<td>Integrating 3D CAD and Cost Estimating at the conceptual design stage of bridge projects</td>
<td>Bashar K Al-Dosary, University of Ottawa; Ahmad Jrade*, University of Ottawa</td>
</tr>
<tr>
<td>214</td>
<td>Energy-Based Safety Risk Management</td>
<td>Dillon Alexander, University of Colorado; Matthew R Hallowell*, University of Colorado; John A Gambatese, Oregon State University</td>
</tr>
<tr>
<td>34</td>
<td>An investigation into current tendering process in Saudi construction projects</td>
<td>Shabbab A Alhammadi*, Shaqra University</td>
</tr>
<tr>
<td>26</td>
<td>BIM Obstacles in Industrial Projects: A Contractor Perspective</td>
<td>Mostafa Ali*, University of Alberta; Yasser Mohamed, University of Alberta; Hosein Taghaddos, PCL; Rick Hermann, PCL</td>
</tr>
<tr>
<td>188</td>
<td>Integrating Building Information Modeling And Conceptual Design Towards Effective Facilities Management: A Framework Title</td>
<td>Elaf T Al-Kattan*, University of Ottawa; Ahmad Jrade, University of Ottawa</td>
</tr>
<tr>
<td>27</td>
<td>Culture and Construction</td>
<td>Leigh Allison*, University of Washington; Jessica Kaminsky, University of Washington</td>
</tr>
<tr>
<td>167</td>
<td>Benefits Of Integrating Building Information Modeling And Geographical Information System In Construction Management And Control</td>
<td>Ahmad A Al-Saggaf*, University of Ottawa; Ahmad Jrade, University of Ottawa</td>
</tr>
<tr>
<td>109</td>
<td>Integrating Building Information Modeling (BIM) With Sustainable Universal Design Strategies To Evaluate The Costs And Benefits Of Building Projects</td>
<td>Bader T Alsayyar*, University of Ottawa; Ahmad Jrade, University of Ottawa</td>
</tr>
<tr>
<td>258</td>
<td>A Novel Framework For Bim Enabled Facility Energy Management – A Concept Paper</td>
<td>Firas Al-Shalabi, Iowa State University; Yelda Turkan*, Iowa State University</td>
</tr>
<tr>
<td>262</td>
<td>BrIM Implementation for Documentation of Bridge Element Condition for Inspections</td>
<td>Firas Al-Shalabi, Iowa State University; Yelda Turkan*, Iowa State University</td>
</tr>
<tr>
<td>142</td>
<td>Guideline To Apply Hedging To Mitigate The Risk Of Construction Materials Price Escalation</td>
<td>Mohammad Ammar Al-Zarrad*, University of Alabama; Gary P Moynihan, University of Alabama; Stephanie Vereen, University of Alabama</td>
</tr>
<tr>
<td>226</td>
<td>Discovering The Values Of Residential Building Occupants For Value-Sensitive Improvement Of Building Energy Efficiency</td>
<td>Kadir Amasyali*, University of Illinois at Urbana-Champaign; Nora El-Gohary, University of Illinois at Urbana-Champaign</td>
</tr>
<tr>
<td>78</td>
<td>Development and Validation of Regression Models to Predict Annual Energy Consumption of Office Buildings in Different Climate Regions in the United States</td>
<td>Shideh Shams Amiri; Mohammad Mottahedi; Somayeh Asadi*, Penn State University; David Riley</td>
</tr>
<tr>
<td>275</td>
<td>Real-Time Accident Detection Using UWB Tracking</td>
<td>Carlo Andolfo *, University of Calgary; Farnaz Sadeghpour, University of Calgary</td>
</tr>
<tr>
<td>179</td>
<td>The Influence of Public-Private Partnerships on Design Flexibility and Downstream Design Feedback in the Presidio Parkway</td>
<td>Eric I Antillon*, University of Colorado; Amy Javernick-Will, University of Colorado Boulder; Keith R Molenaar, University of Colorado Boulder</td>
</tr>
<tr>
<td>212</td>
<td>Brazilian and Canadian Oil &amp; Gas Industries – Similarities, Differences, Challenges and Perspectives for a Sustainable Industry</td>
<td>Rodrigo R Aragao*, University of Toronto; Tamer El-Diraby, University of Toronto</td>
</tr>

