 5 is used to calculate the energy consumption of pumping stations in the system dynamics model as flows.

\[ \text{Energy Loss of Pumping Stations} = \text{Initial Value} + \frac{d(Energy Loss of Pumping Stations)}{dt} \]

Water main break events affect both the water utilities and communities in several ways, such as the social cost for communities and the financial loss for water utilities in repairing breaks. Agent-based modeling (ABM) is used in this study to capture the micro-behavior and emergent behavior outcomes from the activities and interactions between the water utility and consumer agents. ABM models the stakeholders (water utilities and customers) as autonomous agents in order to understand their behaviors toward water main breaks and to assess the potential increases in costs that may be passed on to the users from non-revenue water and energy loss. Figure 4 shows the beliefs, knowledge, and information (BKI) of the water utility and customer agent.

![Figure 4: Representation of environment and agents interactions](image)

### Micro-Behaviors of Water Utility
1. Water main breaks increase operational cost because of repair and renewal.
2. Water main breaks lead to water loss and increase the non-revenue water.
3. Water main breaks leads to energy bill for water supply.
4. Three choices to compensate the revenue loss: increase water rates, federal fund, and local tax.

### Micro-Behaviors of Customer
1. Water main breaks decline the level of services because of interruptions in services.
2. Increase in water rates from water utilities increase the customer complaints.
3. Increase in water rates leads to decrease in water consumption.
4. Decline in water consumption decreases the water utilities revenue.

2 RESULTS & DISCUSSIONS

The proposed methodological framework is used to assess the energy footprint of water main breaks and evaluate the stakeholder’s interactions from the main breaks. This section focuses on the assessment of interdependencies between water and energy infrastructure systems resulting from water main breaks in water distribution system. Figure 5 shows the energy footprint for City A due to water main break events based on different types of pipe materials. This energy footprint includes the energy loss in the water
supply system. The energy loss due to breaks in CIP pipes is higher compared to that in DIP and PVC pipes. This may be related to the aging CIP pipes, which were installed more than 100 years ago in North America. (McKim 1997), and hence show higher rate of breaks. PVC pipes have a lower energy footprint, because of the material’s high resistance to corrosive environments and longer life expectancy (Folkman 2012; Davis et al 2007; Moser et al. 1994).

Figure 5: Energy footprint of water main breaks for each pipe material

Figure 6 shows the energy footprint estimates of water main breaks based on the three different categories of pipe diameters: 6” pipe, 12”pipe, and higher than 16” pipe. 6” diameter pipes in water distribution system have higher rates of energy loss, three times higher than 12” diameter pipes and five times higher than larger than 16” diameter pipes. This is mainly because of higher length of installation and smaller diameter. The small diameter pipes, such as 6” pipes, have a smaller thickness and they are more likely to be affected by the corrosive soil environment and the number of breaks rates for the small diameter pipes are higher (Kettler and Goulter 1985; Loganathan et al 2002).

Figure 6: Energy Footprint of Water Main Breaks for Three Categories of Pipe Diameter

The analysis of this study revealed that as the diameter of the pipes increases (and the thickness increase), the energy footprint decreases. For example, the 6” pipes have a 1523 miles installation in the City A in compare with 12” pipes, which have 936 miles though the city.
Single factor sensitivity analysis was conducted to observe the impact of the different parameters on the energy footprint of the water main breaks. The variable with the highest uncertainty spans the largest range in the tornado diagram. Figure 7 shows the tornado diagram for the citywide energy footprint from water main breaks in City A. The tornado diagram captures the impact of water pipeline characteristics on energy loss of water supply and distribution system. Smaller diameter pipes with the oldest materials types as well as the higher installation lengths have higher energy footprints. PVC pipes with diameters higher than 16" have lower energy footprint rates. 12" PVC pipes and 6" PVC pipes have approximate similar energy footprints.

![Tornado diagram for citywide energy footprint of water distribution system](image)

Figure 7: Tornado diagram for citywide energy footprint of water distribution system

3 CONCLUSION

This paper presented a framework to assess the energy loss of water main breaks to assist in decision making by water utilities in areas of energy cost and operation cost. A hybrid system dynamics-agent based modeling was proposed to evaluate the interaction between water main breaks and energy infrastructure system, as well as the micro-behavior of stakeholders toward water main break events. A system dynamic simulation framework was created and analyzed to estimate the water energy footprint of water main breaks based on the water distribution characteristics. Single factor sensitivity analysis was conducted to identify significant factors affecting the energy footprint of water supply and distribution system in a citywide case. For the case study, 6" CIP pipes were found to be energy-intensive components of water distribution system in case of water main break events, followed by 12" pipe material pipes. Large diameter pipes (greater than 16") were also found to experience lower energy loss due to breaks in water distribution and supply system. The next stage of this research is implementing the agent based modeling to capture the stakeholders behaviors and potential increases in costs that may be passed on to the consumers from non-revenue water and energy loss.

APPLICATION OF FAHP AND SHANNON ENTROPY IN EVALUATING CRITERIA SIGNIFICANCE IN PIPELINE DETERIORATION

Z. Zangenehmadar1,2, O. Moselhi1
1 Concordia University, Montreal, QC, Canada
2 z_zange@encs.concordia.ca

Abstract: Water Distribution Networks (WDNs) are the most important element in water supply systems. According to the Canadian Water and Wastewater Association (CWWA), there are more than 112,000 kilometers of water mains in Canada and their replacement cost is estimated to be $34 billion. Another $12 billion is required to service the projected growth. It is important to assess the long-term condition of WDNs to find their respective rate of deterioration in order to prevent disastrous failures and/or sudden shutdowns. Due to the limited data about water mains, condition of pipeline should be estimated based on available data. Therefore, to predict the pipeline condition, importance of each factor should be known. This study aims to calculate the weight of importance of factors that affect deterioration of pipelines. For this purpose, Fuzzy Analytical Hierarchy Process (FAHP) and Entropy Shannon are employed to prioritize the selected factors and calculate their relative weights based on their individual importance. Results show that pipe installation, age and material are the most effective parameters in modeling deterioration. These weights will be used in condition rating models to find the condition of pipelines based on their pipe characteristics, soil and water properties in order to estimate deterioration rate and expected remaining useful life.

1 INTRODUCTION

As Water Distribution Networks age, they experience the problem of deterioration and leakage. The frequency of leaks and breaks increase which result in loss of healthy drinking water. In Qatar, 35% of the drinking water is wasting through leaking only in Doha and 30% is wasting through other area (GWI 2010). Therefore, identifying the deterioration rates and the remaining useful life will help in performing more economical and efficient replacement and maintenance measures. Since in a number of cases, data needed for generating deterioration curves and estimating remaining useful life may be insufficient, prediction models should be employed to forecast the condition of the pipelines based on the available data such as pipe design. This paper utilizes different methods to calculate weight of importance for the most important factors affecting the condition of pipelines in condition rating models. It uses the integration of two methods to take into account the uncertainty and fuzziness of human judgements and decision making. The main objective of this research is to calculate criteria significance in pipeline deterioration in order to be used for future deterioration and remaining useful life models that will be utilized in developing a value-driven optimized intervention plans.
2 BACKGROUND

2.1 Shannon Entropy

In 1984, Claude Shannon proposed a mathematical theory to measure the amount of information content of an information source. In this theory, the term of Entropy, refers to the portion of information content. This portion indicates the uncertainty of both the information source and the random variable and defines how much information is earned when result i is observed. When the raw data of the decision making matrix are identified completely, Entropy method could be used to evaluate the weights. There is more chance of occurrence for each value of i when entropy is higher. Considering P as a random variable and \( P_i \) as the probability, the theory identifies the relationship between Entropy (E) and random variable as for all the m criteria (Shannon 2001):

\[
E_i = S(P_1, P_2, ..., P_n) = -E_0 \sum_{i=1}^{n} P_i \ln(P_i)
\]

Where \( n \) is the total number of possible outcomes. Measuring uncertainty of a random variable \( i \) means that when \( E_i = 0 \), \( i \) would be a certain variable not a random one. Also in case of maximum quantity of \( E_i \), \( i \) is a random variable with a uniform distribution. In this formula, entropy and uncertainty are used for the same concept. In other words, average quantity of information which is collected after the observation of result \( x_i \) in the random variable of \( X \), is entropy. The concept of Shannon Entropy refers to an accepted measure of uncertainty and fuzziness. This is the main reason for choosing this method for calculating the weights. Entropy recently has been used in reliability assessment studies in WDN (Prasad and Tanyimboh 2008, Tanyimboh et al. 2011, Shibu and Reddy 2012) and was used along with AHP in weight determining in Zheng and Tian (2009).

2.2 Fuzzy Analytic Hierarchy Process (FAHP)

AHP gives weights to set of variables by organizing experiences and judgments of individuals into hierarchical structure. This structure illustrates relationships between goal, parameters and sub-parameters. Fuzzy analytical hierarchy process (FAHP) is the fuzzy format of AHP and is a well-known multi criteria decision making technique introduced by Saaty in 1988. It could be said that the ultimate goal of the AHP is collecting the expert's judgment; however it could not reflect the uncertainty in the judgments and knowledge of humans in decision making process precisely. The uncertainty could be modeled using fuzzy logic. Keliner et al. (2005) proposed a fuzzy Markov deterioration process to model failure risk of PCCP, cast and ductile iron water mains. Triangular memberships and fuzzy rules of “if-then” were employed to solve the problem. Condition of the asset was calculated from the present condition and deterioration rate, which had been identified from Markov deterioration process. Makropoulos and Butler (2005) developed a neuro-fuzzy spatial decision support system for pipe replacement prioritization. The model includes fuzzy logic and neural network back propagation algorithm which relates certain characteristics to pipe replacement. Najjaran et al. (2006) presented a fuzzy expert system to assess corrosion of cast/ductile iron pipes from backfill properties. The model comprises subjective and objective parts and two systems were suggested for fusion of the subjective and objective models. This methodology was also used in two other articles of “A Fuzzy Expert System for Deterioration Modeling of Buried Metallic Pipes” (Najjaran et al. 2004) and “Fuzzy-Based method to evaluate soil corrosivity for prediction of water main deterioration” (Sadiq et al. 2004).

Al-Barqawi and Zayed (2006) presented a model using analytic hierarchy process (AHP) for water main conditions assessment. In this model, the effective factors were first recognized; then pair-wise comparisons were performed between each two of the factors, priorities were assigned and condition assessment records were calculated form priority matrices. Rajani and Tesfamariam (2007) proposed an approach for estimating time to failure of cast-iron water mains. The fuzzy membership function employed in this model is triangular fuzzy numbers. This model is identical to one presented in “Estimating Time to Failure of Ageing Cast Iron Water Mains under Uncertainties” (Rajani and Tesfamariam 2005) and “Possibilistic Approach for Consideration of Uncertainties to Estimate Structural Capacity of Aging Cast Iron Water Mains” (Tesfamariam et al. 2006). Al-Barqawi and Zayed (2008) also did another research about an integrated AHP/ANN model to evaluate municipal water mains’ performance. They utilized AHP to calculate the weights and assign a value between 0 (critical) to 10 (excellent) to the condition of
pipeline. Zhou et al. (2009) developed a Fuzzy based pipe condition assessment model which generates pipe condition rating using AHP from fuzzy first-level and second-level condition indicators. Fares and Zayed (2010) presented a hierarchical fuzzy expert system for risk of failure in water mains. The risk of failure varies between 0 (least risk) and 10 (highest risk). The impact factors of the parameters of four categories were evaluated utilizing the Mamadani rule system at first step. Then, they were used to calculate the risk of failure. FAHP is used to solve the hierarchical and multi criteria decision making problems by using trapezoidal and triangular fuzzy numbers. These two mentioned fuzzy numbers are mostly used to reduce the complexity of the problem due to the large number of criteria and decision makers. AHP has some limitations such as subjectivity and it doesn’t consider uncertainty in inputs. FAHP has solved this problem. In FAHP, the experts are asked to enter all possible outcomes of modal, lowest and highest possible values in the pairwise comparison matrix. It means that they are entering the values three times more than they enter in regular AHP which is difficult and time consuming (Fares, 2008).

3 RESEARCH METHODOLOGY

The overall flow of the research process is depicted in Figure 1 and consisted of the following steps: 1) Data collection including questionnaire design, distribution and collection, 2) Data analysis and building the matrix of pairwise comparison, 3) Calculating the weights of importance of factors affecting pipeline deterioration through FAHP and Entropy individually, 4) Integration of weights calculated in previous step to find final weight of importance.
3.1 Data Collection

The survey was performed in Fall 2014. The questionnaire was designed in an online format on Qualtrics website which is a data collection platform. 38 questionnaires were collected from experts around the world to find the weight of importance of each factor in water pipeline deterioration. The years of experience and demographic distribution of these experts is summarized in Figure 2 and 3. In the five-question questionnaire, the experts are asked to identify the relative importance of each criterion in pipeline deterioration both separately and respect to others by using linguistic variables of Table 1.
Table 1: Linguistic variables for the importance weight of each criterion (Chen, 2000)

3.2 Fuzzy Analytic Hierarchical Process (FAHP)

3.2.1 Pairwise comparison matrix

The very early step for analysis is building the matrix for pairwise comparison and checking its consistency. After that, the relative weights of parameters and sub-parameters were determined (Vahidnia, Alesheikh, Alimohammadi, & Bassiri, 2008).

\[ A = \begin{bmatrix} 1 & W_{12} & \cdots & W_{1n} \\ W_{21} & 1 & \cdots & W_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ W_{n1} & W_{n2} & \cdots & 1 \end{bmatrix} \]

In this matrix, \( W_{ij} \) is the weight of parameter 1 respect to parameter 2. All the arrays in matrix \( A \) are fuzzy triangular numbers of \( (l_{ij}, m_{ij}, u_{ij}) \).

3.2.2 Extent Analysis Method

To analyze FAHP, Larhorn and Pedric (1983) suggested a method which was based on minimum logarithmic squares. This method did not become popular due to its complexity and ambiguity (Nepal, Yadav, & Murat, 2010). After that, Chang (1996) proposed ‘Extent Analysis Method (EA)’ that used fuzzy triangular numbers which becomes more common in FAHP calculations (Nepal et al., 2010) and is used in this study. Considering \( M_1 = (l_{1}, m_{1}, u_{1}) \) and \( M_2 = (l_{2}, m_{2}, u_{2}) \), the arithmetic functions are (Chang 1996):

\[ M_1 + M_2 = (l_1 + l_2, m_1 + m_2, u_1 + u_2) \]
\[ M_1 \times M_2 = (l_1 \times l_2, m_1 \times m_2, u_1 \times u_2) \]
\[ M_1^{-1} = \left( \frac{1}{l_1}, \frac{1}{m_1}, \frac{1}{u_1} \right), \quad M_2^{-1} = \left( \frac{1}{l_2}, \frac{1}{m_2}, \frac{1}{u_2} \right) \]

In this method, the triangular number of \( S_k \) is calculated for each row of the pairwise comparison matrix from below in which \( k \) is row number, \( i \) is alternative and \( j \) is criterion.

\[ S_k = \sum_{j=1}^{n} M_{kj} \times \left[ \sum_{i=1}^{n} \sum_{j=1}^{n} M_{ij} \right]^{-1} \]

Computing \( S_k \), their magnitude should be determined respect to others and the result should be normalized from equation 9.

\[ W_i = \frac{w_i}{\sum w_i} \]

After finding acceptable results, the priority matrices are combined together by multiplying the weight of factors \( (W_i) \) and weight of sub-factors \( (Y_i) \), to calculate the overall scores (Saaty, 1988). Subsequently, Consistency index (CI) which is a degree of deviation from consistency is checked. Afterward, consistency ratio (CR) defined as the ratio of the consistency index (CI) divided by the random inconsistency index (RI) for random comparisons is calculated (Saaty, 1988).
Table 2: Random inconsistency indices (Saaty, 1988)

3.3 Shannon Entropy

The built pairwise comparison matrix for FAHP was used again to perform Shannon Entropy method. Normalizations were performed in Step 1 and entropy was calculated from Step 2. In Step 3, the degree of diversification and weight of importance were computed from calculated entropy.

\[
W_i = \frac{W_{ij}}{\sum_{j=1}^{n} W_{ij}} \quad j = 1, \ldots, n; \quad i = 1, \ldots, n
\]

Compute entropy \( E_i \) as

\[
E_i = -E_0 \sum_{j=1}^{n} W_{ij} \ln W_{ij} \quad i = 1, \ldots, n \quad \text{where} \quad E_0 = \frac{1}{\ln(n)}.
\]

\[
d_i = 1 - E_i
\]

\[
w_i = \frac{d_i}{\sum_{i=1}^{n} d_i} \quad i = 1, \ldots, n.
\]

3.4 Integration of FAHP and Shannon Entropy

After finding the weights of importance from FAHP (\( w_j \)), they can be combined with computed degree of importance from Entropy (\( y_j \)) using equation below.

\[
W_j = \frac{y_j w_j}{\sum_{j=1}^{n} y_j w_j} \quad \forall j
\]

4 RESULTS AND DISCUSSION

The collected responses were analysed and total weight of importance for parameters identified through FAHP are summarized in Table 3. As can be seen, physical factors has the highest effect in deterioration of the water pipelines. Operational and Environmental factors are ranked as second and third important categories in pipeline deterioration. In physical factors, pipe material, pipe installation and pipe age are the first three significant factors. In category of Environmental factors, bedding soil type, seismic activity and backfill material are the most important factors in deterioration of water pipelines respectively. Furthermore, water pressure and O&M practices are the operational parameters that affect the deterioration of water pipelines at most. Computed global weight of importance for each category is multiplied by the local weight of importance of each sub-category to find the total weights of importance for each factor. It can be seen that criteria of pipe material, water pressure, pipe installation, pipe age and bedding soil type are the most important factors in pipeline deterioration in water infrastructure which has been determined by FAHP method. Consistency was checked for the pairwise comparison matrices and results are summarized in Table 3. The pairwise comparison matrix for identifying the global weights is also presented in Table 4.

\*e_i = entropy
\nd_j = degree of diversification
\nw_j = weight of importance

Since Outputs are not the same in both Entropy and FAHP methods, therefore the final weight will be an integration of both methods. Equation 14 is used to find the weights of importance of the parameters.

Table 7: Weights of factors from Entropy and FAHP

\begin{center}
\begin{tabular}{|l|c|}
\hline
Criterion & Weights of importance \\
\hline

\hline
\end{tabular}
\end{center}
The weights of importance from FAHP, Entropy method and integration of both methods are illustrated in Figure 4. The factors are organized based on the weights from the integration of both methods. It can be seen that the prediction of weight of importance for most of the criteria are approximately the same in the 3 calculations and the differences are less than 2%. Greater differences are detected in water pressure, dissimilar metals, lining and coating and pipe wall thickness respectively. This confirms that the computed weight of importance for each of the criterion is calculated correctly and shows that more researches and clarifications are required to identify the effects of these criteria precisely.

Figure 4 : Comparison of weights from different methods

5 CONCLUSIONS

As pipelines deteriorate, they are more exposed to failure from internal and/or external causes, therefore knowing the importance of effective factors in deterioration of water pipeline is essential in infrastructure management. This study applies Fuzzy Analytic Hierarchical Process (FAHP), Shannon Entropy and Integration of two methods to determine the weight of importance of the selected factors considering the deterioration process. Results show that physical factors and operational factors are the most and least important category of factors respectively. Pipe specifications such as installation, age, material, utilizing dissimilar metals and lining and coating proved to have the most influence on pipeline deterioration through analysis which should be take into account while designing durable and reliable pipelines. The outcome of this research also reveals consistency between the weights calculated in three highlighted ways except in water pressure, dissimilar metals, lining and coating and pipe wall thickness which brings the need for further investigations on the effect of these factors. The calculated weights of importance from integration of FAHP and Entropy will be used for future development of models for condition rating and deterioration.

AN ONTOLOGY-SUPPORTED TRANSACTION FORMALISM PROTOCOL IN INFRASTRUCTURE MANAGEMENT

Jehan Zeb and Thomas Froese
1 Department of Civil Engineering, University of British Columbia, Vancouver, Canada

Abstract: Infrastructure organizations use diversified information systems to exchange data (transaction). Presently, data exchange in the area of infrastructure management is accomplished in a manual and ad hoc basis. The growing trend is to transform these manual data exchanges to a computer-to-computer based exchange of information. “How to formalize these data exchanges or transactions?” is the core research question, which was dealt with developing and applying an ontology-supported Transaction Formalism Protocol (TFP). The proposed solution is composed of two parts: ontology and protocol. Two ontologies, the Transaction Domain Ontology and Tangible Capital Asset ontology, were developed using an eleven-step methodology to represent transaction knowledge and Tangible Capital Asset knowledge respectively to support the design and implementation of transactions in infrastructure management. The proposed TFP is an eight-step procedure developed using a four-step methodology from two perspectives: the TFP Specification modelled each step of the protocol as a function for which inputs, controls, mechanisms, tools/techniques, and outputs were defined, whereas the TFP Tool includes a set of forms and guidance developed for specific steps of the protocol. The TFP was applied to develop transaction specifications for the Asset Inventory and Condition Assessment Reporting (AI&CAR) Reporting, which was implemented in the Asset Information Integrator System for the exchange of Tangible Capital Asset information between the municipal and provincial governments. The main contributions of this research work include the development of the two ontologies, protocol, and Asset Integrator Information System.

1 INTRODUCTION

Infrastructure agencies, including shallow utilities own, operate, and manage infrastructure systems using a wide range of information systems, each based on different proprietary data models. Various agencies and utilities interact with each other and exchange infrastructure information to accomplish a wide range of collaborative tasks. As infrastructure agencies increasingly rely on computer-based systems to manage infrastructure data, much of the information that was traditionally exchanged using manual and ad hoc communications can now be exchanged electronically through computer-to-computer data exchange. This allows for more extensive, rapid, and error-free exchange of information, but it requires more formal specifications to govern these data exchanges (i.e. transactions). A transaction is defined “as any communication or interaction between the sender and receiver roles that make up the information flow through a single or collection of a sequenced set of messages” (Zeb and Froese, 2012). Transaction example includes: communications during a disaster response (“Is power available in this area?” “Who is responsible for this section of roadway?” “When will water to be restored to this area?”); coordination between buried utility agencies; aggregation of data from multiple infrastructure management software with regards to the asset inventory and condition assessment reporting and formalized transactions used in the multi-agency situational awareness system wherein the provincial government requires information...
from many other organizations outside the provincial jurisdiction to prepare for and mitigate the impacts of emergency incidents (Stewart, 2010).