</table>
104 Design and validation of the first phase of the new Chronographical Standard Protocol for construction project scheduling Fabian Ardila, École de Technologie Supérieure; Adel Francis*, École de Technologie Supérieure

6 3D Finite Element Modeling of Recycled Glass Cullets in Asphalt shingles Marwa Hassan*, Louisiana State University; Somayeh Asadi, Penn State University; Ali Beheshhti, Louisiana State University

16 Comparative Evaluation of LEED and QSAS Credits using Life Cycle Analysis: Case Study from Qatar Sherif O Attallah*, Ball State University; Amr Kandil, Purdue University; Ahmed Senouci, Qatar University; Hassan Alderham, Qatar University; Karim Abdelwarith, Purdue University

322 Hazardous Proximity Zone Design for Heavy Construction Equipment Ibukun Alwolusi, University of Alabama; Eric Marks*, University of Alabama; Nipesh Pradhananga, Florida International University; Tao Cheng, ExxonMobile Upstream Research Company

186 Understanding the implications of augmented reality out of context in engineering education Steven K Ayer*, Arizona State Univ.; John I Messner, Penn State University; Chima J Anumba, Penn State University

269 Effectiveness of Automated Machine Guidance Technology in Productivity Improvement: Case Study Ehsan Rezaeazadeh Azar*, Lakehead University; Gabriel Agnew, Lakehead University; Andrew Parker, Lakehead University

105 Hybrid Object Detection and Marker Recognition System to Monitor Performance of the Hauling Dump Trucks Ehsan Rezaeazadeh Azar*, Lakehead University

92 Optimization Of An Office Building Envelope For Environmental Impact Minimization Rahman Azari*, University of Texas at San Antonio; Samira Garshasbi; Pegah Amini; Yousef Mohammadi; Hazem Rashed-Ali, University of Texas at San Antonio

301 Public-Private Partnerships – Analysis of Government Implementation Units Ahmed M Abdel Aziz*, University of Washington; Amr Elmahdy, University of Washington

100 A Simulation Framework for Ex-Ante Analysis of Safety Hazards in Construction Projects Amin Alvanchi*, Sharif University of Technology; Farshid Baniassadi, Sharif University of Technology; Ali Mostafavi, Florida International University

102 Assessment of Network-level Environmental Sustainability in Infrastructure Systems using Service and Performance Adjusted Life Cycle Analysis Mostafa Batouli*, Florida International University; Ali Mostafavi, Florida International University

218 Live safety demos: New method to enhance situational awareness and situational interest through emotional engagement. Siddharth Bhanbadri, University of Colorado; Matthew R Hallowell*, University of Colorado

202 A Decision-making Algorithm for Selecting Building Information Modeling Functions Sneha Bhoir, University of Nebraska–Lincoln; Aimee Schwab, University of Nebraska–Lincoln; Behzad Esmaeili*, University of Nebraska–Lincoln; Paul M Goodrum, University of Colorado Boulder

222 Measuring Construction Workers’ Attention Using Eye-Tracking Technology Sneha Bhoir, University of Nebraska–Lincoln; Sogand Hasanzadeh, University of Nebraska–
ICSC15 - The CSCE International Construction Specialty Conference, Vancouver, June 7 - 10, 2015

265 **Closing the Contractual Circle: Investigating Emergent Subcontracting Approaches**

Salvatore Antonio Biancardo*, University of Naples Federico II; Natasha Osmanbhoy, University of Washington; Jeff Ottesen, University of Washington; Giovanni Migliaccio, University of Washington; Caroline M Clevenger, University of Colorado Boulder

81 **An Exploration Of Image-Based Walk Through Technologies**

David Cody Bradley, O’Kane Consultants Inc. Fredericton, NB, Canada; Sara Rankohi*, University of New Brunswick; Jeff Rankin, University of New Brunswick; Lloyd Waugh, University of New Brunswick

67 **Maintaining Vertical Gardens Using Quadrotor Aerial Inspection**

Alexey Bulgakov*, SWSU Kursk, Russia; Rainer Schach, Technical University Dresden; Sergei Emelianov, SWSU Kursk, Russia; Dafer Sayfeddine, South Russian State Polytechnic University, Novocherkassk, Russia; Vladimir Erofeev, State University Mordovia, Saransk, Russia

148 **Analytical and simulation modeling of bulldozer’s workflows**

Alexey Bulgakov*, SWSU Kursk, Russia; Georgy Tokmakov, South Russian State Polytechnic University, Novocherkassk, Russia; Thomas Bock, TU Munich