Although the inevitable trend in the communication technology is towards increasing computerization, which requires transaction formalization, but there are many challenges that prevent this formalization from being an easy or efficient process. These challenges include: lack of an appropriate process for carrying out this formalization; heterogeneity in data formats, data (class) definitions, and data aggregation (Felio, 2012). These issues were dealt with developing an ontology-supported Transaction Formalism Protocol (TFP) in the domain of infrastructure management.

The TFP is a procedure developed to formalize transactions and create transaction specifications effectively and efficiently. To support the development and application of the TFP, two ontologies were built: the Transaction Domain Ontology (Trans_Dom_Onto), and the Tangible Capital Asset Ontology (TCA_Onto). According to Gruber (1995), an ontology is a “formal explicit specification of a shared conceptualization.” The Trans_Dom_Onto represents transaction related knowledge to support the design, management, implementation of transactions, and development of the TFP. The TCA_Onto represents the Tangible Capital Assets (TCAs) to support the design of message templates in a neutral data format to address message-based interoperability between information systems of the infrastructure organizations. According to PSAB (2009), the TCAs are “non-financial assets having physical substance that are acquired, constructed, or developed and: are held for use in the production or supply of goods and services; have useful lives extending beyond an accounting period; are intended to be used on a continuing basis, and are not intended for sale in the ordinary course of operations.”

The proposed TFP protocol is an eight-step procedure that was developed from two different perspectives. The TFP Specification represents each step of the protocol as a distinct function for which inputs, controls, mechanisms, tools/techniques, and outputs were defined. The TFP Tool is comprised of a set of Excel-based forms and guidance developed for specific steps of the protocol that the transaction development personnel can use to define transaction specifications for IT based solutions.

The proposed TFP was applied to develop transaction specifications for the Asset Inventory (PSAB, 2008) and Condition Assessment (SORP, 2008) Reporting/Tangible Capital Asset (AI&CAR/TCA) Reporting. The formalized transaction specification was implemented in a prototype Asset Information Integrator System (AIIS). The prototype system collects, stores, visualizes, and analyzes the asset inventory and condition assessment information received from different municipalities to help the provincial government to: understand long-term financial needs of municipalities for infrastructure management; develop a consistent and planned approach for funds allocation; and present the case to the federal government for additional funding, if required.

This paper is divided into the following seven sections. Background information and related literature are discussed in section 1 and 2 respectively. Section 3 describes the methodology used, whereas section 4 briefly explains the development of the ontologies and TFP. Application of the TFP is presented in section 5 and evaluation is elucidated in section 6. Conclusions and contributions are discussed in section 7.

2 LITERATURE REVIEW

The literature review is discussed from two perspectives: ontologies in the domain of infrastructure management and related work process and communication formalization standards and methodologies.

Ontologies in infrastructure management—three ontologies in the domain of infrastructure management are of particular importance: Infrastructure Product Ontology, IPD-Ono (Osman, 2007); Infrastructure and Construction Process Ontology, IC-Pro-Onto (El-Gohary, 2008); and Actor Ontology, Actor-Onto (Zhang and El-Diraby, 2009). The IPD–Onto (Osman, 2007) represents infrastructure product knowledge (e.g. pipe, valve, pump, etc.). The IC-Pro-Onto represents process knowledge, e.g. core design and construction processes, management processes, knowledge integration processes, and support processes (El-Gohary, 2008). The Actor-Onto represents knowledge related to various actors and actor-roles in the construction industry (Zhang and El-Diraby, 2009). While these three core formalism
dimensions have been completed, there remains a need to formalize information exchange processes (transactions) to enable computer-to-computer, message-based exchange of information. Transaction formalism involves specifying and defining not only the process, actor and infrastructure system information, but also the specification of information exchange details, which is to be addressed through the development of the Transaction Domain Ontology (Trans_Dom_Onto). In addition, these ontologies do not completely support the design of the message templates that are required to be exchanged in the AI&CAR/TCA Reporting (information transaction). The IPD-Onto doesn't represent a complete set of the infrastructure products, and it was extended in this research in terms of the TCAs to provide payload information for the design of the message templates for the AI&CAR/TCA Reporting, which led to the development of the TCA_Onto. The header information in these message templates, meanwhile, was captured from the Trans_Dom_Onto that was developed as part of this research work.

State-of-the-art standards—some process and communication formalization techniques currently exist in the Architecture, Engineering, Construction and Facilities Management (AEC/FM) industries, but these standards do not fully address the requirements for transaction formalism in the domain of infrastructure management. In the AEC/FM industries, the Information Delivery Manual (IDM) formalizes work processes in the construction industry (IAI-IDM, 2012). It is a requirement specification methodology focusing on model-based exchange of information between different parties using building information models (BIM). The IDM defines information in terms of informational elements (objects and their attributes) rather than informational products (documents), hence the methodology is BIM specific. In addition, the exhaustive nature of the IDM makes it time-consuming to develop and difficult to share with others on projects (Berard and Karlshoej, 2012). Because of the IDM's explicit focus on BIM, it does not meet the requirements for a general communication formalism technique for the infrastructure sector, but it is a very relevant exemplar for this research work, and therefore, some features of the IDM specifications were adopted with modifications. The Model View Definition (MVD) is a methodology developed to formally define a subset of an Industry Foundation Class (IFC) BIM model (IAI-MVD, 2005). The MVD is relevant since it is typically used to formally specify the particular BIM information to be exchanged during a specific type of data transaction, but again, it is BIM specific and it lacks a step-by-step procedure describing how to capture requirements. The Voorwaarden Scheppen Voor Invoering Standaardisatie (VISI), which means “Terms and Conditions for the Implementation of Standardization in ICT” is a Dutch communication management standard developed to define transactions in the AEC/FM industry (VISI, 2011). The VISI standard lacks a step-by-step process to capture transaction requirements and define transactions, and it depends on an Extensible Markup Language (XML) based model representing information in a local context (i.e. the Dutch construction industry). A related standard, the Construction Objects and Integration of Processes and Systems Engineering Method (COINS-EM/CEM), is a Dutch standard developed to create agreements on working methods and organization of production processes and information (Schaap et al., 2008). As with the IDM, COINS-EM/CEM focuses on exchange of model-based/3D object data rather than communication in general, and it also lacks a systematic procedure for requirement specification. Another initiative, the agcXML, focused on developing a set of XML schemas to enable industry experts to exchange electronic building information reliably and efficiently between heterogeneous proprietary software applications to improve interoperability and integration of the information systems (Zhu, 2007). The agcXML doesn’t include a general data transaction specification, it does include a format for transaction use cases and a use case for generic document distribution (Froese, 2007), but does not include a procedure for transaction design.

In summary, none of the standards discussed above fully meet all of the objectives of this research work in terms of developing a step-by-step procedure to define transaction specifications in the domain of infrastructure management. Most of the standards are work-process-centric rather than communication-centric. Most do not address how to assess needs and capture information that is required in a given communication. Most of the standards are IT-expert-centric and are not suitable for the end users. These shortcomings led to the development of the proposed ontology-supported TFP.

3 METHODOLOGY

Methodology to develop ontologies—a ten-step methodology was devised to build the Trans_Dom_Onto and TCA_Onto, which was a hybrid version of the various approaches developed by Fernandez-Lopez et
al., (1997); Uschold and Gruininger (1996); and Noy and McGuinness (2001). (i) Define ontology coverage—purpose, use, and users of the ontologies are defined in this step. (ii) Capture competency questions—a set of competency questions were developed that the ontology should be able to answer. (iii) Generate/create taxonomy—a preliminary taxonomy of various concepts was developed. (iv) Reuse existing ontologies—as long as possible, use was made of the existing ontologies and relevant concepts were captured from existing ontologies. (v) Develop Transaction Domain Kernel Ontology, (Trans_Dom_Kernel_Onto) and Tangible Capital Asset Kernel Ontology, (TCA_Kernel_Onto)—representing concepts at the very abstract level to easily categorize and integrate diversified knowledge in the domain of infrastructure management. (vi) Extend Trans_Dom_Kernel_Onto and TCA_Kernel_Onto to develop Transaction Domain Extended Ontology (Trans_Dom_Extended_Onto) and Tangible Capital Asset Extended Ontology (TCA_Extended_Onto)—abstract concepts represented in the kernel ontologies are extended to develop detailed taxonomies. (vii) Capture ontology—represents explicit declaration of the concepts in terms of soft and hard axioms. (viii) Code ontology—the knowledge represented in both the ontologies was formally coded using Protégé Ontology Editor (Protégé, 2014). (ix) Evaluate ontology—the knowledge represented in both the ontologies was verified using Protégé Ontology Editor and competency questions, and validated through industry experts. (x) Document ontology—the knowledge was finally documented for future use.

Methodology to develop the protocol—the proposed TFP was developed using a four-step methodology devised based on the approach formulated by Adesola and Baines (2005) for the development of business process improvement methodologies. The approach involves reviewing and analyzing current frameworks/methodologies and then selecting the relevant candidates based on the key selection criteria. These steps include: (i) select the candidate standards; (ii) benchmark existing standards; (iii) link and build on existing standards; and (iv) develop the proposed TFP.

4 ONTOLOGY-SUPPORTED TRANSACTION FORMALISM PROTOCOL

The development of the proposed ontology-supported TFP includes two parts: development of ontologies and development of the protocol.

4.1 Ontology Development

4.1.1 Transaction Domain Ontology

To support the design, implementation, and management of transactions in the domain of infrastructure management, the Trans_Dom_Onto was developed. The knowledge represented in the ontology was organized according to the core and support concepts totaling to about 420. The core concepts represent the core building blocks of the transaction domain knowledge in the area of infrastructure management. The core concepts are: transaction, message, actor/actor-role, and information. The transaction is the complete communication between two parties. The message or message template represents the information that is required to be exchanged in a given transaction between the actor-roles. Actors are either organizations or individual that plays a specific role (i.e. sender or receiver) in a given transaction. The information is the discrete processed data that the actor-roles need to exchange to accomplish a transaction successfully. Detailed taxonomies of the core concepts were developed based on the concept of modality (i.e. a specific view of the concept categorization) while the explicit declaration of each concept is presented in Zeb and Froese (2012).

On the other hand, the support concepts support or assist in modelling the core transaction domain knowledge and is the focus of this paper. The support concepts encompass modality, attribute, mechanism, constraint, axiom, and relationship. The modality is a "characteristic that describes a thing and denotes it's belonging to a particular group or category", (El-Gohary, 2008).

According to Osman (2007), an attribute is a characteristic, feature, or property that describes a thing, entity, or concept. The transaction has five transaction attributes. Transaction function attribute—is a characteristic that describes a transaction based upon the function it performs in a given communication. Transaction dependency attribute—is a characteristic that describes a transaction based on the logical,
geographic, and cyber dependencies. Dependencies govern the design and implementation of transactions in practical scenarios. **Transaction performance attribute**—is a property that describes the performance of a transaction in terms of transaction efficiency. **Transaction cost attribute**—is a property that describes the transaction design, implementation, and operational cost. **Transaction control attribute**—is a characteristic that describes the transaction security in terms of transaction authorization.

According to El-Gohary (2008) and Osman (2007), the mechanism is an umbrella concept that has three sub-classes: guide, method, and measure, which includes all the tools and means required to accomplish a transaction successfully. The **guide** is a basic information or instructions needed to support the work of an actor role in all communications. It has the following four sub-classes: theory, best practice, strategy, and algorithm. The **method** is a generic concept that covers all such means, mediums, and techniques used to exchange and store transactions. In the Trans_Dom_Onto, methods for transaction transmission and transaction archiving are represented. According to Osman (2007), the **measure** is an abstract concept used to gauge conformance of an entity's attribute to a pre-defined requirement as prescribed by specifications and codes. It has two types: test and metric. The **test** is used to measure conformance of the characteristics of a physical entity to the desired specification and code requirements. The **metric** is used to gauge conformance of the attribute of an abstract entity with respect to predefined requirements. The metric for the transaction (abstract entity) efficiency (attribute) is represented in the Trans_Dom_Onto. **Objective metric**—captures quantitative measurement of the transaction efficiency. It has two sub-classes: transaction cost savings and transaction time savings. **Subjective metric**—captures qualitative measurement of the transaction efficiency. The quality of a transaction is measured in terms of user convenience (Zott et al., 2000) and transaction righteousness.

The transaction is controlled by a set of transaction constraints, which refer to the conditions, factors, requirements, and obligations that restrict the way transactions are to be designed, implemented, and managed in the domain of infrastructure management. It has two sub-classes: internal and external constraints. The **internal constraints** are the requirements and obligations of the collaboration partners in a given transaction. It is categorized into two sub-classes: user requirement and contractual constraints. The **external constraints** are those constraints that are beyond the control of the collaboration partners. It has two sub-classes: regulatory and environmental constraints.

According to (Osman, 2007 and El-Gohary, 2008), **axiom** unambiguously defines the concept represented in the ontology and constrain its interpretation. According to Gruninger and Fox (1995), axiom specifies unambiguous definitions of the concepts in a specific domain. The transaction axioms were classified as soft and hard axioms. The **soft axioms** define the concepts in plain English Language, whereas the **hard axioms** explicitly define the concepts using a formal language—Ontology Web Language (OWL) based Description Logic Syntax (DL). The hard axioms are of three types. **Subsumption axiom**—explicitly defines classes in hierarchies with parent-child relationship. **Disjoint axiom**—explicitly describes that the concepts are disjointed from each other, which mean an individual as a member of class “x” cannot be an instance of another class. Property restriction axiom—According to Horridge (2009), **properties** describe the binary relationship between the concepts, whereas the **datatype properties** describe the relationships between the individuals and data values, where individuals in OWL represent the instances of a class. In OWL, classes are defined in terms of the property restrictions, which states that “a restriction describes a class of individuals based on the relationships that members of the class participate in” (Horridge, 2009), and therefore, a property restriction represents a class of individuals. The property restrictions are of three types: quantifier restriction (i.e. existential and universal), cardinality restriction (i.e. minimum, maximum, and exact), and has value restriction. A total 1726 axioms were defined in the Trans_Dom_Onto.

According to Osman (2007), **relationships** are the associations between the concepts to enrich knowledge representation. It has the following two types. The **hierarchical relationships** include the generalization-specialization and aggregation-composition relationships. The generalization-specialization relationships—represent is-a or type-of or parent-child relationship between concepts and has two types: hyponymy and hypernymy, (El-Gohary, 2008). The aggregation-composition relationships—are whole-part relationships that represent the relationship between the whole and its parts, which is also known as partonomy (El-Gohary, 2008). It has two sub-classes: aggregation and composition relationships which...
are further classified as meronymy and holonymy. The association or directed association represents other than “is-a” or “part-of” relationships in a knowledge representation. It has the 13 sub-classes: formalize, characteristic, restrict, devise, human function, relational, communicate, reveal, facilitate, cumulate, partake, ingest, and consequence relationship.

4.1.2 Tangible Capital Asset Ontology Development

To support the design of message templates for the AI&CAR/TCA Reporting, the TCA_Onto was developed. The message templates represent header (meta information, e.g. name, from, to, etc.) and payload information (actual information content that actor-roles requires in a given transaction). The header information was captured from Trans_Dom_Onto and the payload information was captured from the TCA_Onto. The knowledge in the TCA_Onto was organized from four different perspectives or modalities. The individual asset represents the TCAs based on the type of the individual asset. According to PSAB (2009) and TCA (2012), individual asset has eight sub-classes: land, land improvement, building, building improvement, infrastructure, machinery and equipment, vehicle, and work in progress. The function based asset includes the TCAs based on the function they perform. Osman (2007) defined six such functions: control, access, protection, measuring, storage and conveyance assets. Commuting and processing was defined as part of this research work. The composition based asset represents the TCAs based on their aggregation in a given infrastructure system. For instance, system, sub-system, and component level (Osman, 2007). The sector based asset classifies the TCAs based on the sector to which they belong. It has two sub-classes: facility and infrastructure sector assets. The infrastructure sector asset has seven sub-classes: transportation, water, wastewater, solid waste management, gas, electricity, and telecom sector assets. The facility and infrastructure sector assets; specifically, the transportation, water, wastewater and solid waste management sector assets were further specialized and extended to develop detailed taxonomies as presented in Zeb and Froese (2014). Development of the detailed taxonomies of the gas, electricity, and telecom sector assets was omitted as these assets are generally not owned and operated by municipal infrastructure organizations and was covered in other existing ontologies. The TCA_Onto represents 345 classes of various TCAs in the facility and four infrastructure sectors. In addition, 1517 axioms were developed to explicitly describe TCAs in the domain of infrastructure management.

4.2 Development of the Transaction Formalism Protocol

The proposed TFP protocol is an eight-step procedure developed to define transactions in the domain of infrastructure management effectively and efficiently. The protocol was developed from two perspectives; TFP Specification and TFP Tool. The TFP Specification was developed from a conceptual perspective where each step of the protocol was modeled as a distinct function for which inputs, controls, mechanisms, tools/techniques, and outputs were defined. The TFP Specification was developed using the IDEF0 modeling technique. The TFP Specification provides the formal “instruction set” for creating transaction specifications as presented in Zeb and Froese (2013). On the other hand, the proposed TFP Tool includes a set of Excel-based forms and some guidance that the transaction development personnel can use to define transaction specifications. These steps are: assess needs—step 1, define As-is transaction map (TM)—step 2, develop To-be TM—step 3, collect information—step 4, design message template (MT)—step 5, review TM and MT—step 6, adopt and implement TM and MT—step 7, and monitor transaction specification—step 8. The forms for the Tool were developed in step 1, 2, 3, 4, 6, and 8. The forms were developed to capture information easily, accurately, and consistently while defining transactions. For step 5 and 7, only guidance was provided on how to perform these steps because no data is required to be captured in these steps. A brief description of these steps is as follows.

- **Step 1**—a comprehensive needs assessment is conducted to identify and select among a set of transactions that has the greatest potential for IT improvement. The assessment criteria include: manual/paper based transaction, criticality, frequency, importance, likelihood of the management, cost of the transaction, and contractual and regulatory requirements.
- **Step 2**—a preliminary As-is TM is developed based on the needs assessment.
Step 3—a To-be TM is developed that is an improved version of the As-is TM incorporating process, information, and mode improvements.

Step 4—required header and payload information is collected in this step.

Step 5—based on the collected information, MTs are defined.

Step 6—the designed TMs and MTs are reviewed for errors; if any, and make changes before implementation.

Step 7—the designed TMs and MTs are implemented in the Asset Information Integrator System.

Step 8—the implemented transaction specifications are monitored for continuous improvements.

5 APPLICATION AREA AND ASSET INFORMATION INTEGRATOR SYSTEM

The proposed TFP Tool was applied to one of the transactions identified through an IT survey (Zeb and Froese, 2012) conducted as part of this research work—AI&CAR/TCA Reporting. The municipal experts completed the needs assessment form using the above-mentioned criteria. The AI&CAR/TCA Reporting transaction was selected because it scored high against the assessment criterion. Despite the fact that the frequency of this transaction is not high, the municipal experts identified it as one of the potential transactions due to three reasons. Compliance with regulatory requirements—newly imposed regulatory requirements require municipalities to report asset inventory information in compliance with the Public Sector Accounting Board reporting requirements-3150 (PSAB, 2008) and condition assessment in compliance with the Statement of Recommended Practices, SORP reporting requirements (SORP, 2008). Manual/paper based transaction—currently, this transaction is manual as human interpretation of the information is required and organizations find it difficult and time consuming to compile, extract, and compare the TCA information. Costly—this transaction is costly in terms of time spent in extracting and comparing information.

The AI&CAR/TCA Reporting is a communication process in which different municipalities report their AI&CAR/TCA information to the provincial government for financial planning and funds allocation. The provincial government collects and analyzes this information to: (i) understand the long-term funding needs of different municipalities for infrastructure management; (ii) develop a consistent and planned approach to fund allocation; and (iii) to present the case to the federal government for additional funding, if required. This reporting also helps municipalities to update asset data on a regular basis, resulting in better management of their infrastructure systems. The AI&CAR/TCA Reporting case study transaction was used in two ways. First, the TFP Tool was applied to formalize this transaction to develop the transaction specification for the application area. Second, the transaction specification for AI&CAR/TCA Reporting was implemented to develop the prototype system—the AIIS.

The proposed AIIS was developed for the reporting of the AI&CAR/TCA information between the municipal and provincial government. Presently, the municipal organizations exchange this information in a manual and ad hoc way in the form of a PDF or Word file due to heterogeneous and inconsistent data formats. To transform to a more computer-based exchange of the TCA information, the AIIS implemented standardized MTs that were defined based on the knowledge represented in the two ontologies developed as part of this research work.

The proposed AIIS is a web-based prototype system that was implemented using the SharePoint platform. This platform was adopted due to its robustness and ease of use (Microsoft, 2012). The proposed AIIS collects the TCA reports received from various municipalities via standardized MTs, as shown in Figure 1, and integrate them with back-end applications (MS Excel, Excel Services within SharePoint, SharePoint Reporting Services, etc.) for further processing and analysis.
Figure 1: Asset information integrator system

6 EVALUATION

The ontology-supported TFP is composed of two parts and, therefore, the evaluation was separately conducted for each part: ontology and protocol.

Ontology evaluation—both the Trans_Dom_Onto and TCA_Onto were evaluated through industry experts using a criteria-based approach (Gomez-Perez, 2001). The criteria used to validate both the ontologies include: completeness (Gomez-Perez, 1996), correctness (Guarino, 1998), and clarity (Gruber, 1995 and Yu et al., 2007). Clarity judges the level to which a knowledge representation is clear and understandable. The class description communication error was used to measure clarity of these ontologies. Completeness judges the level to which a knowledge representation is incomplete. Completeness is measured in terms of incompleteness. Correctness measures accuracy of the knowledge representation from a real-world perspective. The identity error was used to measure the correctness of both the ontologies. The Trans_Dom_Onto was validated through three domain experts using a structured interview approach. Each of them had more than 15 years of experience in different civil engineering fields. They were extremely familiar with the transportation sector while moderately familiar with the water, wastewater, and solid waste management sector. In addition, they were moderately familiar with the data or information modeling and the process of communication formalization. Similarly, the TCA_Onto was validated through three experts. Each of the experts had more than 15 years of experience in managing different types of infrastructure systems. They were extremely familiar with different infrastructure systems being owned, operated, or managed by municipalities. They were moderately familiar with data or information modeling and TCA reporting under PSAB-3150 reporting requirements. Two separate structured questionnaires were presented to the respondents wherein questions were organized according to three assessment criteria: clarity, completeness, and correctness. For each question, a multi-sheet table was developed to reflect various concepts in rows and respondents’ responses in the columns. The respondents were asked to rate a given concept on a scale of 1 (strongly disagree) to 5 (strongly agree) under each of the three assessment criteria. The responses were recorded for each concept reflected in the tables developed for clarity, completeness, and correctness, and an average score was calculated. In both ontologies, the average score ranged from 4 (agree) to 5 (strongly agree), which indicates that all the respondents were in universal agreement on the clarity, completeness, and correctness of the knowledge represented in the Trans_Dom_Onto and TCA_Onto.

Protocol evaluation—the proposed TFP Tool was validated through experts using a criteria-based approach. Adesola and Baines (2005) identified three criteria: feasibility, usability, and usefulness to validate an improvement methodology, which were adopted with modifications to validate the proposed TFP Tool. An additional criterion—generalizability—was also identified, defined, and used to validate the TFP Tool. Feasibility assesses the appropriateness of the TFP Tool in terms of completeness, correctness, and reasonableness. Usability assesses the ability to learn and work with the TFP Tool, which was evaluated using three measures: understandability, applicability, and guidance/supportability.
Usefulness assesses the utility and value of the tool in terms of five measures: effectiveness, efficiency, consistency, changeability/adaptability/customizability, and reusability. Finally, generalizability assesses the applicability of the Tool across a wide variety of communications within AEC/FM and non-AEC/FM industries, using a single measure of generality. A set of questions was framed under each criteria. The experts answers were recorded on an agreement continuum rating system: unable to rate (0), strongly disagree (1), disagree (2), neither agree nor disagree (3), agree (4), and strongly agree (5). Answers were recorded for each question given under feasibility, usability, usefulness and generalizability and average scores were calculated. The resulting average scores ranged from 4 (agree) to 4.8~5 (strongly agree), indicating that the proposed TFP Tool was feasible, usable, useful, and generic.

7 CONCLUSIONS

Presently, data exchange in the domain of infrastructure is performed on a manual and ad hoc basis. The growing trend is to transform this manual data exchange to a more formalized computer-to-computer based exchange of information. To accomplish the paradigm shift, an ontology-supported TFP was developed. The proposed protocol consisted of two parts: ontologies and protocol. To support the design, implementation, and management of transactions in the domain of infrastructure management, two ontologies were developed: the Trans_Dom_Onto and TCA_Onto. Also, the protocol—an eight-step procedure was developed at two levels of abstraction: TFP Specification and TFP Tool. The TFP Specification is a conceptual model that makes a foundation for the TFP Tool. On the other hand, the TFP Tool includes a set of forms and guidance developed for specific steps of the protocol. The TFP Tool was applied in the domain of infrastructure management to develop transaction specifications for the AI&CAR/TCA Reporting, which was implemented in an AIIS. Both the ontologies and protocol were validated through industry experts using criteria based approach. The evaluation results indicate that the transaction development personnel (i.e. transaction analyst, process modellers, software developers, industry experts, and users) can use the protocol effectively and efficiently.

A DIVIDE-AND-CONQUER ALGORITHM FOR 3D IMAGING PLANNING IN DYNAMIC CONSTRUCTION ENVIRONMENTS

Abstract: On construction sites, engineers need real-time geometries of workspaces for reducing spatial conflicts between construction activities, monitoring construction progress, and controlling construction quality. The dynamic nature of construction environments, however, poses challenges to collecting sufficient and high-quality geometric data to support such needs. Effective uses of advanced 3D-imaging technologies also rely on engineers’ experiences. Manual imagery data collection often results in missing or low-quality data or unnecessary over-detailed inspection and exponentially long computation time, which may bring extra cost to construction project. To overcome these challenges of 3D data collection, the study presented in this paper proposes a new automatic 3D imaging planning method for guiding efficient and effective 3D imagery (e.g., LiDAR) data collection in dynamic environments. This method first establishes a sensor model of laser scanners, and then establishes a divide-and-conquer algorithm for achieving rapid and precise 3D imaging planning for dynamic construction site. For a given jobsite, this algorithm creates a graph that represent objects or features having specific data quality requirements (e.g., level of accuracy, and level of detail) as nodes, and spatial relationships between these objects as edges (e.g., distance, line-of-sight). A graph-coloring algorithm decomposes such a graph into subgraphs for finding their “local” optimal 3D imaging plans. A solution aggregation algorithm then combines those “local” optimal data collection plans into a complete 3D imaging plan for the complete graph representing the scene. Testing results indicate that the divide-and-conquer algorithm can improve the performance and computational efficiency of 3D imaging planning and producing better results than the conventional 3D imaging planning methods.

1 INTRODUCTION

In construction projects, failing to acquire timely, detailed, and accurate spatial information for decision-making may cause low quality, low productivity, and accidents. On construction jobsites, one key reason of deficient 3D imaging data collection is the dynamic nature of construction projects. Different tasks involve different construction environments, facilities, construction activities, and objects. Moreover, the specific requirement of field data will be changing even in the same task in different environments during different stages of construction. This dynamic nature of construction projects not only requires a variety of 3D data, but also brings difficulty of efficient and effective spatial data collection. The problem becomes more serious when the users of technologies have limited experiences of using imaging systems in changing workspaces. Bad data collection will cause low quality (missing, inaccurate, or less detailed) data, or unnecessary interference of jobsite activities. Reliable sensing method and timely, comprehensive data collection of spatial data is necessary in dynamic construction projects.
Compared to traditional inspection methods (e.g. tapes, laser tapes, Global Navigation Satellite System), 3D imaging technologies, such as laser scanning and structure from motion (SFM), is able to provide fast and comprehensive 3D imageries of construction jobsite. However, currently, construction engineers can only manually plan 3D-imaging process based on their intuition or experiences. This experience-based data collection may not effective or efficient, because 3D imaging data collection is a complicated process that involves 3D space domain and time domain configuration, as well as multiple scanner parameters. On one hand, low quality 3D imaging data may impede effective decision making on the site. On the other hand, redundant data collection is wasting time and causing frequent interferences with construction operations during data collection. In addition, hiring an experienced professional for data collection can be very expensive (thousands of dollars per day). An automatic laser-scanning planning method is thus necessary to configure the parameters of laser-scan data collection (e.g. scan position, parameters on the scanner) systematically according to the dynamic construction information needs in a changing environment while maximizing data collection efficiency. The proposed algorithm will help to reduce the cost caused by decision-making error that result in inaccurate inspection, interruption of construction processes by data collection, and training or hiring laser-scanning professionals.

2 BACKGROUND RESEARCH

3D imagery data quality has great influence on the results of data processing (e.g. more precise result of BIM model). One research provided a sensor model describing how various data collection parameters will influence data quality metrics, e.g. level of detail (TANG and ALASWAD. 2012). Another research proposes a model for estimating edge loss in laser scanned data by considering the impacts of various factors, such as scanning distance, density of data and incidence angle on the edge loss (Tang, Akinci, and Huber 2009).

Researchers studied 3D imagery sensor planning problem in order to capture high quality 3D imagery data. Traditional 3D imagery sensor (e.g. LIDAR) planning focuses on fixed sphere planning about a single object (Latimer et al. 2004; Pito 1996; Son, Park, and Lee 2002; Lee, Park, and Son 2001). In mechanics engineering domain, researchers produced an automatic process planning system based on visibility analysis dealing with free form surface (Fernández et al. 2007). On the other hand, fewer researchers focus on sensor planning problem in construction background. One planning algorithm chose sensing locations based on clustered construction information goals and then generated paths to minimize the transit cost between clusters (Latimer et al. 2004). However, this approach did not clearly show the inspection goal and did not take the data quality requirement into consideration (e.g. LOD, LOA). In another sensor planning approach, researchers used 1m³ cubes to represent the construction to obtain the visibility of any cube, and then next-best-view (NBV) scan planning approach could generate the scan positions (Blaer and Allen 2009). This algorithm also ignored data quality and scan efficiency. A third sensor planning research proposed a scan planning algorithm using the next-best-view idea (Song, Shen, and Tang 2014). The major limitation of directly using next-best-view scan planner was the scan resolution was constant for all the scan positions, which might lead to longer calculation time and redundant data collection in areas where the resolution requirement is low. Therefore, the potential of improving the performance of sensor planning problem in construction area is huge.

3 PROBLEM DESCRIPTION AND TERM DEFINITION OF LASER-SCANNING PLANNING

3.1 Problem Description

The goal of 3D imaging planning is to determine positions and scanner parameters of each scan to ensure the collected 3D image meets inspection requirements with optimal time consumption. We can describe the scan planning problem using the following IDEF0 process model, showing in fig.1. The input includes the inspection goals, i.e. specific areas in the jobsite that field engineers need inspect with certain accuracy. The constraints are sensing model of laser scanner, time, cost, and space limits of the dynamic jobsite. The outputs are the scan positions and scan parameters.
The main challenges of 3D imaging planning are as follows: 1) the measurement model of 3D imaging is not clear. 2) It involves both 3D space domain and time domain; 3) the dynamic nature of jobsite require a high demand for reliable data quality and least possible data collection time. We will focus on these challenges in our proposed method.

![Diagram of IDEF0 process model of laser-scanning planning algorithm]

### 3.2 Feature Point

Feature points are our inspection goals indicate areas we care about in 3D imaging process, which are. For 3D-imaging data collection, obtained imageries should contain all the geometric information in need; on the other hand, we want to avoid imageries containing unneeded dense data that waste time for data collection and processing. For example, engineers tend to avoid densely sampling simple geometries (e.g. flat walls) for saving time to focus on complex shapes, such as edges, openings, and decorations. Therefore, we can ensure the completeness and avoid redundancies of data collection only if we provide prior knowledge about geometric complexity. In this approach, we use “feature points” to symbolise objects or area with such high geometric complexity. For instance, if we know the coordinate of the four corners of a wall, we can determine the direction and size of the wall; if we know the coordinates of two ends of edges, we can determine the edges as well as related walls. Such feature points describing objects with high geometric complexity are feature points.

Feature point information needed for 3D imaging planning consists of 3 terms: 1) coordinates of feature points, 2) the normal vector of the wall each feature point is on, and 3) the level of detail (LOD) requirement of each feature point. The first 2 terms can describe the location of the area with geometrical complexity; the third term can describe the data quality requirement of the corresponding area (detailed description in the next section). For different construction environment and different tasks, the need for feature point information varies, which we will deeply discuss in further study.

Currently we use three sources to obtain feature point information: building information model (or jobsite plan), precious scan data, jobsite photographs. Fig.2 shows the three sources of feature point information: as designed model; previous 3D-imaging point cloud; series of jobsite photographs.
3.3 Level of Detail

3D imaging data collected by a laser scanner is a point cloud. The data quality of a 3D-imaging point cloud consists of two indices: level of detail (LOD) and level of Accuracy (LOA). LOD represents the point density of a certain area in a point cloud, on which this research will focus. Low point density indicates no sufficient information for further data processing and modeling, while an excessively high point density means extra labor and time consuming in data collection.

There is no well-accepted definition of LOD of 3D-imaging point cloud. However, in literature, researchers used two different methods to describe data density of point clouds. The first method was using number of points in fixed area (e.g. 1 square cm, 1 square meter, etc.) to define the data density (Dai et al. 2013). The second method involved two parameters: 1) distance between two adjacent laser dots within a beam path and 2) distance between beam paths (MacKinnon et al. 2009). In our research, we cared about the 3D-imaging data density in both horizontal and vertical dimension, so we defined Vertical LOD and Horizontal LOD using the second method, shown in fig.3:

Vertical LOD: Keep the horizontal rotation of the laser beam fixed, the distance between current laser dot and the next laser dot after rotation $\delta_v$ in the vertical plane.

Horizontal LOD: Keep the vertical rotation of the laser beam fixed, the distance between current laser dot and the next laser dot after rotation $\delta_v$ in the horizontal plane.
3.4 Feasible Area

In our approach, we use the concept “feasible area” to show the relationship between sensor model of laser scanner and the LOD requirement of a feature point. For any given feature point we need to know where to put the laser scanner to acquire point cloud with a required LOD. Thus, the set of qualified scan position is the feasible area of this feature point. To ensure the LOD of every feature point, we need at least one scan position in each feasible area (obviously, we can utilize the overlapping of feasible areas).

The definition of feasible area is the area on the ground where to put the laser scanner with given laser scanning resolution \( \delta_v \) & \( \delta_h \) so that the collected data of certain feature point will satisfy the LOD requirement. For certain feature point, it is obvious that the higher the laser scanner resolution is, the larger the feasible area is.

Without losing generality, we set the coordinate of a feature point as \((0,0,a)\) while the x-z plane represents the wall. If we put the laser scanner at the point\((x,y,h)\), for vertical LOD requirement we have:

\[
[1] \quad s_v = \frac{\delta_v(\sqrt{x^2+y^2}+(a-h)^2)}{\sqrt{x^2+y^2}} \leq LOD
\]

So \(2|a - h| \cdot \delta_v\) is the minimum \(s_v\) that we can obtain at this feature point, which comes from the nature of inequality.

For horizontal LOD requirement, we have:

\[
[2] \quad s_h = \frac{\delta_h(x^2+y^2+(a-h)^2)}{\sqrt{x^2+(a-h)^2}} \leq LOD
\]

So \(|a - h| \cdot \delta_h\) is the minimum \(s_h\) that we can obtain at this feature point.

Fig.4 shows the shape of feasible area of the vertical and horizontal LOD requirement at height=5m, LOD=0.013m (1/2 inch), resolution=1/4:

4 DIVIDE-AND-CONQUER ALGORITHM OF 3D IMAGING PLANNING

4.1 Overview

Using the terms defined in previous chapter, we can rephrase the goal of scan planning in dynamic construction site as follows: to determine optimal scan positions and corresponding scan resolution, so that the scans will cover all the feature point with a required LOD.

Previous approaches consider the jobsite as a whole, so the scan resolutions for all scan positions are fixed. In this case, the search area of possible scan positions maybe quadratically larger, leading to longer calculation time. Moreover, applying high scan resolution for less important area may be redundant...
and causes unnecessary time and labor consumption. To overcome this drawback, we divide the jobsite into parts according to the layout of the feature points, and then generate scan plan for each part. This divide-and-conquer method consists of three steps: 1) divide the whole jobsite into parts, according to the distribution of feature points; 2) generate scan positions and resolution in different parts; 3) completeness checking and generate the global scan plan. Fig.5 shows the framework of this divide-and-conquer algorithm of 3D imaging planning.

4.2 Divide: Feature Points Clustering

4.2.1 Visibility Conflitction Analysis of Feature Points

Visibility analysis means check whether two feature points can be scanned in a single scan. Obviously, two feature points with visibility confliction (cannot be scanned in a single scan) cannot be clustered into the same group. Therefore, the first step of feature point clustering is visibility confliction analysis and generates visibility confliction relationship between any pair of feature points.

![Current state of dynamic construction site](image1)

![Feature points information](image2)

![Feature points Clustering](image3)

![Scanning position detection and resolution configuration in each group](image4)

![Finalizing Scan Configurations](image5)

**Figure 5:** Frame work of divide-and-conquer algorithm of 3D imaging planning

![Figure 6: Using graph theory to cluster feature points: each edge indicates feature points with visual confliction, and different color shows the clustering result.](image6)

In the proposed scan planning algorithm, we used a series of rules assessing the visibility relationship of any pair of feature points. Parameters involved in these rules are distance and relative orientation. For example, two feature point facing the opposite direction and “back to back” (e.g. on different sides of the same wall) are visibility conflict with each other. Another example is: if the distance between two feature points are greater than 5 times of the maximum height of all feature points, these two feature points are visibility conflict, for we need to use extra high resolution to cover such two feature points. Due to the limited space, we do not represent all the visibility checking rules here. We will give detailed discussion in other literatures.

4.2.2 Clustering Feature Points into Groups According to Visibility

We use the following math problem to represent feature points clustering according to visibility confliction condition: A set \{an\} has \(n\) elements. Any element \(a_i\) has a known relationship (‘conflict’ or ‘not conflict’) with any other element \(a_j\) in this set. A minimum positive integer \(m\) is to be found that the set \{an\} can be divided into \(m\) subsets, so that all the elements in the subsets are not conflict with each other, which means any conflict elements are in different subsets.

We apply the feature point clustering problem to graph theory if we use vertices in a graph to show all feature points and edges between feature points to show visual confliction. If we use different color of vertices to show different groups, two vertices connected by an edge cannot be the same color. So the
smallest number of colors needed to color the whole graph, which called the ‘chromatic number’ of the graph, means the least groups to partition the feature point set into without visual confliction. ‘Chromatic number’ is a heavily discussed topic in modern graph theory and there is multiple coloring algorithm available. Fig.6 shows the idea of grouping feature points according to visibility confliction. Different colors indicate different groups.

4.3 Conquer: Scanning Position Detection and Resolution Configuration in Each Group

4.3.1 Framework

The scan position and resolution detection in each group consists of four steps:

1. Determine the sparsest resolution that can scan all the feature points with required LOD. Because we treat the feature points in different group individually, we need to determine the sparsest resolution in current group. Therefore, we can guarantee sensing all feature points in this group. The sparsest resolution is the initial value of the scanning resolution in this group. Due to page limit, we will show the calculation of sparsest resolution for one group in future papers.

2. Use next-best-view (NBV) algorithm to calculate the scan position and resolution. The input of NBV algorithm is the feature point information in this group and the initial resolution. The output of this algorithm is the scan position(s) in this group; the feature points that remain un-scanned in this group (called “garbage”). Section 4.3.2 will discuss next-best-view algorithm in detail.

3. Use higher resolution and check scanning time. The 3D-imaging time of a single scan is the function of resolution. The higher scan resolution means longer scanning time. After calculating scan position(s) with the lowest scan-able resolution, we try higher resolution and process the next-best-view algorithm again check the total scanning time in order to optimize the scan resolution for short scanning time. If we use a higher resolution, we may apply fewer scans and the total scanning time may be shorter than having more scans but using lower resolution. Therefore, if the total scanning time is shortened we repeat this process, until the total scanning time stops shortening.

4. After we process all groups, restore all feature points remain un-scanned as a new group (garbage collection). After generating scan positions in each group, there may be some feature point(s) remain un-scanned called garbage. The reason why we leave some feature points un-scanned is for higher efficiency. For instance, we have 10 feature points in a group. The first scan covers five feature points and the second scan covers four feature points. So there is one feature point remain un-scanned. If we take one more scan just for this feature point, this scan is inefficient. Instead of doing so we consider this remaining feature point as “garbage” and we combine garbage from every group as a new group. Then we can deal with the “garbage” group using next-best-view algorithm.

4.3.2 Next-best-view Algorithm

The next-best-view algorithm will generate scanning position according to the resolution needs of feature points.

1. For each feature point, this algorithm will generate feasible area represented by many small squares of 0.5 by 0.5 meter. Every square is a potential scan position.

2. Then we define the temperature of one square as number of feasible areas that overlapping at this square. The heat map visualizes such temperature across all squares of the whole site. The algorithm first chooses the area consisting of squares with the highest temperature as a scan position. If more than one areas have the equally highest temperature, the algorithm will randomly select one. The algorithm then deletes all the feasible spaces that covers the selected area and update the heat map.
3. After that, the algorithm repeats step 2 in the updated heat map until no more than 7% (empirical) of all feature points left. The positions chosen by such a progressive process will be a scan plan that covers all feature points with satisfied LODs.

### 4.4 Combine: “Garbage Processing” and Finalizing Scan Configurations

Garbage processing deals with a group of feature points consisting of all the remaining feature points from each group using next-best-view algorithm. The framework is the same with section 4.3; however, there are some technical details in difference. “Garbage processing” consists of the following seven steps:

1. Combine feature points remaining un-scanned as a new group

2. Examine whether previous scans has already cover any of the feature points. If so, delete these feature points from the “garbage” group, because the scans in Group A may cover the “garbage” feature points in Group B.

3. Determine the lowest scan-able resolution in “garbage” group.

4. Use the next-best-view algorithm to calculate the scan positions for “garbage” group. If a scan will only cover 2% of total number of feature points, we consider it inefficient and discard this scan. This is a trade-off between data quality and scanning efficiency. In addition, doing this improves the robustness to outlier feature points due to inaccurate data or model.

5. Repeat step 2-3 and process all remaining feature point (either scanned or discarded).

### 5 CASE STUDY AND DISCUSSION

To validate the proposed 3D imaging planning algorithm, we conducted the data collection using the proposed automatic planning method, and compared the quality of the collected data against data collected by an experienced user of laser scanners. This experiment focused on a campus building, ASU McCord Hall. Fig.7 shows the front view photo and google map photo of Arizona State University (ASU) McCord Hall.