203 **Photobiological Treatment Plants Which Are Integrated with Building’s Architectural Shell**

Natália Buzálo*, South Russian State Polytechnic University, Novocherkassk, Russia; Pavel Ermachenko, Platov South-Russian State Polytechnic University (NPI); Alexey Bulgakov, SWSU Kursk, Russia; Rainer Schach, Technical University Dresden

251 **Evaluation of Organisational Context and Requirements for Leveraging Building Information Models to Support Handover and Operations & Maintenance**

Hasan B Cavka*, University of British Columbia; Sheryl Staub-French, University of British Columbia; Rachel Pottinger, University of British Columbia

252 **Characterizing Bottlenecks in Building Design Coordination Meetings**

Hasan B Cavka*, University of British Columbia; Sheryl Staub-French, University of British Columbia; Melanie Tory, University of Victoria

110 **Data Collection Framework for Construction Safety Research**

Yuting Chen*, University of Toronto; Emilie Alderman, University of Toronto; Brenda Y McCabe, University of Toronto; Douglas Hyatt, Rotman School of Management

51 **Analysing Parties’ Behaviours on Mediating Building Management Cases**

Sai On Cheung*, City University of Hong Kong; Tsz Yeung Chan, City University of Hong Kong; Kenneth T.W. You, University of Auckland

145 **Multi-Perspective Assessment Method For Measuring Leading Indicators In Capital Project Benchmarking**

Jiyong Choi, University of Texas at Austin; Sungmin Yun*, Construction Industry Institute; Stephen P Mulva, Construction Industry Institute; Daniel P Oliveira, Construction Industry Institute; Youngcheol Kang, University of Seoul

173 **Culture And Organizational Culture In The Construction Industry: A Literature Review**

Jin Ouk Choi*, Iowa State University; Ghada M Gad, Bowling Green State University; Jennifer S Shane, Iowa State University; Kelly Strong, Colorado State University

189 **Development and Utilization of the Project Definition Rating Index for Small Industrial Projects**

Abstract: According to the recent the Intergovernmental Panel on Climate Change (IPCC), Fifth Assessment Report (AR5) globally, buildings were responsible for about 32% of energy consumption and emission of 19% of energy-related greenhouse gases in 2010. These shares impact negatively on the environment and communities. Many studies reveal that emerging Building Information Modelling (BIM) has a great potential to contribute to improving sustainable design practices that can lead to the mitigation of climate change impacts. Despite the wide use of BIM in performing sustainable building analysis, building occupants’ behaviour is hardly considered. Recent studies including the IPCC AR5 reveal that occupants’ behaviour contributes significantly to household energy consumption. The use of emerging BIM in modelling human behaviour and influences on energy efficiency of buildings is still very sketchy. This study aims to investigate the use of BIM in modelling household occupants’ behaviour and impacts on energy consumption. The research methods to be adopted are three-fold. First, in order to understand the nexus between occupants’ behaviour and energy simulation, a review of behavioural practices in homes and current BIM-energy simulation software packages is undertaken. Secondly, based on the first, suitable BIM-energy simulation software systems are identified and used for simulating occupants’ behaviour vis-à-vis energy consumption. Thirdly, a building with well-known and established characteristics is employed as a case study to investigate different behaviour options and impacts and results discussed.

1 BACKGROUND STUDY

The major factors that influence energy consumption in a building are its physical characteristics, the equipment installed to provide comfort (the heating, ventilation and air-conditioning system, auxiliary production of electricity and hot water), household and portable devices, the outdoor environment and the behaviour of occupants. While advances in technologies supported by research have facilitated the assessment of impacts of the first four factors on energy consumption, studies about the latter are still very scanty. Research have revealed that occupants influenced the final energy consumption of buildings (Gram-Hanssen 2014; Steemers and Yun 2009; Makashini et al. 2014). Buildings are often designed
based on scientific assumptions on how it will be used. However, when the building is erected it may be used differently by occupants in some cases deviating significantly from the designer’s assumed intentions and underlying scientific assumptions (Fabi et al. 2011). While early collaboration of project team members to capture client’s requirements is common today, occupant’s daily behaviour is hardly considered. This may be partly due to the fact that clients may not necessarily be the future occupants of the buildings. Even if clients were to be, in most cases occupants generally behave unconsciously and in a very unpredictable manner making it difficult for these requirements to be properly captured at the early design stages. Furthermore, even when these requirements have been captured, modelling them for predictive purposes is often a daunting task. This partly explains why statistical and probabilistic algorithms have often been used in modelling human’s behaviour in buildings (Baetens and Saelens 2011; Page et al. 2007). Also, to automate computation, simulation software packages are widely being used in modelling the same (Gram-Hanssen 2014; Ben and Steemers 2014). Simulation tools have been great in modelling physical characteristics, the equipment installed to provide comfort (the heating, ventilation and air-conditioning system, auxiliary production of electricity and hot water), household and portable devices, the outdoor environment and the behaviour of its occupants. With regards to occupants’ behaviour, simulation tools have generally relied on fixed profiles of typical occupant presence and associated implications of their presence (Page et al. 2007).