![Figure 7: Photos of Arizona State University (ASU) McCord Hall: (a) front view photo, (b) google map photo.](image)

5.1 Feature Point Information Collection

The researchers obtained the building information model of ASU McCord Hall and then picked feature points as follows: corner of the walls, corner of the windows and doors because these points contain important geometry information. Knowing the coordinates of these feature point we will know the layout of
the whole building. Then we manually extract the coordinates of these defined feature points shown in fig.8. Feature point information consists of the 3D coordinates, normal vector, and LOD requirement of each feature point. We set the LOD requirement of each feature point as 25mm (one inch).

![Building information model](image1)

![Feature points extracted from building information model](image2)

Figure 8: (a) Building information model. (b) Feature points extracted from building information model.

### 5.2 3D Imaging Planning

According to feature point information, the 3D-imaging planning algorithm generated the scan positions and corresponding scan resolutions as shown in fig. 9(a).

![Scan planning result generated by proposed algorithm](image3)

Figure 9: Scan planning result generated by proposed algorithm. In (a) we need to choose one scan position in each colored block, while in (b) we use brown stars to show the chosen scan positions.

In fig.9, red circle means the XY coordinates of all feature points, indicating the layout of the jobsite. Color blocks consisting of colored dots are applicable scan positions. We need to take one scan for each separated color block and the scan positions can be any dots in the block. For saving transportation time, we chose the points that close the building. Considering actual environment, brown stars are the actual scan positions, as shown in fig.9 (b). According to the scan planning algorithm, resolution for all scans are the same, being ½. At last, we scanned the building following the scan plan generated by the algorithm.
5.3 Comparing the Automatic Laser Scan Planning against Manual Planning

We acquired the point cloud of ASU McCord Hall through data collection and registration. After manually checking the data quality we found: the LOD of 100% of the feature points are under 0.025m (1 inch). Fig.10(a) shows the overall 3D-imaging point cloud of ASU McCord Hall. Fig.10 (b)–(d) show the neighbourhood of four random feature points. We can see from fig.10 that the data quality satisfied both the horizontal and vertical level of detail. On the other hand, in the 3D imaging data following manual planning, we found only 60% feature points are with required LOD. This result shows that automatic 3D imaging planning algorithm will guarantee the collected data quality.

6 CONCLUSION AND FUTURE STUDY

This paper propose a 3D imaging planning method, output all scan position and resolution that field engineers can follow to accomplish efficient and effective 3D-imaging data collection. Compared to previous data collection planning method, the new 3D imaging planning algorithm not only satisfy the completeness of data collection, but also focus on guarantee the collected data quality. Evaluation results on a campus building show the effectiveness of the proposed algorithm. The 3D imaging plan generated by the algorithm will lead to high quality data collection without time and labor waste.

On the other hand, this paper identified several challenges for the further developments of this scan planning approach: 1) the feature point information generation relies on manual work; also the registration of scanned point clouds is also a manual process, which is time consuming; 2) the algorithm didn’t consider the environment of the jobsite; sometimes the given scan position may not be accessible; 3) we can also integrate the time domain (schedule, or work flow) in to the scanning plan so that the proposed data collection plan will better inform the construction productivity analysis and real-time control. The authors will address these challenges in future studies.

Figure 10: 3D imaging result of ASU McCord Hall. (a) point cloud; (b), (c), and (d) are neighbourhood of three random feature points, showing that the collected data satisfy the LOD requirement (0.025m).

A SEMANTIC SIMILARITY-BASED METHOD FOR SEMI-AUTOMATED IFC EXTENSION

Jiansong Zhang¹ ², and Nora El-Gohary¹
¹ Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, USA
² jzhang70@illinois.edu

Abstract: The Industry Foundation Classes (IFC) schema was designed as a comprehensive data schema to cover information of all phases of a building project and all disciplines of the AEC industry. But due to its limited coverage of details in certain subdomains, the IFC schema needs to be extended for many information processing tasks such as information extraction for automated regulatory compliance checking. Previous IFC extension efforts typically extended IFC in an ad-hoc and subjective manner. A more objective, standardized, and application-independent method for extending IFC is, thus, needed. To address this gap, a new method for extending the IFC schema objectively and semi-automatically is proposed. The proposed method utilizes a semantic relation-based concept matching algorithm to find concepts – from domain documents – to incorporate into the current IFC schema class hierarchy. It utilizes the hypernymy, hyponymy, and synonymy semantic relations. This paper focuses on presenting the proposed semantic relation-based concept matching algorithm: the ZESeM (Zhang and El-Gohary Semantic Matching) algorithm. The ZESeM algorithm was tested on processing concepts from Chapter 12 of the International Building Code 2006. Different semantic similarity computation methods were tested in combination with the proposed ZESeM algorithm. The ZESeM algorithm was evaluated based on adoption rate, which is the number of concepts found by the ZESeM algorithm that are adopted divided by the total number of concepts found by the ZESeM algorithm. An adoption rate of 85.8% was achieved. The proposed semantic relation-based concept matching algorithm offers a more efficient concept matching method for semi-automatically extending the IFC schema.

1 INTRODUCTION

Building projects must comply with various regulations, such as the International Building Code (IBC), the Americans with Disabilities Act, the federal Fair Housing Act, and the Occupational Safety and Health Administration regulations. Due to the large amount of requirements that are covered by these regulations, the manual process of compliance checking is costly, time-consuming, and error-prone (Zhang and El-Gohary 2013). In comparison to manual compliance checking, automated compliance checking (ACC) is expected to reduce the time, cost, and errors of the compliance checking process (Zhong et al. 2012, Eastman et al. 2009). To conduct ACC, building information need to be represented in a computer-processable format.

The IFC schema is the most popular building information modeling (BIM) data schema and is becoming the official ISO standard. It was designed as a comprehensive data schema that covers information of all phases of a building and all disciplines of the architectural, engineering, and construction (AEC) industry to support a variety of tasks during a building life cycle including ACC. However, the IFC still lacks
necessary information (i.e., key concepts and relations) that is needed to perform ACC. Different ways to extend the IFC were proposed and/or utilized in previous ACC efforts, such as creating new project parameters (Nguyen and Kim 2011, Sinha et al. 2013), developing new Information Delivery Manuals (IDM) and Model View Definitions (MVDs) (Nawari 2011), and adding new data items (Kasim et al. 2013). Despite the importance of these efforts, previous extension methods mostly extended the IFC in an ad-hoc and subjective manner (i.e., relying on subjective judgements and case-specific developments), and their resulting extended models usually still suffer from missing essential ACC-related information (Niemeijer et al. 2009, Martins and Monteiro 2013). A more generalized and objective method (i.e., relying on rigorous techniques/algorithms for objective judgments that are consistent across different cases) for extending the IFC is, thus, needed.

To address this gap, the authors developed a new method for extending the IFC schema objectively and semi-automatically. The proposed method utilizes semantic natural language processing (NLP) techniques to extract concepts from construction regulatory documents (e.g., building codes) and insert the extracted concepts into the IFC concept hierarchy. NLP aims to enable computers to understand and process natural language text in a human-like manner (Liddy 2001). One key challenge that is faced when developing an IFC extension method is how to relate concepts with no shared terms (e.g., "outdoors" and "outside horizontal clear space"). To address this challenge, in the framework of the proposed IFC extension method, the authors developed a new semantic relation-based concept matching algorithm: the ZESeM (Zhang and El-Gohary Semantic Matching) algorithm. This algorithm aims to match concepts based on their semantic relations. This paper presents the proposed IFC extension method, with a focus on presenting the proposed ZESeM algorithm and the results of testing the algorithm on processing concepts from Chapter 12 of IBC 2006.

2 BACKGROUND

2.1 Natural Language Processing

Natural Language Processing (NLP) is a subdomain of artificial intelligence that aims to enable computers to understand and process natural language text and speech in a human-like manner (Cherpas 1992). NLP has a wide range of applications, such as text classification (Zhou and El-Gohary 2014), information retrieval (Khhokale and Atique 2014), information extraction (Zhang and El-Gohary 2013), text understanding (Karthikeyan and Karthikeyani 2013), and machine translation (Zhao et al. 2014). The analysis used in NLP is categorized into the following levels: (1) morphology, which is the analysis of meaningful components of the words; (2) syntax, which is the analysis of the structural relationship between words; (3) semantics, which is the analysis of meanings of words; (4) pragmatics, which is the analysis of how language is used to accomplish goals; and (5) discourse, which is the analysis on joining of linguistic units larger than utterance and words (Kumar 2011). NLP analysis in each subsequent level is more difficult than its previous level; and the results of the analysis in each subsequent level is more useful than its previous level. State-of-the-Art NLP techniques performed well at the first two levels and is developing fast at the semantic level.

2.2 Semantic Similarity

Semantic Similarity (SS) is the conceptual/meaning distance between two entities such as concepts, words, or documents (Slimani 2013). Semantic similarity plays an important role in information and knowledge processing tasks such as information retrieval (Rodri guez and Egenhofer 2003), text clustering (Song et al. 2014), and ontology alignment (Jiang et al. 2014). The measurement of semantic similarity between two entities typically requires established relations (directly or indirectly) between the two entities in an underlying structured knowledge model. Taxonomy and ontology are two types of such knowledge models. A variety of SS computation methods are based on the use of these models.

There are two main types of information that are utilized by SS computation methods: (1) shortest path, and (2) least common consumer. Shortest path is the length of the shortest path (counting nodes or edges) between two entities in a structured knowledge model. Least common consumer is the lowest common superconcept of two entities in a structured knowledge model.
Examples of SS computation methods using shortest path information are Shortest Path Similarity and Leacock-Chodorow Similarity (Table 1). Shortest Path Similarity relies solely on the shortest path information to calculate the SS score between two entities. Leacock-Chodorow Similarity, on the other hand, utilizes the maximum depth of the structured knowledge model in addition to the shortest path information to calculate the SS score between two entities.

Examples of SS computation methods utilizing least common consumer information are Resnik Similarity, Jiang-Conrath Similarity, and Lin Similarity. Resnik Similarity utilizes only the information content of the least common consumer of two entities to calculate the SS score between the two entities. Jiang-Conrath Similarity utilizes the information content of the two entities themselves, in addition to the information content of their least common consumer, to calculate the SS score between the two entities. Lin Similarity takes one step further to use the ratio of the information content of the least common consumer of the two entities to the sum of the information contents of the two entities to calculate the SS score between the two entities (Resnik 1995).

SS provides a measure for semantic-level language analysis, which can be used for many applications that require concept matching. For example, for geographic information service matching, Wang et al. (2013) identified the use of SS as a key enabler of matching, and combined two types of SS measures to enhance the matching efficiency for geographic information services. For ontology alignment, Jiang et al. (2014) showed the importance of SS measurement by improving the performance over existing ontology alignment methods through the utilization of a new SS measure. For ontology mapping, Pan et al. (2008) achieved a maximum precision of 80% on ontology mapping using relatedness analysis. Their analysis utilized term-based matching and term co-occurrence statistics. Thus, their method is limited by the corpus used to calculate co-occurrences and may miss concepts that match through general semantic relations because it is difficult for any corpus to capture all semantic relations.

2.3 **WordNet**

WordNet is a lexical database of English developed by Princeton University. In WordNet, nouns, verbs, adjectives, and adverbs are grouped into synsets (sets of cognitive synonyms). Each of the nouns, verbs, adjectives, and adverbs category is organized into a subnet. Four types of semantic and lexical relations are used to link the synsets to one another: synonymy, hyponymy (sub-super or is-a relation), meronymy (part-whole relation), and antonymy (Fellbaum 2005). Synonymy is the semantic relation between different concepts who share the same meaning. For example, “girder” and “beam” share the same meaning of “a horizontal structural component for framework of buildings and other structures.” Hyponymy is a semantic relation where one concept is the hyponym (i.e., superclass) of the other. For example, “structural component” is a hyponym of “beam.” Hyponymy is the opposite of hyponymy, where one concept is the hyponym (i.e., subclass) of the other. For example, “beam” is a hyponym of
“structural component.” Meronymy is a semantic relation where one concept is “part of” another concept. For example, “window sill” is a meronym of “window.”

Because of the abundant semantic information structurally represented in WordNet, WordNet could be used as the knowledge model for computing SS scores. However, because the basic element in WordNet is a word (or term) rather than concept, WordNet could only be used to compute term-level SS scores using the above-mentioned SS computation methods. Thus, for the remainder of this paper, the above-mentioned SS computation methods are called term-level SS computation methods.

3 PROPOSED METHOD

To extend the IFC schema objectively, the authors developed a four-step method (Figure 1). The method: (1) extracts regulatory concepts from regulatory documents; (2) selects IFC concepts (i.e., concepts in the existing IFC concept hierarchy) that are most relevant to each extracted regulatory concept; (3) classifies the relationship between two concepts for each pair of extracted regulatory concept and selected IFC concept; and (4) constructs the new concept hierarchy by extending the original IFC concept hierarchy with the classified concept pairs. One thing to note in this four-step method is that once a regulatory concept has been added into the IFC concept hierarchy, the regulatory concept becomes an IFC concept.

For the IFC concept selection, a new semantic relation-based concept matching algorithm was developed: the ZESeM algorithm. The rest of the paper presents the ZESeM algorithm and its testing on extending the IFC concept hierarchy with regulatory concepts from IBC.

The ZESeM algorithm has three main components (Figure 2): (1) a term-based matching mechanism for finding IFC concepts that share term(s) with an extracted concept; (2) a semantic relation-based matching mechanism for finding related IFC concepts to an extracted concept; and (3) a semantic similarity (SS) scoring function for ranking related IFC concepts according to their relatedness to the extracted concept measured by SS scores.
Depending on the part-of-speech pattern of an extracted concept, the first term and last term of this concept are used to search for matched IFC concepts in both term-based and semantic relation-based matching mechanisms. If the extracted concept only has one term or the first term of the extracted concept is not a noun (i.e., singular or mass noun, plural noun, gerund, or proper noun), then only the last term of the extracted concept is used to search for matched IFC concepts. If the extracted concept has multiple terms and the first term of the extracted concept is a noun, then the first term of the extracted concept is used to search for matched IFC concepts, in addition to the last term. The matching term (first term or last term of the extracted concept) is compared with each term of an IFC concept, and the IFC concept is preliminarily selected if it includes at least one occurrence of the matching term of the extracted concept. In both matching mechanisms, stemming is used to ensure that matches in different forms of a word are not missed. For example, through stemming, “foot” could be matched with “feet”, and “reinforcing” could be matched with “reinforced”. In the term-based matching mechanism, the matching is pure term-based (i.e., string match) with stemming applied to both terms. In the semantic relation-based matching mechanism, the matching is based on three types of semantic relations: hyponymy, hyponymy, and synonymy (Fellbaum 2005).

For each extracted concept, term-based matching is applied first. If no matches are found using term-based direct matching, semantic relation-based matching is applied. As such, after the matching is conducted, there are three possible consequences: no matched IFC concept found, one matched IFC concept found, and more than one matched IFC concept found. In the first case, the extracted concept will be abandoned. In the second case, the matched IFC concept is selected. In the third case semantic-similarity based ranking is applied to find the highest ranked IFC concept; the highest ranked IFC concept is then selected.

Equation 1 shows the proposed SS scoring function that was used in the third case. The meaning of each parameter in the function is explained as follows:

1. \( SS_{RF} \) is the SS score between extracted concept \( R \) and IFC concept \( F \).

2. \( SS_{RmFk} \) is the term-level SS score between the matching term \( m \) in the extracted concept \( R \) and the \( k_{in} \) term in the IFC concept \( F \). \( SS_{RmFk} \) is calculated utilizing existing term-level SS score computation methods such as Shortest Path Similarity and Leacock-Chodorow Similarity.
3. \(2k/(n(n+1))\) is a term pair discount factor in which \(k\) is the ordinal number for the term \(F_k\) in IFC concept \(F\) and \(n\) is the length of \(F\) measured in number of terms.

4. \(1/(n)\) is the final discount factor which linearly discounts the summation using the length of the IFC concept.

\[ SS_{RF} = \frac{1}{n} \sum_{k=1}^{n} \left( \frac{2k}{n(n+1)} \right) SS_{termk} \]

The term pair discount factor \(2k/n(n+1)\) is based on the heuristic that in a multi-term concept, the contribution of each term’s carried meaning to the meaning of the whole concept decreases from right to left. The final discount factor \(1/n\) is based on the heuristic that the length of a concept name is related to its level in a concept hierarchy. The shorter the length of a concept name, the more general the concept is; and thus the higher its level in a concept hierarchy.

4 EXPERIMENTAL EVALUATION

The ZESeM algorithm was tested on processing extracted concepts from Chapter 12 of IBC 2006. IBC was selected because of its prevailing adoption in the United States (adopted by 46 states). Chapter 12 of IBC 2006 was then randomly selected. The longest span for each noun phrase in Chapter 12 of IBC 2006 was manually recognized and extracted as a concept. For example, concepts in the list \(L_1\) were recognized and extracted from Sentence \(S_1\). In total, 368 concepts were extracted. WordNet (Fellbaum 2005) was used to define the semantic relations between terms. Five term-level SS computation methods were tested in the ZESeM algorithm for comparison: Shortest Path Similarity, Leacock-Chodorow Similarity, Resnik Similarity, Jiang-Conrath Similarity, and Lin Similarity (Resnik 1995). The term-based matching and semantic relation-based matching mechanisms were evaluated separately. The evaluation was conducted using the measure of adoption rate, which was defined as the number of found IFC concepts that were adopted divided by the total number of found IFC concepts. The evaluation was conducted using a gold standard.

- \(S_1\): “The minimum net area of ventilation openings shall not be less than 1 square foot for each 150 square feet of crawl-space area.”

- \(L_1\): ['minimum_net_area', 'ventilation_openings', 'square_foot', 'square_feet', 'crawl-space_area']

The ZESeM algorithm was implemented using Python programming language (v.2.7.3). The "re" (regular expression) module in python was utilized to implement the matching mechanisms. The hypernymy, hyponymy, and synonymy relations in WordNet were utilized through the NLTK (Natural Language Toolkit) WordNet interface in python. The Porter Stemmer (Porter 1980) was utilized to implement stemming.

5 EXPERIMENTAL RESULTS

The experimental results for term-based matching and semantic relation-based matching are summarized in Table 2. The adoption rate for different term-level SS computation methods ranged from 80.7% to 87.1%. For term-based matching, the highest adoption rate exceeds the lowest adoption rate by 5.1%. For semantic relation-based matching, the highest adoption rate exceeds the lowest adoption rate by 2.2%. Table 3 shows some randomly selected example concepts that were extracted and matched using the different term-level semantic similarity computation methods, for term-based matching and semantic relation-based matching. The matched IFC concepts that were not adopted are shown in italics.

6 DISCUSSION

Shortest Path Similarity achieved the best adoption rate for both matching mechanisms. Shortest Path Similarity only utilizes the shortest path between two concepts in a concept hierarchy for SS score computation, whereas Leacock-Chodorow Similarity utilizes both the shortest path between two concepts and the maximum depth of concepts in the hierarchy and other term-level SS computation methods utilize information content of the least common consumer (i.e., the lowest concept in the concept hierarchy that is the superclass of the two concepts). The higher performance of Shortest Path Similarity over Leacock-Chodorow Similarity indicates that the additional information of concept depth did not help in concept matching. The higher performance of Shortest Path Similarity over Jiang-Conrath Similarity, Resnik Similarity, and Lin Similarity indicates the advantage of the shortest path over the information content of the least common consumer in measuring semantic similarity for concept matching. Thus, based on the comparative experimental results of different term-level SS computation methods, the Shortest Path Similarity was selected as the term-level SS computation method in the ZESeM algorithm.

Both term-based matching and semantic relation-based matching achieved good performance of over 80% adoption rate. The examples in Table 3 show the effectiveness of the ZESeM algorithm. The matches between “interior spaces” and “space” and between “square foot” and “feet” show the effectiveness of term-based matching, including the use of stemming. The matches between “floor joists” and “beam”, between “enclosed attics” and “additional story”, and between “cornice vents” and “openings” show the effectiveness of semantic relation-based matching in leveraging the semantic relations between terms to find concept matches that would have otherwise been missed (if only utilizing term-based matching, without the use of semantic information, because those concept pairs do not share any terms).

The processing using term-based matching has larger variation in performance than that using semantic relation-based matching (adoption rate relative difference of 5.1% compared to 2.2%) among the term-level semantic similarity computation methods. Because term-based matching can easily find more candidate IFC concepts to match than semantic relation-based matching, more candidate IFC concepts lead to a higher probability of variability in performance. However, semantic relation-based matching finds semantically related concepts that cannot be found using term-based matching. Thus the combination of semantic relation-based matching and term-based matching finds more matched concepts than using either one of them.

7 LIMITATIONS AND FUTURE WORK

One limitation of this study is that only semantic relation-based matching on unigram (single terms) was used for finding semantically related IFC concepts to an extracted concept. While the combinatorial nature of term meanings [i.e., the meanings of single terms (e.g., “exterior” and “door”) in a concept name are combined to form the overall meaning of the whole concept (e.g., “exterior door”)] renders this unigram method effective, there may be cases where semantic relation-based matching on bigram (pairs of terms) or multigram (groups of three or more terms) could be effective. As such, in future work, the authors plan to extend the semantic relation-based matching mechanism to incorporate semantic relations between bigram and multigram to test whether such bigram or multigram considerations could further improve the performance of concept matching.

8 CONCLUSION

This paper presents a new natural language processing (NLP)-based method for extending the IFC schema objectively. As part of the proposed IFC extension method, a new semantic relation-based concept matching algorithm, called ZESeM algorithm, was developed. The ZESeM algorithm utilizes both term-based matching and semantic relation-based matching to find matching IFC concepts for extracted regulatory concepts. A new function was proposed to compute concept-level semantic similarity (SS) scores between concepts based on their term-level SS scores. The proposed algorithm was tested on finding matching IFC concepts for extracted concepts from Chapter 12 of IBC 2006. The experimental results verify the effectiveness of the proposed concept-level SS function and the proposed ZESeM algorithm in concept matching. An 85.8% adoption rate was achieved. For term-level SS computation, Shortest Path Similarity showed the best performance. One limitation of the proposed method is that only unigram (single terms) semantic relation-based matching was used, while bigram or multigram semantic relation-based matching may further improve the matching performance. In their future work, the authors plan to extend the semantic relation-based matching mechanism to further test the effectiveness of bigram and multigram semantic relation-based matching.

AXIOLOGY-BASED VALUE QUANTIFICATION MODELING FOR BUILDINGS

Lu Zhang1 and Nora M. El-Gohary1
1 Department of Civil and Environmental Engineering, University of Illinois at Urbana-Champaign, USA

Abstract: A report published by the National Research Council of the National Academies identified the research on understanding and quantifying the value of our infrastructure systems to their stakeholders and how this value is impacted by the various planning, design, construction, and operation decisions as a “national imperative”. However, there is still a lack of understanding and formalized modeling of what different stakeholders value (e.g., energy conservation, safety, economic growth) in our infrastructure systems and how to valuate (i.e., quantify the worth) our infrastructure systems based on these values. This paper presents the authors’ work in the area of axiology-based valuation modeling of buildings. “Axiology” is a theory of value (worth) that explores questions such as what are the objects that we value and how to measure the value of these objects. In this paper, the authors propose a mathematical value quantification model for quantifying the degree that a building (and its objects) fulfills stakeholder values based on its properties. The proposed model is primarily theoretically grounded in axiology. It builds on two key notions in Hartman’s formal axiology that (1) object valuation depends on its properties, and (2) valuation has systemic, extrinsic, and intrinsic dimensions. The model was initially validated through a case study. The model offers a way to assess the value of our built infrastructure based on stakeholder values; it could facilitate value-sensitive decision making by embodying stakeholder values into project planning and design towards better synergy between human values and the built environment.

1 INTRODUCTION

A report published by the National Research Council of the National Academies (NRC) identified the research on understanding and quantifying the value of infrastructure systems to their stakeholders and how this value is impacted by the various planning, design, construction, operation, and investment decisions as a “national imperative” (NRC 2009). Similarly, industry organizations and institutes (e.g., SE 2012, NIBS 2012) and individual researchers (e.g., Levitt 2007) have emphasized the need for maximizing the lifecycle environmental, social, and economic value of infrastructure projects. "Potential projects for one type of infrastructure are not evaluated against other projects to determine how the greatest overall value might be achieved” (NRC 2009). The lack of such value quantification methods has led many stakeholders to debate the value of our infrastructure and, in turn, has reinforced the need of value-sensitive decision making (NRC 2009). In order to quantify the value (worth) of an infrastructure, there is a need to understand what stakeholders value (e.g., safety, energy conservation, cost saving), and accordingly, quantify the value (worth) of the infrastructure based on these stakeholder values. Discovering stakeholder values and quantifying the value of infrastructure based on these values are, thus, key prerequisites for facilitating value-sensitive decision making towards maximizing the collective value of our built infrastructure.
Despite the evident need for infrastructure value quantification and value-sensitive decision making, inadequate attention has been given to the theoretical and empirical study of value over the years (Barima 2009). Major gaps still exist in the area of value analysis of built infrastructure: (1) existing value approaches (e.g., value engineering) usually focus on function analyses and define value as a ratio of “function” to its “cost” (Kelly 2007) without a comprehensive interpretation of the concept of “value” based on stakeholder values, (2) existing integrated approaches (e.g., integrated project delivery) promote collaboration with the aim to increase value (AIA 2007), but do not provide a metric for measuring “value” or a well-defined method for value-sensitive analysis. As such, two main knowledge gaps exist: (1) there is a lack of understanding and modeling of what the value (worth) of an infrastructure is, and (2) there is a lack of formalized quantification models that can quantify such value. In the context of built infrastructure development, there is a need to better understand, conceptualize, and reason about “value quantification” in a holistic sense and considering stakeholder values.

To address this need, in this paper, the authors propose a mathematical value quantification model for quantifying the degree that a building (and its objects) fulfills stakeholder values based on its properties. The proposed model is primarily theoretically grounded in axiology. Axiology is a theory of value (worth) that explores questions such as what are the things that we value and how to measure the value of these things (Smith and Thomas 1998). The model builds on two key notions in Hartman's formal axiology that (1) object valuation depends on its properties, and (2) valuation has systemic, extrinsic, and intrinsic dimensions.

2 BACKGROUND

Axiology is a theory of value or worth. It is a study of value concepts, value types, interrelationships, and valuation methods (Allen and Varga 2006). The term “axiology” is derived from the Greek word “axios” meaning value or worth. Axiology aims to answer questions such as how to define and measure the value (worth) of things (Smith and Thomas 1998). Formal axiology is a branch of axiology that was introduced by Robert Hartman. Hartman (1967) proposed to mathematically define the value of “things” in an objective manner based on their properties. He proposed that the value of an object depends on the extent to which its properties correspond to the properties of its concept. According to Hartman, a “good” thing (1) has a concept name, (2) this concept is characterized/defined by a set of properties, and (3) this thing possesses all of the properties in this set (El-Gohary 2010). Hartman also introduced three basic dimensions (types) of valuation (El-Gohary 2010): (1) Systemic Valuation: valuates a “thing” based on a finite number of properties in terms of rigid conformance to a system or a formal construct (e.g., conformance to the definition of circle, or conformance to a regulatory system). Systemic valuation, thus, sees “things” either black or white (e.g., a thing is a circle or not a circle, a person is complying with the law or not); (2) Extrinsic Valuation: valuates a “thing” based on a finite number of properties, but in a flexible way in terms of goodness and badness degrees based on practical aspects, such as functionality, economics, etc. A “thing” has potentially an infinite number of properties, but in practice extrinsic valuation is based on only a few of these properties; and (3) Intrinsic Valuation: valuates a “thing” based on an infinite number of properties in terms of personal judgment based on aesthetical, emotional, or spiritual aspects, etc. A “thing” can be valuated systemically, extrinsically, and/or intrinsically (El-Gohary 2010).

3 APPROACH AND METHODOLOGY

The proposed value quantification model is developed using an axiology-based approach. The model builds on two key notions in Hartman’s formal axiology that (1) object valuation depends on its properties, and (2) valuation has systemic, extrinsic, and intrinsic dimensions. Hartman’s three types of valuation (i.e., systemic, extrinsic, and intrinsic valuation) were adapted to the context of building valuation. In the context of building valuation, both extrinsic and systemic valuation valuate a building (or its objects) based on how good its properties are in fulfilling each of the stakeholder values. Systemic valuation is a rigid valuation that views property goodness as either “black or white” (i.e., a property is either good or bad), while extrinsic valuation is a flexible valuation that views property goodness as a spectrum (i.e., a property is good, fair, bad, etc.). Intrinsic valuation, on the other hand, valuates a building (or its objects) based on personal stakeholder judgment in terms of aesthetical, emotional, or spiritual aspects. In
developing the mathematical quantification functions of the proposed model, the authors also benchmarked some techniques (e.g., simple additive weighting) of multiple attribute decision making (MADM) approaches and adapted concepts from social welfare theory.

The methodology for developing the proposed model included five main tasks: (1) conducting theoretical studies on formal axiology, (2) identifying and modeling the main concepts for value quantification, (3) identifying potential indicators to measure the goodness of properties, (4) selecting indicators based on a set of well-defined principles, (5) constructing mathematical formulations for value quantification, and (6) conducting a case study for initial validation. In their prior work, the authors presented their research efforts in indicator identification and selection (Zhang and El-Gohary 2014). In this paper, the authors focus on presenting the mathematical formulations for value quantification and its initial validation.

4 PROPOSED VALUE QUANTIFICATION MODEL

4.1 Main Model

The proposed main value quantification model, showing the most abstract value quantification concepts, is depicted in Figure 1. At the highest level of abstraction, a thing is a “stakeholder value”, a “value bearer”, a “value bearing property”, a “property indicator”, a “benchmark of measure”, a “property goodness degree”, a “property value significance”, or a “value fulfillment degree”. A “stakeholder value” is a thing that is of worth, merit, or utility to a stakeholder (e.g., energy conservation, safety, cost saving). The hierarchy of stakeholder values, which includes 50 stakeholder values, is presented in Zhang and El-Gohary (2015). A “value bearer” is an object (e.g., a building or a building element) that holds value. A “value bearer” has one or more “value bearing properties” (e.g., thermal resistance, fire resistance, height). A “benchmark of measure” is a yardstick against which an indicator is measured to define the goodness of a property. A “property goodness degree” is a numeric degree that defines how good/bad a property is in fulfilling a specific “stakeholder value”. A “property value significance” is a quantifiable measure of the importance/relevance of a specific property in fulfilling a specific “stakeholder value” for a specific “value bearer”. A “value fulfillment degree” is a numeric degree indicating how much a value is fulfilled. As per Figure 1, each “function of” relation represents the mathematical function between the different quantification concepts. The following subsections describe how property goodness, property value significance, and value fulfillment are quantified.

![Figure 1: Main value quantification model](image)

4.2 Quantifying Property Goodness

Property goodness indicates how good/bad a property is in fulfilling a specific stakeholder value. Property goodness could be systemic, extrinsic, or intrinsic. Systemic property goodness is “black or white” – a property is either good or bad. Extrinsic property goodness is a spectrum of goodness – a property could be good, fair, bad, etc. Intrinsic property goodness is mostly assessed based on personal
judgment in terms of aesthetical, emotional, or spiritual aspects. The degree of goodness of a property is expressed as a metric-free numerical number called “property goodness degree” (PGD), and is derived based on comparing property indicators (PIs) against well-defined benchmarks. PGD is, thus, a function of PI and benchmark of measure (BOM). Corresponding to the type of property goodness, PGD could be assessed systemically, extrinsically, and/or intrinsically.

Systemic property goodness is assessed systemically. In this type of assessment, a property is either good or bad; the PI either meets or not meets the BOM. Systemic property goodness assessment, thus, results in a dichotomous PGD (either 1 or 0). For example, the PGD of land type (value bearing property) [of a building (value bearer) in fulfilling land pollution prevention (stakeholder value)] is either 1 (if the developer selects a previously developed field for project development) or 0 (if the developer selects a greenfield).

Extrinsic property goodness is mostly assessed extrinsically. In this type of assessment, a property has a spectrum of goodness in terms of how the PI measures up against a BOM. Extrinsic property goodness assessment, thus, results in a PGD that ranges from 0 to 1, which indicates how good the property is. Different extrinsic property goodness assessment functions are defined, depending on the type of assessment: max-best, min-best, or mid-best assessment. Accordingly, PGD is defined based on Eq. 1 to Eq. 3, where PGD_{ijk} = property goodness degree of property i of value bearer k in fulfilling stakeholder value j; PI_{ijk} = property indicator of property i of value bearer k in fulfilling stakeholder value j; BOM_{minij} = minimum benchmark of measure of property i in fulfilling stakeholder value j; and BOM_{maxij} = maximum benchmark of measure of property i in fulfilling stakeholder value j.

When conducting a max-best assessment (Eq. 1), the minimum benchmark represents the lowest degree of goodness, below which the property becomes totally bad; whereas the maximum benchmark represents a high enough degree of goodness, above which a property becomes “good-enough”. Accordingly, (1) when the PI falls below the minimum benchmark, the PGD falls to 0, (2) when the PI falls within the range of minimum and maximum benchmarks, the PGD monotonically increases with the increase of the PI until reaching the maximum benchmark, and (3) when the PI reaches (or is above) the maximum benchmark, the PGD becomes at its maximum of 1. For example, low-emitting material (value bearing property) [of a ceiling (value bearer) in fulfilling indoor air quality improvement (stakeholder value)] can be assessed using max-best assessment, where a higher percentage of compliant low-emitting material (PI) indicates better/more low-emitting material until it reaches 100% (maximum benchmark).

\[
[1] \text{PGD}_{ijk} = \begin{cases} 
0 & \text{if } PI_{ijk} < BOM_{minij} \\
\frac{PI_{ijk} - BOM_{minij}}{BOM_{maxij} - BOM_{minij}} & \text{if } BOM_{minij} \leq PI_{ijk} < BOM_{maxij} \\
1 & \text{if } PI_{ijk} \geq BOM_{maxij}
\end{cases}
\]

When conducting a min-best assessment (Eq. 2), the minimum benchmark represents a high enough degree of goodness, below which a property becomes “good-enough”; whereas the maximum benchmark represents the lowest degree of goodness, above which the property becomes totally bad. For example, water consumption (value bearing property) [of a water closet (value bearer) in fulfilling water conservation (stakeholder value)] can be assessed using min-best assessment, where a lower amount of water usage per flush (PI) indicates better water consumption until it falls to 1.28 gpf (minimum benchmark).

\[
[2] \text{PGD}_{ijk} = \begin{cases} 
1 & \text{if } PI_{ijk} \leq BOM_{minij} \\
\frac{BOM_{maxij} - PI_{ijk}}{BOM_{maxij} - BOM_{minij}} & \text{if } BOM_{minij} < PI_{ijk} \leq BOM_{maxij} \\
0 & \text{if } PI_{ijk} > BOM_{maxij}
\end{cases}
\]

When conducting a mid-best assessment (Eq. 3), there is a certain range within which the property becomes “good enough”; when the PI falls within that range, the PGD is at its maximum. The PGD
decreases when the PI falls out of this range until it becomes totally bad, when the PI reaches the minimum or maximum benchmark (both representing the lowest degree of goodness). For example, thermal comfort level (value bearing property) [of a living room (value bearer) in fulfilling thermal comfort improvement (stakeholder value)] can be assessed using mid-best assessment, where the thermal comfort level is the best when the air temperature is within a range of 69 °F to 73 °F (good enough range).

\[
P_{D_{i,j,k}} = \begin{cases} 
0 & \text{if } PI_{i,j,k} < BOM_{min_{i,j}} \\
\frac{BOM_{min_{i,j}} - PI_{i,j,k}}{BOM_{max_{i,j}} - BOM_{min_{i,j}}} & \text{if } BOM_{min_{i,j}} \leq PI_{i,j,k} < BOM_{max_{i,j}} \\
1 & \text{if } BOM_{max_{i,j}} \leq PI_{i,j,k} \\
0 & \text{if } PI_{i,j,k} \geq BOM_{max_{i,j}} 
\end{cases}
\]

Intrinsic property goodness is mostly assessed intrinsically. In this type of assessment, a property is assessed flexibly based on personal stakeholder judgment in terms of aesthetical, emotional, or spiritual aspects. Stakeholders can directly assign a PGD within the range of 0 to 1 based on their personal judgment of the goodness of the property. For example, a stakeholder can directly assign a PGD of 1 to a white interior wall color if white is his/her most favorite color for a wall. The detailed methodology for assessing intrinsic property goodness is beyond the scope of this paper.

4.3 Quantifying Property Value Significance

Property value significance (PVS) represents the significance, importance, or relevance of a specific property of a specific value bearer in fulfilling a specific stakeholder value. Properties may have different significances to value quantification. Determining the PVSs for the various building properties may not be easy or apparent. PVSs could be determined extrinsically and/or intrinsically.

Using extrinsic PVS determination approaches, PVSs are determined in a flexible and objective manner based on norms, relative impact of property, expert opinion, etc. Selecting which approach to use for extrinsic PVS determination depends on the type of property, the type of PVS, and the availability of data. A norm-based approach determines PVSs based on weightings embedded in applicable norms, such as standards, advisory practices, rating systems (e.g., LEED, BREEAM). For example, the PVSs of recycled material, reused material, and regional material (value bearing properties) [of a wall (value bearer) in fulfilling material conservation (stakeholder value)] can be directly obtained from LEED, which uses “credit weighting” to represent the point allocation between different credit categories. The LEED credit weightings for “material reuse”, “recycled content”, and “regional materials” are equal (2 points for each) (USGBC 2009). Accordingly, the three properties are assigned equal PVSs of 0.33 (after normalization). Because norm-based data are well-established by an authority or advisory body, a norm-based approach is preferred for PVS determination, if relevant norm-based data (e.g., score/point weightings) are available. Other approaches should be used when such data are not available.

An impact-based approach determines PVSs by evaluating the potential impacts of each property with respect to a set of impact categories. For example, disability adjusted life years (DALY) weighting (Blanc et al. 2008) can be used to determine the significance of environmental-related properties (e.g., air pollutant emissions) of a value bearer (e.g., a building or a building element) in fulfilling the environmental values (e.g., air pollution prevention) by assessing their potential impacts on human health using existing assessment tools (e.g., IMPACT 2002+). For example, particulate matter (PM) emissions (value bearing property) of a building (value bearer) affect human health more severely than lead emissions (value bearing property) (Blanc et al. 2008) and, thus, has a higher PVS (0.98) than that of lead emissions (0.02).

An expert-based approach determines PVSs based on expert opinion. It is a suitable approach to use when norm-based data are not available or when it is difficult to assess the potential impact of the
properties. For example, the PVS of sound resistance and sound absorption (value bearing property) [of a wall (value bearer) in fulfilling acoustical performance improvement (stakeholder value)] can be determined by soliciting acoustical consultant/expert opinion using a budget allocation process (BAP). In BAP, an expert is given a set of properties of a value bearer in fulfilling a specific stakeholder value. The expert is asked to allocate a “budget” of one hundred points to the individual properties in the property set, based on their expert judgment of the relative PVSSs of the respective properties. To ensure objectivity and correctness in PVS determination, it is important to select experts with knowledge and expertise in the specific technical domain related to the type of value bearer and stakeholder value (e.g., expertise in acoustical performance of buildings).

Using intrinsic PVS determination approaches, PVSSs are determined in a flexible and personal manner based on personal stakeholder judgment in terms of aesthetical, emotional, or spiritual aspects. For example, the significance of color (value bearing property) [of a wall (value bearer) in fulfilling aesthetics (stakeholder value)] is determined based on the personal opinion of the stakeholders. Similar to intrinsic property goodness assessment, stakeholders can directly assign a numerical number between 0 to 1 to a PVS based on their personal judgment of the significance, importance, or relevance of the property of the value bearer in fulfilling their own stakeholder value. The detailed methodology for intrinsic PVS determination is beyond the scope of this paper.

4.4 Quantifying Value Fulfillment

Value fulfillment represents how much a value is fulfilled. It depends on how good/bad the properties fulfill the value (i.e., PGD) and how significant the property is in fulfilling this particular value (i.e., PVS). “Highly good” properties (e.g., net-zero energy consumption), in comparison to “good” properties, tend to contribute to the fulfillment of a stakeholder value in extra higher degrees. Thus, to quantify value fulfillment of each stakeholder value, a value fulfillment degree (VFD) is defined by aggregating the PGDs and PVSSs of individual properties, while taking into account the extra higher level of contribution of highly good properties. The VFD function, thus, is composed of two sub-functions: (1) a property goodness aggregation (PGA) function that aggregates the PGDs and PVSSs of individual properties, and (2) a high property goodness (HPG) function that rewards states of HPG.

The PGA function aggregates the PGDs and PVSSs of individual properties to define how much a value is fulfilled by these properties. The PGA function uses simple additive weighting. Simple additive weighting is one of the most widely used MADM methods (Andresen 2000). A simple additive weighting function is a linear aggregating function that allows for compensability (i.e., possibility of offsetting a disadvantage on some criteria by a sufficiently large advantage on another criteria) among criteria (OECD 2008). Simple additive weighting is suitable for value fulfillment quantification for three reasons. First, when aggregating PGDs and PVSSs for individual properties to define the VFD of a stakeholder value, properties of one value bearer are compensatory in value fulfillment. For example, for fulfilling material conservation (stakeholder value), a floor (value bearer) with small amount of recycled material (value bearing property) can be compensated with large amount of reused material (another value bearing property). Second, a simple additive weighting method is able to provide an aggregated VFD (numerical number) for each value bearer. This allows further aggregation of the VFDs and for valuating a value bearer irrespective of the existence of other alternatives. Third, research shows that simple additive weighting methods yield “extremely close approximations” to other non-linear aggregating methods (e.g., generalized means) while remaining easier to understand (Andresen 2000).

The HPG function rewards states of HPG because of its higher contribution to the fulfillment of stakeholder values. The HPG function adapts concepts from social welfare theory. Social welfare theory is the study that assesses the collective welfare of a society or a group by combining individual opinions, preferences, interests, or welfare (Feldman and Serrano 2006). When calculating the degree of value fulfillment during value quantification, the aim is to find a good/satisfactory overall state of the aggregated value bearing properties based on the goodness degrees and value significances of the individual properties. This is analogous with social welfare assessment in which a social welfare function is used as a measure of the aggregated well-being (the good or satisfactory state) of a group based on the allocation of requisites (such as income) among the individuals of that group. However, unlike social welfare
assessment in which states of poverty are undesirable (and thus penalized), in value assessment states of “wealth” (i.e., states of high goodness of individual properties (“highly good properties”) such as net-zero energy consumption) are valued (and thus rewarded). While “highly bad properties” (e.g., 15 min fire rating) are also undesirable (not valued) during value quantification, such states of badness are already eliminated during regulatory compliance assessment. As such, for defining the VFD, two lines are established: “high property goodness (HPG) line” and “high property badness (HPB) line”. The HPG line represents the state of high goodness for a property, and is above the minimum benchmark and below the maximum benchmark. When the PGD of a property is at/above the HPG line, such property contributes to the fulfillment of a stakeholder value in an extra high degree. The HPB line represents the state of the property being highly bad and is usually at (or below) the minimum benchmark established by regulatory requirements. An HPB line is, thus, unnecessary in well-regulated societies that establish minimum requirements in the form of regulations, codes, standards, etc.