Emerging BIM has been hailed as one of the solutions to enhanced sustainability in the built environment. The strength of BIM lies in the fact that a building can be virtually modelled and then embedded with rich data that can be manipulated to explore alternative options even before construction on a site. This quality of BIM makes it quite suitable for modelling data that can be used in evaluating building energy efficiency. Thus, the current trend in research and practice is to integrate BIM with specialist building energy simulation software to optimise performance with regards to sustainability building assessment. Despite this, current integrated BIM-energy simulation software systems are great in modelling building physical characteristics, the equipment installed to provide comfort (the heating, ventilation and air-conditioning system, auxiliary production of electricity and hot water), household and portable devices with very little emphasis on the modelling of behaviour of occupants. The proposed study aims to explore the use of BIM in modelling household occupants’ behaviour and impacts on energy efficiency. The key research questions are: What are the different human behaviour factors to be considered in building energy assessments? What is the connection between BIM/energy simulation systems? How do human behaviour factors fit with the BIM/energy simulation system connection? What is the whole assessment procedure and challenges? To answer these questions, appropriate research methods (see Figure 1) will be pursued.

2 RESEARCH METHODS

The first step consists of undertaking an extensive literature review about the different domain relevant to this study. Specifically, behaviour of building occupants, BIM and energy analysis software are reviewed. This led to the understanding of nexus between occupants’ behaviour and household energy consumption.
consumption. Furthermore, BIM and energy analysis software from vendors’ websites and peer-reviewed publications (Abanda and Tah 2014; Kurul et al. 2013; Nguyen et al. 2014; Bambardekar and Poerschke 2009; Attia et al. 2009; 2011; 2012; Sharma and Prouhit 2014; US Department of Energy 2014; Crawley et al. 2008) and their suitability established. Secondly, based on the different software identified in the previous step, their uses in modelling of building and energy simulation are investigated. The details of the simulation will be presented in Figure 2. Thirdly, based on the preceding step, the simulation processes are implemented on a chosen case study building with well-known information. Choosing a building with well-known and established characteristics is important as it allows authors to easily analyse and interpret findings from iterating the different modelling of occupants’ behaviour. This allowed for an in-depth analysis of the potential in modelling household occupants’ behaviour.

3 AN OVERVIEW OF BEHAVIOURAL PRACTICES IN HOMES

The aim of this section is to establish what drives behaviour, how occupants react to external/internal stimuli to meet their needs and which systems are available in facilitating their desire to meet the needs. Recent studies have revealed that climate and building characteristics are insufficient in determining energy demand. Occupants’ behaviour and socio-economic factors are also important factors that have recently gained importance (Steemers and Yun 2009; Lucon et al. 2014). Lucon et al. (2014) reported behavioural changes coupled with recent technological advances, design practices and know-how can achieve a two to ten-fold reduction in energy requirements of individual new buildings and a two to four-fold reduction for individual existing buildings largely cost-effectively or sometimes even at net negative costs. Providing feedback about energy consumption is crucial and can influence the behaviour and lifestyle of building occupants. Although the impact or effectiveness of feedback to household occupants is quite a highly contested issue (Vine et al. 2013), Darby (2006) argued that feedback can reduce electricity consumption in homes by 5 to 20%. Integrating feedback information into BIM energy simulation software can help drive changes in occupants’ behaviour that can potentially lead to efficient energy management. What are the occupants’ behavioural actions? Presently, there is an abundance of literature on occupants’ behaviour, however, there are hardly structured. This weakness is currently being investigated by an ongoing research project (Turner and Hong 2013) with the aim to develop a technical framework that describes human-related behaviour in buildings. The framework proposes four main components — drivers, needs, actions and systems (Turner and Hong 2013):