The HPG line could be assessed extrinsically or intrinsically. Systemic property cannot have HPG states because it could only be either good or bad. Similar to extrinsic property goodness assessment, extrinsic HPG line assessment assesses the state of high goodness in terms of how it measures up against a BOM, which could use max-best, min-best, or mid-best assessments. Accordingly, the HPG line is defined based on Eq. 4 to Eq. 6, where HPGL\textsubscript{ij}= high property goodness line of property i in fulfilling stakeholder value j; HGBOM\textsubscript{ij}= high goodness benchmark of measure of property i in fulfilling stakeholder value j; BOM\textsubscript{minij}= minimum benchmark of measure of property i in fulfilling stakeholder value j; and BOM\textsubscript{maxij}= maximum benchmark of measure of property i in fulfilling stakeholder value j. Eq. 4 to Eq. 6 are used for max-best, min-best, and mid-best assessment, respectively.

\textbf{[4]} \quad \text{HPGL}_{ij} = \frac{\text{HGBOM}_{ij} - \text{BOM}_{\text{minij}}}{\text{BOM}_{\text{maxij}} - \text{BOM}_{\text{minij}}} \quad \text{BOM}_{\text{minij}} \leq \text{HGBOM}_{ij} < \text{BOM}_{\text{maxij}}

\textbf{[5]} \quad \text{HPGL}_{ij} = \frac{\text{BOM}_{\text{maxij}} - \text{HGBOM}_{ij}}{\text{BOM}_{\text{maxij}} - \text{BOM}_{\text{minij}}} \quad \text{BOM}_{\text{minij}} < \text{HGBOM}_{ij} \leq \text{BOM}_{\text{maxij}}

\textbf{[6]} \quad \text{HPGL}_{ij} = \begin{cases} \frac{\text{HGBOM}_{ij} - \text{BOM}_{\text{minij}}}{\text{BOM}_{\text{maxij}} - \text{BOM}_{\text{minij}}} & \text{BOM}_{\text{minij}} \leq \text{HGBOM}_{ij} < \text{BOM}_{\text{minij}}' \\ \frac{\text{BOM}_{\text{maxij}} - \text{HGBOM}_{ij}}{\text{BOM}_{\text{maxij}}' - \text{BOM}_{\text{maxij}}} & \text{BOM}_{\text{maxij}}' \leq \text{HGBOM}_{ij} < \text{BOM}_{\text{maxij}} \end{cases}

Similar to intrinsic property goodness assessment, intrinsic HPG line assessment is a flexible and personal high goodness assessment that is conducted based on personal stakeholder judgment in terms of aesthetic, emotional, or spiritual aspects. The detailed methodology for intrinsic HPG line assessment is beyond the scope of this paper.

The HPG function is a measure of the extent of high goodness in the set of properties of the value bearer. The function estimates the degree of HPG in the whole set by considering how far each PGD is above the HPG line. HPG is then rewarded by the HPG function, using a coefficient α, because of its higher contribution to the fulfillment of stakeholder values. The coefficient α defines the extent of rewarding HPG; and is a numerical number between 0 and 1. An α of 1 represents a full extent of reward, while an α of 0 represents no reward at all.

The VFD function is an addition of the PGA function (which ranges from 0 to 1) and the HPG function (which ranges from 0 to 1), thereby making the HPG acting as an “extra bonus”. The VFD function is defined in Eq. 7, where VFD\textsubscript{jk}= value fulfillment degree of stakeholder value j by value bearer k; n = total number of properties that contribute in fulfilling stakeholder value j; PGD\textsubscript{ijk}= property goodness degree of property i of value bearer k in fulfilling stakeholder value j; PVS\textsubscript{ij}= property value significance of property i in fulfilling stakeholder value j; α = a coefficient for rewarding high property goodness; and HPGL\textsubscript{ij}= high property goodness line of property i in fulfilling stakeholder value j.

\textbf{[7]} \quad \text{VFD}_{jk} = \sum_{i=1}^{n} \text{PGD}_{ijk} \times \text{PVS}_{ij} + \alpha \sum_{i=1}^{n} \text{PVS}_{ij} \times \max[0, (\text{PGD}_{ijk} - \text{HPGL}_{ij})]
5 CASE STUDY

A case study was conducted to initially validate the proposed value quantification model. A duplex apartment building model was used in this case study. It is one of the common Building Information Model (BIM) published by buildingSMART alliance (a council of the National Institute of Building Sciences) for evaluating model or software functionality and applicability (buildingSMART 2015). The case study focused on analyzing the value fulfillment of the exterior wall system of the building. The exterior wall system is designed using concrete block with brick veneer. The detailed information on the design of the exterior wall system is summarized in Table 1. A set of stakeholder values were selected for this case study analysis, including: (1) material conservation, (2) indoor air quality improvement, (3) acoustical performance improvement, and (4) fire safety.

The results of the model-based analysis, including the PIs, BOMs, HGBOMs, PVSs, PGDs, and VFDs, are summarized in Tables 2 and 3. A 0.5 α coefficient was used in the analysis, which represents a mid-extent of rewarding high property goodness. The results of the VFDs of material conservation, indoor air quality improvement, acoustical performance improvement, and fire safety are 0.442, 0.852, 0.738, and 1.000, respectively. These results indicate that this concrete block wall fulfills material conservation value in a low degree, fulfills indoor air quality improvement and acoustical performance improvement in a relatively high degree, and fulfills fire safety in an extremely high degree. This value quantification results could provide decision makers with a sound numerical measurement as a basis for decision making, for example when making trade-offs (e.g., which values to fulfill in priority) or selecting design alternatives.

6 CONCLUSIONS AND FUTURE WORK

This paper presents an axiology-based mathematical value quantification model for quantifying the value fulfillment of one value bearer based on one stakeholder value. A value fulfillment degree (VFD) function is proposed for value quantification. The VFD function identifies the fulfillment degree of each stakeholder value based on the goodness of the properties and the significances of the properties in fulfilling particular stakeholder values. In doing so, a highly good property is rewarded in the function because of its higher contribution to the fulfillment of stakeholder values. Property goodness is a measure that defines how good a property is in fulfilling a specific stakeholder value, which is assessed systemically, extrinsically, or intrinsically. Property value significance is a measure that represents the significance, importance, or relevance of a specific property of a specific value bearer in fulfilling a specific stakeholder value, which is determined extrinsically or intrinsically. The model was initially validated through a case study, which demonstrates the applicability of the model in quantifying the VFDs of material conservation, indoor air quality improvement, acoustical performance improvement, and fire safety (stakeholder value) of a concrete block exterior wall system (value bearer).

In their future/ongoing research, the authors will further explore value aggregation that includes three types of aggregation: (1) subvalue aggregation (along a stakeholder value hierarchy): mathematically aggregating the subvalues (e.g., resource conservation, pollution prevention) to define the supervalue (e.g., environmental value), (2) object value aggregation (along an object hierarchy): mathematically aggregating the values of the parts (e.g., wall, ceiling, floor, etc.) to define the value of the whole (e.g., building), and (3) collective value aggregation (along a stakeholder hierarchy): mathematically aggregating the values of individual stakeholders to define the collective value of the group of stakeholders.

Abstract: Infrastructure condition information is critical for effective asset management. Infrastructure managers are tasked with regularly assessing asset conditions to make effective maintenance, repair, and rehabilitation decisions. Currently there are two types of methods broadly adopted for infrastructure condition assessment: on-site evaluation methods and airplane-based observation methods. On-site evaluation methods are expensive, labor-intensive, time-consuming, potentially dangerous to inspectors, inconsistent, and requiring specialized staff on a regular basis. Airplane-based observation methods can provide reliable overall condition information for ground infrastructure assets such as roadways, bridges, dams, or buildings, but the spatial resolutions of 0.075-meter (3-inch) to 1-meter are insufficient to examine detailed asset conditions such as individual cracks on a pavement surface or on a bridge. Using roadway pavement assets as an example, this research explored the utility of hyper-spatial resolution (3-millimeter) multispectral digital aerial photography acquired from a low-altitude unmanned remote sensing system to permit characterization of detailed surface distress conditions. With the help of orthogonal regression analysis, detailed pavement surface distress rates manually estimated from hyper-spatial resolution multispectral digital aerial photography were compared to reference pavement distress rates manually collected on the ground. The results show that the hyper-high spatial resolution imaging techniques provide detailed and reliable data suitable for informing infrastructure system management decisions. These results open the way for the future application of low-cost hyper-spatial resolution digital aerial photography for automated assessment of detailed infrastructure system condition.

1 INTRODUCTION

Infrastructure condition information is critical for effective infrastructure system management (Zhang and Bogus 2014). Decisions involving maintenance, repair, and rehabilitation of infrastructure systems require accurate and current information describing the conditions of these systems and their components (Maser 2005). This information is required not only to characterize current conditions but also to project future performance and remaining life (Maser 2005). Therefore, infrastructure managers are tasked with regularly assessing asset conditions to make effective maintenance, repair, and rehabilitation decisions.

Currently, infrastructure management agencies use either on-site evaluation or airplane-based observation methods for infrastructure condition assessment. On-site evaluation methods are labor-intensive, time-consuming, and potentially dangerous to inspectors (Maser 2005). Airplane-based observation methods can provide reliable overall condition information for ground infrastructure assets...
such as roadways, bridges, or buildings (Zhang and Bogus 2014), but the spatial resolutions of 0.075-meter (3-inch) to 1-meter are insufficient to examine detailed asset conditions such as individual cracks on a pavement surface or on a bridge. In recent years, unmanned remote sensing systems (URSS) have emerged as an important platform for hyper-spatial resolution aerial data collection. URSS can fly lower to the ground than traditional airplanes, and thus allow for more detailed data to be collected without specially-designed, cost prohibitive sensors (e.g. LiDAR). Using roadway pavement assets as an example, this research explored the utility of hyper-spatial resolution (3-millimeter) multispectral digital aerial photography (H-DAP) acquired from a low-altitude URSS, in this case a tethered weather balloon, to permit characterization of detailed surface distress conditions. Detailed pavement surface distress rates manually estimated from H-DAP were compared to reference distress rates manually collected on the ground to assess the feasibility and potential utility of automated approaches.

2 BACKGROUND

The ability to assess the condition of infrastructure systems (e.g. roads and bridges) rapidly and accurately is critical to making decisions within any infrastructure management systems (Maser 1988; Karaa 1989). Infrastructure condition data are collected and used by infrastructure management agencies to determine the serviceability of infrastructure systems and to help make decisions on the distribution of limited resources for maintenance, repair, and rehabilitation.

Traditionally, infrastructure assessment is performed with “boots on the ground” by having experts visually inspect the condition of infrastructure systems with subjective judgment (Aktan et al. 1996) or by using vehicle-mounted electronic sensors to automatically detect the infrastructure conditions (Hudson and Uddin 1987). This type of assessment method is classified as on-site evaluation and still broadly used by infrastructure system management agencies. In recent history, one might still remember structural engineers scaling the Washington Monument in Washington, D.C. after the 2011 earthquake to determine the structural integrity of the monument (Figure 1). On-site condition assessment can collect detailed infrastructure condition data. However, on-site methods are expensive, labor-intensive, time-consuming, potentially dangerous to inspectors, requiring specialized staff on a regular basis, and data collected by different inspectors can exhibit a high degree of variability (Maser 2005; Bogus et al. 2010).

Figure 1: Post-earthquake assessment of Washington Monument (Source: NPS.gov)

Another method to assess infrastructure conditions is using remote evaluation methods. This technology is typically deployed on airplanes that fly over infrastructure systems. This type of assessment method is classified as airplane-based observation evaluation and is becoming more and more popular (Jensen and Cowen 1999). The resulting images (Figure 2), which typically have spatial resolutions ranging from 0.075-meter (3-inch) to 1-meter, can be used to evaluate the overall condition of infrastructure systems rapidly and inexpensively (Zhang and Bogus 2014). There are limitations, however, on the spatial resolution of these images which can limit the ability to detect and assess small defects, such as cracks on a pavement surface or on a bridge (Guo 2010).

The intellectual significance of this research is that it addresses the limitations inherent in both the “boots on the ground” method and the aerial data collected from airplane-based technology by using a novel middle ground approach of data collection for detailed infrastructure condition assessment. The proposed
The methods uses an unmanned airborne system (UAS), which can fly lower to the ground than traditional airplanes, and thus allow for more detailed infrastructure condition data to be collected without specially designed, cost prohibitive sensors. The improved detail associated with the data holds the potential to provide much better condition assessment of infrastructure systems at dramatically reduced cost when compared to on-site (i.e. manual methods or automatic methods) approaches.

Figure 2: Routinely available airplane-based observation images for infrastructure condition assessment; this image has a spatial resolution of 0.1524-meter (6-inch).

In recent years, UAS have emerged as an important platform for collection of hyper-spatial resolution aerial data (i.e., sub-centimeter ground sampling distances) – a trend that is all but certain to continue. For now, due to a wide variety of regulatory and safety concerns, the legal use of UAS is severely restricted in the United States. In anticipation of an established regulatory environment and availability of UAS for routine infrastructure condition assessment, this research used a tethered helium weather balloon system to simulate the collection of hyper-spatial resolution aerial image data from untethered UAS. The process of measuring spatial properties from aerial photography or images is referred to as “photogrammetry”. Aerial triangulation (AT) is the basic photogrammetric method for analyzing aerial images to determine X, Y, and Z ground coordinates of individual points based on measures take from a series of overlapping aerial photographs (Zomrawi et al. 2013). AT traditionally requires the identification of thousands of control points linking images to one another and to a reference dataset to enable least squares estimation of the optimal triangulation model. New computation approaches (e.g., structure-from-motion, graphic processing unit based image processing) have enabled automation of traditional AT to permit routine estimation of 3-dimensional surface structure and subsequent orthocorrection of large datasets at approximately the spatial resolution of the input images (Zhang et al. 2011; Zomrawi et al. 2013). When coupled with hyper-spatial resolution image data such as that collected by low altitude UAS, this technology holds the potential to permit the estimation of horizontal and vertical measurements at sub-centimeter scales (Zhang et al. 2011), and ultimately, the detection and assessment of infrastructure damages at finer scales than has traditionally been possible by airborne survey.

Hyper-spatial resolution aerial data have been used to facilitate research in many fields, such as archaeology, intertidal ecology, marine ecology, zoology, emergency management, vegetation and soil monitoring, and topographic mapping (Scoffin 1982; Aber et al. 1999; Fraser et al. 1999; Guichard et al. 2000; Aber et al. 2001; Sklaver et al. 2006; Wundram and Loffler 2008; Marzolff and Poesen 2009; Smith et al. 2009; Verhoeven 2009). However, previous studies regarding application of H-DAP to detailed infrastructure condition assessment are limited. The only published research on this topic was performed by Chen et al. (2011). This research shows the potential to use H-DAP to evaluate crack-level infrastructure condition, but the assessment ability is limited to inch-level large cracks on bridge pavements because the spatial resolution of the used aerial images is 0.0254-meter (1-inch).

Using roadway flexible pavement (i.e. asphalt concrete) assets as an example, we explore the application of H-DAP to detect and assess detailed infrastructure condition. Key items for evaluating flexible pavement distress were identified from United States Department of Transportation Highway Performance System (HPMS) Field Manual, including rutting (item 50), alligator cracking (item 52), and transverse cracking (item 53). Rutting is an unrecoverable longitudinal surface depression in both wheel paths (Cordova et al. 2009). Alligator cracking is interconnected cracks resembling chicken wire or alligator skin (Cordova et al. 2009). Transverse cracking is cracking that is predominantly perpendicular to the pavement centerline. Transverse cracking is a result of pavement expansion and contraction due to
temperature changes, as well as shrinkage of asphalt binder with aging (Cordova et al. 2009). With AT, it is possible to generate sub-centimeter scale mosaicked orthophotos and digital surface models (DSMs) for standardized evaluation of detailed infrastructure condition, potentially reducing the cost and duration of assessment while improving the comparability of results.

3 METHODOLOGY

Using H-DAP acquired from a low-cost UAS as input, AT was used to generate 3-millimeter spatial resolution mosaicked orthophotos and same spatial resolution DSMs for pavement surfaces. Key metrics (HPMS Field Manual 2010) used to measure flexible pavement distress, including cracking length, cracking area percentage, and rutting depth, were measured from the orthophotos and DSMs and then compared to ground reference data measured manually using standard protocols (Cordova et al. 2009).

3.1 Data Acquisition and Preparation

A low-cost unmanned remote system was developed to simulate the collection of image data from other untethered low-altitude UAS that are now common in the marketplace. This system includes a tethered helium weather balloon with customized rigging. The sensor affixed to the balloon rigging is a small-format Canon digital camera (SX260 HS). This camera has a 12 megapixel detector array collecting in the visible blue, green, and red wavelength via Bayer array sampling, a rugged cased with protected lens, built-in GPS unit, and intervalometer capability. A firmware enhancement application known as the Canon Hack Development Kit (CHDK), was employed to permit more control over the operation of the Canon SX260 HS digital camera, including shutter speed, shutter lag, aperture size, and intervalometer.

Data were collected for ten sites (i.e. road sections) on US Highway 66 and New Mexico Highway 0333 near the City of Albuquerque, NM. Approximately 200 overlapping hyper-spatial resolution aerial images were acquired for each site at about 40 meters above ground level (AGL). The ground area covered by each frame is approximately 20-meter by 15-meter and the ground sampling distance is approximately 2-millimeter. A Real Time Kinematic (RTK) surveying system was used to collect the horizontal and vertical coordinates of the ground control points (GCPs) on the pavement surface with a National Oceanic and Atmospheric Administration (NOAA) Online Positioning User Service (OPUS) reported root mean squared error (RSME) of 0.004-meter horizontally and 0.006-meter vertically. Sixteen GCPs were collected along with detailed photos of each GCP for each site.

A reference data set was collected by a trained two-person crew at each of the preselected data collection sites. Crew members performed manual (i.e., visual) evaluation with safety precautions (e.g. safety training and high visibility garments) based on the standard protocol adopted by the HPMS Field Manual. Both inspectors assessed pavement distresses (rutting, alligator cracking, and transverse cracking) independently and the results are the average value of the two independent evaluations. In accordance with the HPMS Field Manual, rutting and shoving depth was measured for only the rightmost driving lane for both inner and outer wheel paths at three locations along the wheel path within each site and then the depth averaged for each wheel path. The HPMS Field Manual requires reporting the percent area of total alligator cracking to the nearest 5%. In addition, the HPMS Field Manual requires reporting an estimation of relative length in feet per mile (feet/mile) of transverse cracking.

3.2 Aerial Triangulation (AT)

After excluding blurry and oblique images, approximately 150 overlapping hyper-spatial resolution aerial images were used for each site. The commercial software Agisoft was selected as the tool to perform AT as it permitted minimal human intervention at a low cost. Among the sixteen GCPs collected for each site, ten were used to calibrate the AT process while the remaining six were reserved to evaluate the horizontal and vertical accuracy of the orthophotos and DSMs. For each site, millions of control points were identified from the input overlapping images to build a dense cloud, and then a triangulation irregular network (TIN) mesh was generated based on the identified control points. Orthophotos and DSMs were exported as raster datasets in TIFF format at a spatial resolution of 3-millimeter. Orthophotos and DSMs are generated in a single processing routine and are therefore tightly co-registered. Orthophotos were
used to assess the horizontal accuracy while DSMs were used to assess the vertical accuracy. The accuracy assessment results (RMSE) show that the overall horizontal accuracy for all data collection sites is 0.004-meter, while the vertical accuracy is 0.006-meter. The number of overlapping images used and accuracy information for each data collection site is reported in Table 1.

3.3 Rutting Depth Measurement

In manual evaluation, rutting depth was measured with a wooden bar and a measuring tape. The actual measured points are the lowest points as visually determined by inspectors. DSMs exhibit the modeled 3-dimensional pavement surface. Points and polygons were created on DSMs to simulate the locations of the actual measuring points and wooden bars for rutting depth measurement. The actual measuring points and the locations of the wooden bars are shown in Figure 3.

The minimum scale of the measuring tape used for manual inspection was 0.001-meter. The length and width of the wooden bar is 1.22-meter (48-inch) and 0.02-meter (0.8-inch). With the actual field measured point (as photographed) as the center, two polygons (one on either side of the field measured point) with a size of 0.61-meter (20-inch) by 0.02-meter were created to simulate the location of the wooden bar. Using the polygon as the boundary, the DSM pixels were extracted and the highest measured points were identified to correspond to the field method of rutting depth calculation. Figure 4 illustrates the method used to calculate rutting depth from the DSM.

As shown in Figure 4, we consider the two highest points of the rutting section points A and B and the two measured points of the rutting section Points C and D. The distance from Point C to Point D is the rutting depth. Points A, B, and C will have the same height if the heights of Points A and B are equal. However, under most circumstances the heights of A and B are different. Therefore, a weighted average method was used to estimate the height of Point C.
\[ [1] \text{HC} = \frac{(HA \times DA + HB \times DB)}{(DA + DB)} \]
\[ [2] \text{RD} = \text{HC} - \text{HD} \]

In Equation 1, HC represents the height of Point C, while HA and HB represent the heights of Point A and Point B, respectively. DA represents the horizontal distance from Point A to Point D, while DB represents the horizontal distance from Point B to Point D. In Equation 2, RD represents the rutting depth. HA and HB were determined based on the DSMs, while DA and DB were determined based on the orthophotos.

3.4 Alligator Cracking Measurement

As required by the HPMS Field Manual, alligator cracking should be reported as the percent of total alligator cracking section area to the nearest 5% at a minimum. In the manual evaluation protocol (Cordova et al. 2009), pavement inspectors pace off the cumulative length of alligator cracking and mark the location of occurrence in 1 or 2 wheel paths. For example, typically the width of the driving lane is 3.66 meters (12 feet), and therefore, for a 1.6 kilometer (1 mile) section, the total area is 5886 square meters (63360 square feet). If the total length of alligator cracking paced off by inspectors is 152 meters (500 feet) in both wheel paths and the width of the evaluated alligator cracking is 0.61 meters (2 feet), the total area of the alligator cracking is 185 square meters (2000 square feet). Therefore, the reported area percentage should be 5 percent (2000/63360 = 3.2 percent which should be rounded up to the nearest 5 percent). In order to simulate the alligator cracking measurement prescribed by the HPMS, polygons were created to represent the whole pavement surface section used for manual evaluation and the boundary of the occurred alligator cracking. The polygon defining the manual evaluation zone was used to calculate the total area while the polygon defining the alligator cracking was used to calculate the total area of alligator cracking, and then the percent of alligator cracking was calculated by comparing the two polygons. The usage of polygons to determine the area percentage is shown in Figure 5. It should be noted that both actual percentage and rounded percentage were calculated for each site, but only rounded percentage was used for the following analyses.

3.5 Transverse Cracking Measurement

According to the HPMS Field Manual, pavement inspectors should count the number of transverse cracks extending at least half the lane width (1.83 meters [6 feet] or longer cracks) to estimate the total length of cracking in terms of feet per mile (or meters per kilometer) normalized by the total length of the manual evaluation zone. In order to simulate the transverse cracking measurement, any transverse cracks longer than 1.83 meters (6 feet) were digitized in a GIS as polylines to facilitate the calculation of the total length of transverse cracking (Figure 6). The same polygon created in alligator cracking measurement representing the whole pavement section was used to measure the total length of the evaluation zone.

3.6 Measurement Result Comparison

Rutting depth, alligator cracking area percent, and transverse cracking length measured from the DSMs and orthophotos were compared to manual evaluation results to examine the feasibility of using the H-DAP derived outputs to detect and assess the pavement surface distress metrics. Linear regression analyses revealed that the H-DAP derived measurement and the manual measurement for all three
distresses fit closely to the regression lines. Therefore, a paired-t test was not performed to examine if the H-DAP derived measurement and the manual measurement are statistically different from each because these data clearly violate the assumption that there is no linearity between the two groups of sample values (Carroll and Ruppert 1996). Pavement surface distresses measured from these two methods were compared with orthogonal regression analysis because it does not assume independence between variables. Orthogonal regression examines the linear relationship between two continuous variables and is often used to test whether two instruments or methods are measuring the same thing (Staiger and Stock 1997). For both linear regression and orthogonal regression, the dependent variable is the reference distress rate measured by manual method. This also makes the usage of orthogonal regression appropriate because unlike linear regression, both the independent and dependent variables in orthogonal regression contain measurement error (Carroll and Ruppert 1996).

![Figure 5: Alligator cracking boundary within entire manual evaluation boundary; blue polygons are the alligator cracking area while the red polygon is the entire manual evaluation zone; areas for these polygons can be calculated within the geographic information systems (GIS) and therefore, alligator cracking area percentage can be determined.](image1)

![Figure 6: Transverse cracking and entire manual evaluation polygon boundary; the red polygon is the entire manual evaluation zone, while the blue polylines are the transverse cracks; lengths of these transverse cracks and the length of the manual evaluation zone can be calculated within the GIS and therefore, transverse cracking length normalized by the total evaluation zone length can be calculated.](image2)

4 RESULTS AND DISCUSSION

The manually-evaluated and H-DAP derived rutting depths are summarized and exhibited. It should be noted that the results are organized by inner and outer wheel paths for each data collection site (See Table 2 for details). Table 3 summarizes the manually-evaluated and H-DAP derived alligator cracking area percent and transverse cracking length.
Therefore, instead of using a paired-test, orthogonal regression analysis was used in this study because it does not assume independence between variables. Interpretation of the
orthogonal regression results should be focused on the CI. It indicates that the measurements from the manual method and H-DAP method are not statistically different if zero is contained in the CI for the intercept and one is contained in the CI for the slope. Results revealed that there is no evidence showing that distress rates measured by manual method and H-DAP method are statistically different.

</table>

Ultimately, these results show that H-DAP method works as effectively as the manual evaluation does. Given the horizontal and vertical accuracy of the DSMs and orthophotos, the discrepancy between manual method measurement and the H-DAP method measurement could be from either method. Distresses measured by different inspectors have been shown to exhibit a high degree of variability (Bogus et al. 2010) because this method relies on subjective visual observation, suggesting that manual assessments will naturally exhibit variability. These results can be interpreted to indicate that H-DAP based method is at least as accurate as manual methods.

5 CONCLUSIONS

We present a novel approach for detailed infrastructure condition assessment using H-DAP acquired from a low-altitude URSS. Using roadway pavement assets as an example, results indicate that pavement surface distress conditions measured by manual methods and the H-DAP method are not statistically different from each other and that the proposed method is likely more accurate than manual methods. In the near-term, the proposed H-DAP method could be used to measure infrastructure conditions in situations where field inspectors cannot evaluate except with considerable labor costs (e.g. sections in remote areas) or where vehicles cannot access, but in the longer-term, the proposed method is capable of completely replacing field infrastructure condition assessment due to its high accuracy, potential for full automation, and dramatically reduced long term cost.

EX-ANTE ASSESSMENT OF VULNERABILITY TO UNCERTAINTY IN COMPLEX CONSTRUCTION PROJECT ORGANIZATIONS

Jin Zhu¹, and Ali Mostafavi²

Abstract: Modern construction projects are operated in extremely uncertain environments. Uncertainties affect the performance of projects. Despite an extensive body of literature in the area of performance assessment, there is a gap in knowledge pertaining to an integrated methodology for ex-ante evaluation of vulnerability of project organizations to the impacts of uncertainties. The objective of this paper is to address this gap in knowledge by creating a framework for ex-ante assessment of vulnerability in construction project organizations. In the proposed framework, construction project organizations are conceptualized as complex meta-networks and analyzed using dynamic network analysis. Accordingly, the impacts of the uncertain events (e.g., late design deliverables, equipment breakdown, safety accident and injury, and severe weather conditions) are translated into perturbations in different node entities (i.e., human agent, information, resource and task) and the corresponding links in project meta-networks. These uncertainty-induced perturbations cause transformations in the project topological structure, and thus, negatively affect the efficiency of project organizations’ meta-networks. The extent of the variation in the efficiency is used as an indicator of a project organization’s vulnerability to uncertainties. The application of the proposed framework is shown in a numerical example related to a tunneling project. Various scenarios related to different uncertain events were simulated to quantitatively investigate the vulnerability of the project and evaluate the impacts of different planning strategies on mitigating vulnerability. The results demonstrate the capability of the proposed framework for quantitative assessment of vulnerability and evaluation of planning strategies in construction projects. Hence, it provides a tool for proactive evaluation and mitigation of vulnerability in construction project organizations.

1 INTRODUCTION

Modern construction projects are complex and are executed in highly uncertain environments. Similar to other complex systems, construction project organizations have a greater likelihood for successful performance if they are less vulnerable to uncertainties. Despite a growing body of literature in the areas of performance assessment and risk analysis in construction projects, our understanding of the determinants of performance vulnerability in complex construction projects remains limited. First, the existing studies (e.g., Baloi and Price, 2003; Zou et al., 2007) mainly focus on identification of risks and uncertainties affecting the performance of construction project organizations. However, a better understanding on the extent and severity of performance variation in a project which also depends upon the vulnerability of the project organization is missing. Second, the majority of the existing risk and uncertainty assessment approaches (e.g., Nieto-Morote and Ruz-Vila, 2011) in construction projects are rather subjective and do not provide a robust quantitative basis for ex-ante evaluation of planning strategies to reduce the
vulnerability of project organizations to uncertain events. Third, the existing methods for performance assessment and risk analysis in construction projects do not capture the complex interactions between human agents, information, resources, and tasks in project organizations. Capturing these complex interactions is a critical step toward development of an integrated methodology for performance assessment in complex construction projects (Zhu and Mostafavi, 2014). To address these methodological limitations and gaps in knowledge, an integrated framework for ex-ante assessment of vulnerability in complex construction project organizations is proposed in this paper.

In the proposed framework, project organizations are conceptualized as dynamic multi-node and multi-link meta-networks composed of different node entities (e.g., agents, information, resources and tasks) and their interdependencies. Accordingly, the uncertain events in construction projects are translated into perturbations in the node entities and links of the meta-network. Then, using stochastic simulation, the impacts of uncertainty-induced perturbations on the performance of project organizations are captured based on the changes in the efficiency of the meta-network. Finally, the proposed framework enables ex-ante evaluation of different planning strategies and their significance in mitigating vulnerability.

2 A FRAMEWORK FOR ASSESSMENT OF PROJECT ORGANIZATION’S VULNERABILITY

There are four components in the proposed framework: abstraction of project meta-network, translation of uncertainty-induced perturbations, vulnerability assessment, and evaluation of planning strategies. Figure 1 shows the four components in a workflow for integrated vulnerability assessment in complex construction projects. The details of each component are explained in this section.

![Figure 1. A Framework for Integrated Vulnerability Assessment in Construction Projects](image)

2.1 Abstraction of Project Meta-network

Complex construction projects are systems-of-systems consisting of interconnected networks of human agents, information, resources and tasks (Zhu et al., 2014). The ability of project organizations to cope with uncertainty is an emergent property that arises from the interactions between different entities. Hence, for evaluating the vulnerability of a project organization to uncertainty, different entities and their interconnections should be properly abstracted. In order to facilitate the abstraction of the entities and their interactions in complex project organizations, Zhu and Mostafavi (2014a; 2014b; 2014c) proposed conceptualization of project organizations as systems-of-systems or meta-networks (Carley 2003). The meta-network of the construction project organization is composed of four types of node entities (i.e., agents, information, resources, and tasks) and ten types of links, as shown in Figure 2. To abstract the node entities and their interconnections, the first step is to identify the task nodes. A task node is an entity...
with a measureable outcome. In construction project, a task node could represent decision making, information processing or production work. A task is being implemented by one or more agent nodes which utilize information and resources to complete the task. After identification of the task nodes, the agent nodes can be identified. An agent node is an entity that implements the task. It could be an individual, a crew, or a team depending on the nature of tasks. Then, information and resource nodes can be identified accordingly based on the requirement of the tasks. The interdependencies and relationships between different node entities build the links in the project meta-network. Each type of links represents one type of relationship (e.g., agent-information link represents who knows what, agent-task link represents who is assigned to what task). One type of links and their corresponding nodes form an individual network [e.g., social network of agent-agent relationships (AA), assignment network of agent-task relationships (AT)]. Different networks are interconnected as a whole in the project meta-network. Changes in one node entity or network cascade into changes in the other node entities and networks.

![Nodes and Links in Project Meta-Networks](image)

**Figure 2. Nodes and Links in Project Meta-Networks**

### 2.2 Translation of Uncertainty-induced Perturbations

Conceptualizing project organizations as meta-networks provides a novel perspective for understanding the uncertain events and their corresponding impacts on the performance. According to the principles of network science, perturbations in networks affect their topological structures and stability (Dalziell and McManus, 2004). Using the theoretical underpinnings of network science, in the proposed framework, the impacts of uncertain events are translated into perturbations in the node entities and links in a project organization’s meta-network (Zhu and Mostafavi, 2015). Table 1 summarizes three main types of perturbations in construction projects (i.e., agent-related perturbations, information-related perturbations and resource-related perturbations) and examples of events corresponding to each type of perturbation. One uncertain event may cause perturbation in a single node entity (i.e., single-effect event) or multiple node entities (i.e., multi-effect event). For example, equipment breakdown on a jobsite may lead to a single-effect event, while the failure of the power system may cause multiple perturbations in different resource node entities. In the proposed framework, each uncertain event is abstracted using two attributes: its perturbation effect and likelihood of occurrence. The perturbation effect depends upon the node entities and links impacted due to the uncertain events. The likelihood of an uncertain event is determined using historical data or other probability encoding techniques (Clemen and Winkler, 1999).

*Table 1: Perturbations in Project Meta-networks*
2.3 Vulnerability Assessment

The vulnerability of the project can be measured based on the extent of the changes in the relevant topological measure (i.e., task completion measure) of the meta-network before and after a perturbation (Holme et al. 2002, Criado et al. 2005). The greater the change in the topological measure due to uncertain-induced perturbations, the greater the vulnerability of the network. More specifically, network vulnerability denotes the decrease of network efficiency due to a selected removal of nodes or links. For example, a network is moved from its equilibrium state $N$ to $N'$ due to exposure to uncertain event(s) $\mathcal{E}$. The corresponding vulnerability of the network to this exposure then can be defined using Equation 1:

$$[1] \nu(\mathcal{E}) = \varphi(N) - \varphi(N')$$

where $\varphi$ denotes the performance efficiency (i.e., functionality) of the network. There are different approaches to assess the performance efficiency of a network depending upon its type. In project organizations’ meta-networks, efficiency could be measured based on the percentage of tasks that can be completed by the agent assigned to them (i.e., based on whether the agents have the requisite information and resource to do the tasks) (Carley and Jeff, 2004). Equations 2-4 show the procedure for computation of information-based task completion. In Equations 2-4, binary matrices are generated based on the abstraction of the project meta-network (e.g., $AI$ represents a binary matrix representing the agent-information relationships, with agent node entities as the row and information node entities as the column). Similarly, resource-based task completion can be calculated by replacing matrices $AI$ and $IT$ with matrices $AR$ and $RT$ in the equations. The overall performance efficiency of a project organization’s meta-network is the average of information-based task completion and resource-based task completion values (Equation 5).

Hence, the vulnerability of a project organization to uncertain events can be obtained using Equation 1 and by assessing performance efficiency of the meta-network (from Equation 5) prior and after perturbations. The value of vulnerability ranges from 0 to 1. A higher value means that the project organization is more vulnerable to the uncertain events.

$$[2] Need = [(AT' \times AI) - IT']$$

$$[3] S = \{i | 1 \leq i \leq |T|, \exists j: Need(i, j) < 0\}$$

$$[4] Information \, based \, task \, completion = (|T| - |S|)/|T|$$

$$[5] \varphi(N) = (Information \, based \, task \, completion + Resource \, based \, task \, completion)/2$$

2.4 Evaluation of Planning Strategies

In the proposed framework, different planning strategies are translated to the addition/removal of node entities and/or links in the project organization’s meta-network. Table 2 provides examples of planning strategies and their reflections in the project organization’s meta-network related to task assignment, decision-making authority, as well as resource management. These different planning strategies can be translated to changes in the node entities and links in the meta-network. The same project could exhibit different levels of vulnerability under different planning strategies. The effectiveness of planning strategy is measured based on the reduction of vulnerability.

$$[6] effectiveness \, of \, planning \, strategy \, p = (\nu_p - \nu)/\nu$$

where $\nu$ denotes the vulnerability of the project to the uncertain events in the base scenario, and $\nu_p$ denotes the vulnerability of the same project to the uncertain events with alternative planning strategies.

3 NUMERICAL EXAMPLE

A hypothetical case related to a tunneling project is used here to illustrate the application of the proposed framework. In this example, a tunneling project constructed using New Austrian Tunneling Method (NATM) was modeled. Compared to the conventional tunneling method, which uses the suspected worst rock condition for design, NATM saves cost by adjusting the initial design during the construction phase (De Farias et al., 2004). In NATM, rock samples are collected by the geologist team during the early stage of design. After doing laboratory tests on the rock samples, the test results are compared with the rock quality designation index and the rock mass classification can be identified. The initial design is then conducted based on the identified rock type. The excavation crew performs excavation into the tunnel face based on the initial design, followed by loading explosives and blasting. Before blasting, the safety supervisor performs the safety inspection on the site and issues the safety approval. Right after the excavation work, the support installation crew starts working on the jobsite. Support installation crew applies shotcrete and installs the initial support (e.g., rockbolts, lattices girders or wire mesh) as the initial lining process. Measurement instrumentations are installed to observe the rock deformation behavior after the initial lining. The geologist team reads the data from the instrumentations and reports the rock deformation information to the designer. The designer team then makes the decision on whether a revision on the initial design is needed. The decision depends on whether the rock deformation is within the acceptable range. If no revision is necessary, a final lining process composed of traditional reinforced concrete is conducted; otherwise, the designer team revises the initial design for both initial lining and final lining. In this case, the support installation crew will use the revised design to implement the initial and final lining. The whole tunneling project is constructed in sections. At the end of each section, the project manager reviews the initial design, revised design, as well as the rock deformation, to assess the risks, and makes a decision on the step length for excavation of the next section. For example, if a relatively large deformation is observed, the project manager will decrease the step length to prevent the chance of collapsing. This tunneling project involves multiple dynamic and complex processes. A high level of interdependence exists between different agents, resources, information and tasks. Uncertain events could have negative ripple impacts on the project performance. For example, if a miscommunication happens between the geologist team and design team about the rock deformation information, not only will the task of revising design be directly affected, but also the succeeding tasks (e.g., installation of the final lining may not be performed appropriately due to lack of information related to revised design).

3.1 Integrated Vulnerability Assessment

The proposed framework was used for ex-ante analysis of vulnerability in the case study project. The four components of the proposed framework were all conducted in the context of the case. ORA-NetScenes 3.0.9.9 was used as the network analysis and modeling platform.

Abstraction of Project Meta-network

First, the meta-network of the project organization in the case study was abstracted. The project’s meta-network includes 36 node entities (of four different types) and 118 links (of ten different types) in total. Table 3 provides examples of different node entities and links in the tunneling project meta-network.
Translation of Uncertainty-induced Perturbations

Potential uncertain events, their effects, and the likelihood in the case project were identified. The potential events include single-effect events related to agent, resource, and information (e.g., geologist or designer turnover, delay in obtaining rock deformation data, or excavator breakdown), as well as events with multiple effects (e.g., power system failure or severe weather). Each uncertain event was translated to perturbations in the project's meta-network. For example, if a turnover in the design team happens, the designer node is isolated in the project's meta-network (i.e., with no links to project resource or information). Thus, the design tasks cannot be completed successfully. The likelihood of uncertain events was identified based on three levels of uncertainty: low (10%), medium (20%), and high (50%) (van der Gaag et al., 2002). Table 4 depicts the identified uncertain events, their perturbation effects, and likelihood in the case. For example, the level of uncertainty related to the late delivery of material was identified as high, which implies that, for each type of material used in this project (i.e., explosive, initial support, concrete and reinforcement), there was 50% likelihood of late delivery.

Vulnerability Assessment

The perturbations related to the uncertain events were simulated as independent random events in the case study. Using Monte-Carlo experimentation, 30 runs of the simulation model were implemented. Since the likelihood of one event occurring does not affect the likelihood of the other events occurring, multiple uncertain events happen in each run of the Monte-Carlo simulation randomly. In each run of simulation, the vulnerability of the project organization to the perturbations of the uncertain events that occurred in that run was assessed. Then, a probability distribution related to the vulnerability of the project organization under the identified uncertainties (i.e., uncertain events, their effects, and likelihood) in this case was obtained from the outcomes of the total 30 runs.

Evaluation of Planning Strategies

In the base scenario of the tunneling project studied, planning strategies of the generalization of labor, centralized decision making, and non-redundancy in resource management were adopted. To investigate the influence of different planning strategies on the project vulnerability, three comparative planning scenarios were developed. For comparative analysis, in each scenario, only one aspect of the planning strategy was different from the base scenario. In the first scenario, the planning strategy pertaining to task assignment was changed. In the base scenario, there was only one single agent node for the geologist team and one agent node for the designer team. Tasks of laboratory tests and observing rock deformation were both assigned to the same geologist agent, and tasks of conducting initial design and revised design were both assigned to the same designer agent. In scenario 1, two more agent nodes were added as geologist and designer. Thus, division of labor was achieved (i.e., tasks of laboratory tests and observing rock deformation were assigned to the different geologists, and tasks of conducting initial design and revised design were assigned to the different designers). In the second scenario, the planning strategy pertaining to the decision-making authority of the step length was changed. In the base scenario, the designer should report the corresponding information (e.g., initial design, revised design and rock deformation) in the current section to the project manager and wait for the project manager to make the decision on the step length for the next section. In scenario 2, the decision-making authority related to step length was given to the designer at the lower level, since he/she already holds all the required information for making the decision. Thus, in scenario 2, the project manager node and its corresponding links were removed from the project’s meta-network. In the last scenario, the planning strategy of redundancy in resources was adopted. In the base scenario, no redundancy was considered in the resource management strategy. In scenario 3, nodes of the additional electrical power system, shotcrete machinery, and boomer were added as backup resources. These resource nodes were linked with other related nodes in the project’s meta-network so that they could be used by the corresponding agents for specific tasks. Figure 3 shows all the meta-networks (without any perturbation) related to the four scenarios. Since different planning strategies were translated to different topologies of the project organization’s meta-network, differences in the numbers of nodes, links, as well as the network densities of meta-networks under different planning strategies can be observed. For each scenario, vulnerability assessment was conducted following the same procedures. The effectiveness of different planning strategies was then evaluated.

Figure 3. Meta-networks of the Tunneling Project under Different Planning Strategies
3.2 Results

Figure 4 shows the results related to one run of vulnerability assessment for the tunneling project in the base scenario. In this specific run, no multiple-effect uncertain events happened. However, several single-effect uncertain events happened simultaneously. The safety supervisor left the position and the support installation crew failed to complete the tasks in the project. The geologist didn’t have access to the latest version of rock quality designation index, which led to difficulty in accurately determining the rock type. Also, there was a delay in the delivery of materials to the jobsite, including explosive, initial support, concrete and reinforcement. Finally, the boomer equipment which facilitates the tasks of applying shotcrete and installing support didn’t function properly during the project. In this specific circumstance, the project meta-network was pushed away from its original stable state, as shown in Figure 4. The network efficiency was decreased from 1 to 0.625, which means after the perturbations mentioned above, only 62.5% of the tasks could be completed if no adaptive or restorative actions were taken. Thus, the project vulnerability to the uncertain events assessed in this run is 0.375.

Figure 5 shows the results of vulnerability assessment in the total 30 runs of the Monte Carlo simulation for the base scenario. Figure 5(a) is a boxplot for the vulnerability values in different runs. Each data point shows the vulnerability obtained in one run. The interquartile range box indicates that 25% of the vulnerability values in the 30 runs are less than 0.3645, and 75% of them are less than 0.5. The boxplot also suggests the values of vulnerability obtained in the 30 runs are normally distributed. Figure 5(b) shows the bell curve of the distribution. With the mean value (0.4111) and standard deviation (0.1092) of the 30 samples, the average vulnerability of the project organization to the uncertainties in the case can be predicted. For example, with a 95% confidence interval, the average vulnerability of the tunnelling project under the base scenario to the identified uncertainties is between 0.3703 and 0.4519. A higher level of vulnerability implies more possible losses when facing uncertainties. Thus, construction project companies can use the results of the ex-ante vulnerability assessment to predict the possible disturbance magnitude of project against uncertain events and develop corresponding contingency plans.