- **Drivers** represent the stimulating factors that provoke an occupant into performing an energy-related behaviour or an interaction with a system;
- **Needs** represent the physical and non-physical requirements of an occupant that must be met in order to ensure the satisfaction of the occupant with their environment;
- **Actions** are interactions with systems or activities that an occupant can conduct in order to achieve environmental comfort (e.g. window opening/closing);
- **Systems** refer to the equipment or mechanisms within a building with which an occupant may interact to restore or maintain the environmental comfort of the occupant(s).

To facilitate understanding, a scenario will be described to illustrate the drivers, needs, actions and systems concept in relation to occupants’ behaviour in a domestic home in Section 5.

4 BIM AND BUILDING PERFORMANCE SIMULATION TOOLS: RELATED STUDIES

In this section, the software required for building energy simulation will be identified. The identified software will be used in modelling and performing energy simulation of a case study building. BIM software packages have been reviewed in the literature (Abanda and Tah 2014; Kurul et al. 2013). These studies generally tend to focus on technical and market features of the software (e.g. cost of software and file management facilities), with very little emphasis on their different uses. Thus the application of these software packages in performing building energy analysis is hardly discussed and unclear; talk less of considering occupants’ behaviour in the analysis. This study will build on past efforts (Abanda and Tah 2014; Kurul et al. 2013) with focus on energy modelling and analysis. Furthermore, how occupants’
behaviour can be modelled in these systems will be investigated. To avoid duplicating the works of others (e.g. Abanda and Tah 2014; Kurul et al. 2013; Bahar et al. 2013), this study considered only criteria relevant to household occupants’ behaviour, excluding others already investigated in the preceding studies. One important criterion to note that was considered is interoperability. This defines standards that allow files to be shared over different BIM software packages. It facilitates the integration of accurate information from a variety of disciplines into common data formats such as Industry Foundation Classes (IFC), IFCXML (IFC Extensible Markup Language) and COBie (Construction Operations Building Information Exchange). Other schemes that have emerged with focus on the extraction of environmental data include gbXML (green building Extensible Markup Language), ecoXML and obXML (occupants behaviour XML) (Turner and Hong 2013). Although, these interoperability formats are still under-development, Gupta et al. (2014) argues that they can still facilitate the exchange of rich and useful information between project partners without loss of accuracy or design intent. Other parameters considered are whether the software packages are commercial or open source and whether different systems such as windows and doors have been incorporated in the software packages. A summary of the comparison of the different software systems is presented in Table 1.

Based on Table 1, IES-VE –Pro will be used. IES-VE-Pro incorporate tools for analysing different climatic and energy related scenarios. Furthermore, it is widely used by commercial as well as research communities. Despite this, it is quite a complicated software and requires a stiff learning curve to understanding its potential. Consequently, it is important to provide clarity about some terminologies about the software. The main ones are IES VE-Ware, IES VE Toolkits. The IES VE-Toolkits are a set of analyses that can be run to help influence and direct early stage building designs. These fast analyses can be run with basic model inputs to allow indicative assessment of design options taking into account climate, building fabric, energy & carbon, thermal loads, daylighting and solar shading. VE-Ware is a free
building energy and carbon assessment software that also contains Free VE-SBEM for UK regulation compliance.

Based on Table 1, the types of human behaviour that can easily be modelled in IES-VE Pro are related to the roof, slab and door systems. Within the scope of this study, only the behaviour related to the window systems and their implications related to energy performance of buildings in terms of heating and electricity load will be investigated. This is done in the ensuing section.

5 MODELLING OF OCCUPANTS’ BEHAVIOUR IN BIM SOFTWARE SYSTEMS

5.1 Description of Scenario

As previously discussed in Section 3, a scenario will be used to clarify the concepts that underpin occupants’ behaviour and energy construction (i.e. drivers, needs, actions and systems). This scenario is about the house conditions of a pensioner who spent the Christmas-2014 in his home in Manchester. The indoor room temperature throughout the day has plummeted to below 0°C, until the pensioner has become uncomfortably cold. The pensioner then turns on the radiator to heat the home. As a result, the house temperature increases to a level deemed suitable and comfortable by the pensioner. In this example, the “driver” is the indoor temperature. The “need” is the requirement for thermal comfort of the pensioner. The “action” is the starting of the radiator by the pensioner. The “system” is the radiator. At times it is possible to perform more than one action at a time in response to meeting a single or multiple need(s) or being driven by multiple stimulating factors. For example, still in the preceding example, the pensioner might also want to put on some pullovers, take a cup of hot tea in addition to starting the radiator. In this case the “drivers” and “needs” remain the same while wearing a pullover, drinking hot tea and starting a radiator are “actions” and “systems” are pullover, hot cup of tea and radiator. Given the number of permutations involved in identifying “drivers”, “needs”, “actions”, and “systems” of household occupants’ behaviour, a system approach will be used to identify all possible cases for a generic building. In this approach, a list of all possible “drivers” are determined and summarised in a matrix table (see Table 2) that facilitates the determination of “needs”, “actions” and “systems”.

</table>

It is important to note that while some of the “systems” above do not exist in isolation as they may be interference with socio-cultural issues leading to some of the actions not being able to be undertaken despite the presence of a “need”. For example, in an insecure urban neighbourhood, occupants may not
leave their doors or windows ajar to keep cool despite the building being too hot. Given the understanding of occupants’ behaviour (see Table 2), and the different energy simulation software (see Table 1), a case study building will be used to investigate the integration of in energy simulation software.

5.2 Description of Case Study Building

The case study building is a hypothetical 8-bedroom house with well-known information located in Westminster. The building is made of one ground floor and one first floor. The ground floor consists of 3 bedrooms and the first floor consists of 5 bedrooms. On the ground floor, there are 4 internal doors, 2 external doors and 6 external windows. On the first floor, there are 6 internal doors, and 7 external windows. The modelling of this building is discussed in Section 5.3.

5.3 Modelling Behaviour in the Case Study Building

The key tools used in this modelling process are Revit 2015 and IES. The two can be linked through the interoperability standard gbXML, a leading language for energy simulation. The simulation steps are summarised in Figure 2.

![Figure 2: A framework for integrating behaviour in BIM](image)

The first step in performing energy analysis is to draw the geometry of the building. There are three main techniques of modelling in IES-VE. The first consists of modelling in natively in the ModelIT component of IES-VE. The second consists of modelling in Sketch-Up, then importing in IES-VE with the help of an in-built plug-in. The third consists of using any BIM software that can generate gbXML which can be imported into IES-VE. The model was modelled in and imported from Revit 2015 to IES via gbXML. The output is presented in Figure 3.
The performance parameter to be analysed is total annual energy consumed by the dwelling. This consists of natural gas and electrical energy. This is performed using the MacroFlo component of IES. MacroFlo provides an opportunity to define operable windows in a model and to assess the impacts of natural ventilation on space. According to the UK Building Regulations Part L, the U-values of the major components were: a) windows=1.6 W/m²K, b) door=2.2 W/m²K, c) roof= 3.3 W/m²K. The closest weather station chosen is the London Weather station. The different opening modes used are full opening, partial and semi openings. For purposes of this study only 3 scenarios were considered. The scenarios are presented in Table 3.

Table 3: Scenarios studies for case study

<table>
<thead>
<tr>
<th>Scenario 1</th>
<th>Door operation</th>
<th>Window operation</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>All external doors are closed whether occupied or not</td>
<td>All windows closed when occupied</td>
</tr>
<tr>
<td>Scenario 2</td>
<td>All external doors are closed whether occupied or not</td>
<td>All windows opened during the summer months (June, July, August) from 8am-6pm.</td>
</tr>
<tr>
<td>Scenario 3</td>
<td>All external doors are closed whether occupied or not</td>
<td>All windows opened during the summer months (June, July, August) from 8am-12pm</td>
</tr>
</tbody>
</table>

The scenarios in Table 3 were edited in IES. The model is checked for correctness. For example, rooms should be properly defined in Revit with Room tag definitions. Errors will be identified if rooms are not correctly defined at this stage. This is done by clicking on red box indicated in Figure 4. Once this check is done, data such as type building, heating systems and rooms' conditions are chosen (see Figure 4).

![Figure 4: Preliminary building requirements in IES](image)

After checking the model and choosing the different parameters for the model, the simulation parameters, e.g. simulation period (January-December) are chosen (see Figure 5). One important aspect to note here is that, if the model was not properly designed with rooms properly defined, it would have been difficult to determine the different rooms involved in the simulation as depicted in the red box in Figure 5.
On running the simulations for the different scenarios the results obtained are presented in Table 4.