Figure 4. Changes in Network Efficiency in One Run of Monte Carlo Simulation for the Base Scenario

Figure 5. Project Organization’s Vulnerability for the Base Scenario
The other component of the analysis was to evaluate the effectiveness of different planning strategies in reducing vulnerability of project organization to the uncertainty-induced perturbations. Figure 6 shows the vulnerability of the tunneling project in different scenarios related to planning strategies. The interval plots in Figure 6 depict the mean values of multiple runs of the Monte Carlo simulation for each scenario with a 95% confidence interval. The effectiveness of the planning strategies related to task assignment, decision-making authority and resource management was evaluated by calculating the decreases of the project organization’s vulnerability in different scenarios. From the results, it is obvious that division of labor adopted in scenario 1 is the most effective planning strategy which decreases the vulnerability of the project organization in the base scenario by 16.57%. This is due to the fact that when each agent or agent crew is assigned for one specific task and role, the impact of perturbations on single agent node is limited. The planning strategy of considering redundancy in resource also shows the capability in reducing the vulnerability of project organization. Compared with the base scenario, the mean value of the vulnerability assessed in the samples of scenario 3 is reduced by 12.16%. When the planning strategy of resource redundancy is considered, the project organization becomes more robust especially against resource-related perturbations, as the backup resource could help to maintain the efficiency of project network. The planning strategy related to decision-making authority doesn’t show significant effectiveness in this case. The vulnerability is decreased only by 0.34% in average when adopting the planning strategy of decentralized decision-making authority in scenario 2 compared with the base scenario. As a conclusion, in this tunneling project, the planning strategies of division of labor and redundancy in resource have the most significant impact on reducing project organization’s vulnerability. This kind of information can help the decision makers to select the most effective planning strategies from a list of options in order to decrease the vulnerability of the project organization. Adopting alternative planning strategies usually implies more input into the project (e.g., hiring more agents, ordering backup resource). Knowing the effectiveness of alternative planning strategies provides the basis for the decision makers to conduct cost benefit analysis and make the final decision on whether to adopt certain planning strategy or not.

### 4 CONCLUSION

Traditional methods of risk analysis in construction projects are based on qualitative, descriptive and reactive approaches. In this paper, an integrated framework for ex-ante assessment of vulnerability to uncertainties in complex construction project organizations is proposed. The proposed framework provides
a novel approach for quantitative assessment of project vulnerability based on the theoretical underpinnings of network theory. It provides a quantitative basis for ex-ante assessment of vulnerability and evaluation of planning strategies. The results of the integrated vulnerability assessment can be used for analysis of the benefits of alternative planning strategies and selecting the most effective planning strategies for reducing vulnerability under uncertainty. The application of the proposed framework will facilitate a paradigm shift toward ex-ante assessment of performance vulnerability in complex construction projects. It enhances the design and management of project organization toward proactive reduction of vulnerability. It also will enable creation of novel theoretical constructs for a better understanding of the links between planning strategies, complexity, and vulnerability in construction projects. This understanding will provide prescriptive findings and flexible strategies that lead to predictive assessment and proactive management of performance in construction projects.

Abstract: Construction is one of the most dangerous job sectors over the world. Any accidents that happen on the construction sites will bring the sufferings to the workers and their families and incur the delays and costs to the projects. Therefore, it is necessary for the contractors to monitor potential site safety issues and comply with existing safety regulations all the time. One of fundamental safety regulations is hardhat wearing. The wearing of the hardhats is always mandated and should not be violated anytime on the construction sites. In this paper, a novel method is proposed to facilitate the monitoring of whether any persons on the construction sites are wearing hardhats as required by the safety regulations. The method is built upon computer vision techniques. Under the method, human bodies and hardhats are first detected in the video frames captured by real-time on-site construction cameras. Then, their pair-wise matching is found. For those persons without the matching of the hardhats, they are identified as not wearing hardhats. The proposed method has been tested on real site videos. The test results showed that multiple persons could be monitored even if they are not wearing any real-time location sensors or tags. The test results demonstrate the potential of using live streaming or time-lapse construction site videos to facilitate the safety monitoring work on construction sites.

1 INTRODUCTION

Construction has been identified as one of the most dangerous job sectors. CBC News (2012) once reported that a total of 700 deaths occurred in the construction industry from 2008 to 2010, which almost accounted for 23.3% of all workplace fatalities. Also, the Association of Workers’ Compensation Boards of Canada (AWCBC) mentioned that there were more than 27,000 time-loss injuries in the construction industry each year from 2009 to 2010 (AWCBC, 2011). In order to provide a healthy and safe working environment for construction workers, several onsite safety regulations have been established by the governments. They specify the contractors’ responsibilities and duties on the construction sites, including the appropriate use of appropriate personal protective equipment (PPE). The contractors must ensure that the regulations are enforced. In Quebec, this job is assigned to onsite safety inspectors, called construction site health and safety management guarantors. The guarantors need to take every necessary measure to ensure the general contractors comply with the safety regulations.

Hardhats are one type of important PPE. Any individual person must wear a hardhat, when they enter to a construction site. For example, the Safety Code for the Construction Industry mandates that “any person on a construction site shall wear a certified safety hat in accordance with CSA Standard” (Quebec, 2014). The similar guideline or regulation could also be found in the OSHA (Occupational Safety & Health Administration). It stipulates that “Employees working in areas where there is a possible danger of head
injury from impact, or from falling or flying objects, or from electrical shock and burns, shall be protected by protective helmets” (OSHA, 2012). Therefore, it is one of top priorities for the safety inspectors to check and confirm all employees and site visitors wear hardhats all the time on the construction sites.

However, the statistic data indicated that that most workers who suffered impact injuries to the head were not wearing hardhats, even when performing their normal jobs on their regular worksites. The Bureau of Labor Statistics once noted that "hardhats were worn by only 16% of those workers who sustained head injuries, although two-fifths were required to wear them for certain tasks at specific locations" (OSHA, 2006). The reasons for not wearing hardhats could be various, such as discomfort while wearing hardhats, disassociation with the safety issues, etc. For example, workers might take off their hardhats to cool off, when the temperature is high.

Therefore, it is necessary for the safety inspectors to monitor all persons on the site to wearing hardhats all the time. In order to facilitate the inspectors' monitoring work, this paper proposed a novel method for checking whether persons on the construction sites are wearing hardhats or not. The proposed method is built upon the live streaming or time-lapse construction site videos with computer vision techniques. It mainly include the detection of human bodies and the detection of hardhats. When the human bodies and hardhats are detected, their pair-wise matching is performed, so that those persons without wearing hardhats could be identified.

The effectiveness of the proposed method has been tested with real site videos. The test results showed that the method could monitor the wearing of hardhats on multiple persons simultaneously. These persons do not have to be tagged. This nature makes the method affordable to be used at most construction sites. The proposed method is expected to facilitate the safety inspectors' work and enhance construction site safety. The site safety enhancement could bring several benefits to the contractors, including increasing workers' productivity and reducing project direct and indirect costs due to the cost saving from preventing construction accidents.

2 RELATED WORK

2.1 RTLS-based Site Safety Enhancement

The enhancement of onsite construction safety has been increasingly received attentions of researchers and industrial practitioners. Several research studies have been initiated for the purpose of adding an extra level of proactive safety measures using real-time location systems (RTLS). These RTLS typically relied on the remote sensing techniques, such as radio frequency identification (RFID), global positioning system (GPS), wireless local areas networks (WLAN), and ultra-wide band (UWB).

Most RTLS have been used for proximity warning. Ruff (2007) compared different RTLS in his report for evaluating and implementing proximity warning systems on surface mining equipment. Moreover, Teizer et al. (2010) presented their findings of using Very-High Frequency (VHF) active Radio Frequency (RF) technique to warn ground workers and equipment operators once they are too close in proximity. In the work of Carbonari et al. (2011), they relied on UWB tracking data to implement a proactive virtual fencing system, and demonstrated its capability of reinforcing safety management policies. Also, Chen and Teizer (2013) integrated the real-time GPS and UWB location data into a virtual reality environment representing a construction site for monitoring construction safety.

In addition to the use of RTLS for the proximity warning, the systems could also be adopted for other purposes related to construction safety enhancement. Kelm et al. (2013) designed an RFID-based portal to check whether the workers' personal protective equipment (PPE) complied with the corresponding specifications. Aguilara and Hewageeb (2013) developed an IT based safety management system using web cameras, barcodes and RFID tags installed on construction equipment.

However, existing RTLS come with limitations, when they are used for monitoring the wearing of hardhats on construction workers. First, in order to check whether construction workers are wearing hardhats, it is at least necessary to attach a tag or sensor on each person and hardhat. In addition, the RTLS are mainly
used for real-time location tracking. Therefore, it is difficult to use the RTLS to identify whether the hardhats are appropriately used, considering that workers might take off their hardhats and put them aside while doing their jobs.

2.2 Video-based Site Safety Enhancement

Live streaming or time-lapse video cameras are increasingly placed on construction sites, considering their acceptable return on investment (Bohn and Teizer, 2010). For example, Hydro-Quebec has recently decided to install video cameras on their construction sites to facilitate the monitoring of daily construction activities. The live streaming or time-lapse videos collected by the cameras record project ongoing construction activities on the construction sites. Therefore, they are useful for monitoring construction site safety issues. Abeid and Arditi (2002) relied on live streaming or time-lapse videos collected on construction sites to investigate construction accidents. Liaw et al. (2012) used the live stream or time-lapse videos to create safety training and education media resources.

So far, several research studies have been initiated to investigate the potentials of live streaming or time-lapse videos to create onsite safety alert systems built upon computing techniques. For example, Steele et al. (2003) once proposed to mount a stereo camera on the rear of an off-highway dump truck, and the stereo videos could help the truck driver identify possible on-site obstacles on the mining site. In addition to mounting stereo cameras on the equipment, the cameras are also placed on the site to capture and analyze workers’ unsafe actions, considering these actions might result in accidents. Han and Lee (2013) and Han et al. (2013) relied on Kinect-style cameras to monitor whether construction workers on a ladder are leaning too far to one side or reaching too far overhead to prevent the falls from the ladders.

Similar to the work presented in this paper, Giovanni et al. (2009, 2011) designed a vision-based system to support the workers’ safety by checking the presence of those workers without wearing hardhats on construction sites. In their work, they first used a pedestrian classifier with covariance descriptors to recognize construction workers in video frames, and then used the head and hard-hat detectors. However, there is one major limitation in their system. The system could not function correctly, when the workers on construction sites wear white hardhats. The failure of the detection of white hardhats makes the system generate a lot of false alerts. As illustrated in Figure 1, the safety alert issued by their system (Giovanni et al. 2009, 2011) was false, since the person identified as not wearing a hardhat (red box) was actually wearing a hardhat.

![Figure 1: Failure of detecting white hardhats](image)
3 OBJECTIVE AND SCOPE

The overall objective of this paper is to evaluate the safety issue of whether individuals on construction sites are wearing hardhats as required by existing safety regulations could be monitored with live streaming or time-lapse videos. If any individual on the construction site is not wearing a hardhat, an alert will be produced to ask for the onsite safety inspector's attention. This way, it could facilitate the routine inspection work performed by the onsite safety inspector.

This paper only focuses on the wearing of hardhats, considering the hardhats are one type of important personal protective equipment (PPE) items on the construction sites. They could protect the workers from impact and penetration hazards as well as from electrical, shock and burn hazards. Although the hardhats are play an important role on head protection, individual persons on the construction sites might still be careless about wearing the hardhats, even including construction workers themselves. Moreover, it is difficult for a safety inspector to monitor whether each individual person on the construction site is wearing the hardhat all the time.

4 PROPOSED METHODOLOGY

In order to achieve the objective mentioned before, a novel vision-based method is proposed for monitoring any individual persons who are not wearing the hardhats on the construction sites (Figure 2). The method includes three steps, as illustrated in Figure 2. The human bodies and hardhats are first detected based on their histogram of gradient (HOG) features. Then, their pair-wise matches between the detected human bodies and hardhats are found based on their geometric and spatial relationships. If a human body detection region has no corresponding hardhat detection match, it means that the person in the human body detection region is not wearing a hardhat. Therefore, this human body detection region is highlighted for the onsite safety inspector's attention.

![Diagram](image)

Figure 2: Proposed methodology

4.1 Human Body Detection

The purpose of the human body detection is to locate individual persons on the construction site, such as engineers, labourers, carpenters, etc., in video frames. In order to speed up the human detection process, the background subtraction proposed by Macfarlane and Schofield (1995) is first used to extract the moving blobs in the video frames. The moving blobs are further analyzed with the morphological operations (i.e. dilation and erosion) to remove the small sized ones. Then, the human body detection is limited to the remaining blobs as the foreground regions.

As for the detection of human body in the foreground regions, the detection includes two stages as suggested by researchers such as Dalal and Triggs (2005) and Felzenszwalb et al. (2010). First, a large number of positive training samples (human body images) and negative samples (non human body images) are collected and used for the supervised training of a support vector machine (SVM). Once the training is completed, the detection of human bodies in the test video frames works by sliding a search window across the foreground regions. The HOG feature is extracted from each window and classified by the SVM as a human body or not.
4.2 Hardhat Detection

Hardhats are typically made of fiberglass and rigid plastic. On the one hand, the colors of the hardhats could be white, brown, green, blue, orange, red, etc. to indicate the roles (e.g. managers, engineers, superintendents, and laborers) of the wearers on construction sites. Considering the colors could vary, it would be difficult to rely on the color information as detection cues. On the other hand, most hardhats have similar cap-style shapes. They are rigid and do not have deformations.

Therefore, hardhat detection here is similar to the detection of human bodies. The HOG features of the hardhats are extracted from the video frames as the detection cue, especially considering that the HOG feature is capable of describing detailed shape information in an efficient way. Moreover, the effectiveness of the HOG features has been well-proven in many research studies for shape-based object detection. The hardhat detection includes two stages. First, hundreds of construction site images with different poses of hardhats are collected as a training database, where the hardhat HOG features are calculated and input into an SVM for the supervised training. The training results are compiled into a hardhat detection model. In order to detect hardhats in a video frame, the HOG features extracted from the test frame are input to the detection model, and the best possible placements of the hardhats could be determined. The detection model here only uses the HOG features without color cues. Therefore, it could detect the hardhats with different colors.

4.3 Human Body and Hardhat Pair-wise Matching

After the detection of human bodies and hardhats, the detected hardhats should be matched to the detected human bodies to find out those persons who are not wearing hardhats on the construction sites. The matching here is mainly based on the spatial relationships between the detection regions of the hardhats and human bodies. Typically, the detected hardhat should be located in the upper area of the detected human body region, if the person in the detected human body region is wearing a hardhat. If there is no matching that could be found on that person, it indicates that the person is not wearing a hardhat. Then, a safety alert is produced to ask for the safety inspector's attention. One example of the pair-wise matching between the detected human bodies and hardhats could be found in Figure 3. In the figure, the matches of the hardhats for three persons in the right could be successfully found. As a contrast, the pair-wise matches of the hardhat for the two persons in the left could not be found, since they are not wearing hardhats.

5 IMPLEMENTATION AND RESULTS

The method was implemented and tested with real site videos captured by a Canon VISXIA HF S100 at a project site in Atlanta. The site was managed by Barton Malow Company. The test videos includes a total...
of five persons. Three of them were wearing hardhats on the site and two were not wearing hardhats for
the evaluation purpose. The test video was 166-second long, and recorded with 20 frames per second
(fps) containing 3,320 frames. The resolution of the videos is fixed at 768 pixels by 432 pixels.

5.1 Results of Human Body Detection and Hardhats Detection

Figure 4 illustrates the results of detecting human bodies and hardhats in the test video frames. Most
human body detections made by the method are correct, although the method missed some human body
detections (i.e. the persons in the video frames are not detected by the method). The correct detection of
human bodies is more important than the missed detection in terms of monitoring whether a person is
wearing a hardhat or not on the construction site. If the method could only successfully detect a person
every 10 frames, the miss rate is high, but it is still able to monitor whether the person is wearing a
hardhat once in a second. On the other hand, if the correct detection rate is low, it increases the chances
of false alarms. For example, if the method misrecognizes tree branches as a human body, a false alarm
will be issued, since the hardhat could not be detected in the detection region of that ‘person’.

![Figure 4: The detection of human bodies and hardhats](image)

Compared with the human body detection, most hardhats in the test video frames could be detected by
the proposed method. However not all the detections are correct. The strategy for the hardhat detection is
to reduce the detection miss rate. The low detection miss rate is more important than the correct hardhat
detection rate in terms of monitoring whether a person is wearing a hardhat or not on the construction site.
In other words, most false hardhat detections do not significantly affect the performance of issuing the
final safety alerts, when persons are not wearing hardhats. The reason is mainly due to difficulty in
establishing the links of the incorrect hardhat detection results to the detection of any human bodies.

5.2 Performance of Safety Alerts for not Wearing Hardhats

When there is no hard detected in a human body detection region, it indicated that the individual person
in the human body detection region is not wearing a hardhat. Therefore, a safety alert should be issued o
highlight the person for the onsite safety inspector’s attention. In order to measure the performance of the
safety alerts issued by the proposed method, the issued safety alerts are manually classified as true
positive (TP) alerts, false positive (FP) alerts, and false negative (FN) alerts. The TP alerts are the alerts
that should be issued in reality. The FP alerts are the alerts that do not have to be issued in reality. The
FN alerts are the alerts that should be issued in reality but the alert is not issued by the method. Their
definitions have been illustrated in Table 1. Based on the number of TP, FP, and FN safety alerts, the
precision and recall for issuing the safety alerts could be calculated using the following equations.

[1] Precision = TP / (TP + FP)

[2] Recall = TP / (TP + FN)
Table 1: Definition of TP, FP, and FN safety alerts

<table>
<thead>
<tr>
<th>Category</th>
<th>Issuing the alert based on the method</th>
<th>Issuing the alert based on the safety regulation</th>
</tr>
</thead>
<tbody>
<tr>
<td>TP</td>
<td>YES</td>
<td>YES</td>
</tr>
<tr>
<td>FP</td>
<td>YES</td>
<td>NO</td>
</tr>
<tr>
<td>FN</td>
<td>NO</td>
<td>YES</td>
</tr>
</tbody>
</table>

According to the test results, it was found that the precision for issuing the safety alerts reached 94.3%, while the recall for issuing the safety alerts was 89.4%. The 94.3% precision means that 5.7% of the alerts issued by the proposed method are false. The 89.4% recall indicates that nine out of ten individual persons without wearing hardhats could be successfully monitored when applying the proposed method on construction sites. Both high alert precision and recall show the effectiveness of the proposed method on monitoring whether individual persons on the construction site are wearing hardhats as required by existing safety regulations, such as the Safety Code for the Construction Industry and the Safety and Health Regulations for Construction.

6 LIMITATIONS AND DISCUSSION

There are several limitations found from the tests. Most limitations are more or less associated with the detection of human bodies on a construction site. First, the human body detection is limited to the detection of the persons with standing or walking postures on the construction sites. So far, it is difficult to detect the persons with other postures. For example, when the workers are crouching down, bending, or sitting, it is difficult for the method to detect them. Therefore, the detection template used by the method should be extended to include more training samples of the workers with different postures.

Second, the occlusion is one of the major obstacles that could affect the performance of the proposed method on monitoring the wearing of the hardhats. If the persons are partially or fully occluded on the construction site, the monitoring with the proposed method will fail. The proposed method could only monitor the workers when they are visible in the camera view. Therefore, it is important to install an appropriate number of construction cameras and select the appropriate positions for installing the cameras on a construction site.

In addition, the proposed method relied on the background subtraction to speed up the detection of human bodies. The purpose of the background subtraction is to limit the detection of human bodies only in the foreground blobs in motion. This means only moving persons on the construction site could be detected. If they are static without any motions, the workers are filtered out through the background subtraction, since they are considered as the background. Considering the workers could always be detected when they just enter into the camera view, the integration of the detection and tracking of onsite persons might provide one possible solution to continuously monitor the persons even if they are static.

7 CONCLUSIONS AND FUTURE WORK

Existing safety policies and regulations could enhance construction site safety; however, these policies and regulations might not be strictly followed on the construction site. For example, construction workers might slip up and not exactly keep the requirements in the policies and regulations due to fatigue, distractions, carelessness, etc. Therefore, it is necessary to monitor any violations of the safety policies and regulations on construction sites. Currently, this safety monitoring job is manually performed by onsite safety inspectors (e.g. construction site health and safety management guarantors in Quebec). It might be difficult for the inspectors to monitor all safety policy and regulation violations on the construction site at any time through manual monitoring.

In order to facilitate the safety inspectors’ monitoring work, this paper proposed a novel, vision-based method for automatically monitoring whether any individual persons wear hardhats on the construction site as required by existing construction site safety polices and regulations. The method includes three
main steps: 1) human body detection, 2) hardhat detection, and 3) human body and hardhat pair-wise matching. If there is a human body detection area without the corresponding hardhat detection matched, it means that the person in the area is not wearing the hardhat. Therefore, a safety alert will be issued.

The method has been tested with the video frames captured at a real site. According to the test results, it was found that the overall precision and recall for issuing the safety alerts with the proposed method could reach 94.3% and 89.4%. The high precision and recall indicate the effectiveness of the proposed method on monitoring whether individual persons are wearing hardhats on the construction site. Future work will focus on the following two areas. First, the monitoring of wearing other types of personal protective equipment (safety vests, boots, etc.) on the construction sites will be investigated using vision technologies. Also, more investigations regarding the detection of human bodies with different postures will be performed in the future.