### Table 4: Annual energy consumption

<table>
<thead>
<tr>
<th>Scenario</th>
<th>Duration</th>

<td>27.781</td>
</tr>
<tr>
<td>Scenario 3</td>
<td>One year</td>
<td>22.56</td>
<td>4.771</td>
<td>27.331</td>
</tr>
</tbody>
</table>

From Table 4, for the period when the window is opened for longer periods as in scenario 2, more heat is required to keep the house warm. Of course, within the scope of this paper other comfort parameters such as satisfaction with ventilation when windows are locked as in scenario 1 have not been investigated.

## 6 KEY FINDINGS AND DISCUSSIONS

- Most actions are those related to the geometry of the building. Actions such as taking cup of tea and wearing more clothes are hardly part of energy simulation tools. These actions can consume (e.g. boiling tea) very limited thermal energy or offset energy that would have been used to heat the home (e.g. wearing more clothes);
- There is no direct connection between BIM and energy simulation tools that can allow automatic changes been made in BIM design tool and changes felt in the energy simulation tool. It implies that the building model in BIM should be modelled and required information incorporated to avoid back and forth movement between the two software systems;
- Although the annual energy loads are not significantly different, it is however consistent with the minimal changes or information introduced in the simulation. No detail data were inputted into the IES software;
- It is also important to mention the fact that the export from a BIM model in Revit to IES was not smooth as so many errors emerged and the building model had to be revised so many times before IES could be used.
7 CONCLUSIONS

This study was underpinned by the need to integrate human behaviour in the assessment of energy in buildings. Based on the literature, it emerged that many studies have seldom considered occupants' behaviour in performing energy analysis of buildings. However, recent studies indicate the significant contribution of human behaviour in household energy consumption. It is from this perspective that this study explored how emerging BIM can be employed in integrating human behaviour for assessing energy of buildings. The crucial aspects of this exploratory study are the establishment of human related behaviour factors, modelling of the factors in a BIM authoring and/or energy simulation software, performing analysis and interpreting results. With respect to the first, an established framework for human related behaviour was employed in identifying key human related energy factors (see Table 2). To determine how the human related factors can be modelled, the study assumed knowledge of BIM authoring systems already reviewed in other literature (e.g. Kurul et al. 2013; Abanda and Tah 2014) and then emphasis was instead placed on reviewing building energy simulation software packages (see Table 1). The study exploited the interoperability paradigm of the software to establish the connection between the BIM authoring and energy simulation software packages. IES-VE was adopted as the main software and a hypothetical case study building was used. This building was modelled in Revit, converted to gbXML and then imported into IES-VE before embedding the human related factors. It emerged that the opening and closing of windows can contribute to the energy consumption of a building. Specifically, the more windows are left opened, the more energy is lost and more is needed to keep the home comfortable. While this finding may not be entirely new, its novelty lies in the use emerging BIM to quantitatively assess the impacts virtually demonstrated through 3 scenarios. As part of future study, a detail study involving many scenarios will be conducted to establish the implications of occupants' behaviour on energy consumption. One major challenge was the export of the model from Revit into IES which was very difficult and ridden with so many errors. Also, as part of future study, other software will be explored including the IES plugin for Revit.

Abstract: Buildings are responsible for 38\% of all carbon emissions and 14\% of water consumption in the United States. These negative environmental impacts can significantly be reduced by implementing green upgrade measures such as energy-efficient lighting and HVAC systems, motion sensors, photovoltaic systems, and water-saving plumbing fixtures. Building owners in the public and private sectors often search for an optimal set of upgrade measures that is capable of minimizing the negative environmental impacts of their buildings. This paper presents the development of an optimization model that is capable of identifying optimal selection of building upgrade measures to minimize greenhouse gas emission and water consumption of existing buildings while complying with limited upgrade budgets. The model is developed in four main development steps: metrics identification step that quantifies greenhouse gas emissions and water consumption of existing buildings; model formulation step that formulates the model decision variables, objective function, and constraints; implementation step that executes the model computations and specifies the model input and output data; and validation step that evaluates the model performance using a case study of an existing building. The results of the model illustrate its new and unique capabilities in providing detailed results, which include specifications for the recommended upgrade measures, their location in the building, and required upgrade cost to minimize greenhouse gas emissions and water consumption of existing buildings.

1 INTRODUCTION

Buildings in the United States are responsible for significant GreenHouse Gas (GHG) emissions due to significant percentage of electricity consumption (72\%), energy consumption (39\%), and water consumption (13\%) (U.S. Environmental Protection Agency 2009). These GHG emissions due to energy and water consumption contribute to negative environmental impacts including, global warming, ozone depletion, and air pollution (ICF Incorporated 1995; U.S. Environmental Protection Agency 2009, 2012; United Nation Environment Program 2007). The negative environmental impacts of buildings can be reduced by implementing sustainable measures such as energy efficient building fixtures and equipment, water-saving plumbing fixtures, and installing renewable energy systems. These sustainable measures require high upgrade costs and decision makers are often confronted with a challenging task to identify optimal selection of building upgrade measures within their upgrade budget. In order to support decision makers in this challenging task, there is a pressing need to develop optimization models that are capable of identifying optimal selection of building upgrade measures to minimize negative environmental impacts of existing buildings within available budgets.
Several systems have been developed and studies conducted to estimate the negative environmental impacts of buildings during their construction, operation and demolishing such as Building for Environmental and Economic Sustainability (BEES) (Lippiatt et al. 2010), ATHENA impact estimator (The ATHENA Institute 2013), and envest2 (Building Research Establishment 2003). Other studies focused on evaluating the implementation of various sustainability measures such as energy-efficient lighting systems, energy-efficient HVAC systems and heat pumps (Bloomquist 2001; Chiasson 2006; Das et al. 2013; International and Conference 2003; Narendran and Gu 2005; Phetteplace 2007; RUUD LIGHTING 2010), renewable energy systems (Chapman and Wiczkowski 2009; James et al. 2011; Matthews et al. 2004; State Energy Conservation Office 2006), and water-saving plumbing fixtures (GAO 2000).

Furthermore, several optimization models have been developed to minimize existing buildings' operational costs (Abdallah et al. 2014), identify optimal selection of structural and architecture design of new buildings (Bichiou and Krarti 2011; Fialho et al. 2011), and identify optimal decisions of building renovations (Brandt and Rasmussen 2002; Juan et al. 2010; Kaklauskas et al. 2005).

Despite the significant contribution of the existing research studies, limited or no optimization models exist that are capable of selecting building upgrade measures of existing buildings in order to minimize their negative environmental impacts of greenhouse gas (GHG) emissions and water consumption simultaneously. Furthermore, limited or no optimization models exist that consider various sustainability measures of building fixtures and equipment, renewable energy systems, and plans of managing solid waste simultaneously in order to minimize the negative environmental impacts of existing buildings while complying with a user-specified upgrade budget and building operational performance.

2 RESEARCH OBJECTIVE

The objective of this research study is to develop an optimization model that is capable of minimizing negative environmental impacts of existing buildings. This optimization model is designed to provide the optimal selection of building upgrade measures to minimize GHG emissions and water consumption of existing buildings while complying with available upgrade budgets and specified building operational performance. This optimization model is expected to support decision makers and building owners in their ongoing efforts to minimize negative environmental impacts of their buildings by optimal allocation of their budgets. The optimization model is developed in four main steps: (1) metric identification step, which quantifies the negative environmental impacts of buildings; (2) model formulation step that formulates the model decision variables, objective function, and constraints; (3) implementation step that executes the model computations using Genetic Algorithms (GAs); and (4) evaluation step that validates the model performance using a case study of an existing building. The following sections describe the development steps of the optimization model to illustrate the capabilities of the model and demonstrate its use.

3 OPTIMIZATION MODEL DEVELOPMENT

3.1 Metric Identification

The optimization model is developed to quantify the negative environmental impacts of existing building in terms of GHG emissions that result from buildings energy consumption; energy use for water extraction, treatment, distribution, and wastewater treatment; and buildings solid waste (ENVIRON International Corporation 2013; Flager et al. 2012; ICLEI - Local Governments for Sustainability USA 2010, 2012; Kwok et al. 2012; Liu et al. 2013; Ordóñez and Modi 2011; Safaei et al. 2012; TranSystems|E.H. Pechan 2012; U.S. Environmental Protection Agency 2006; USGBC 2014a; Zhu et al. 2013); and water consumption from plumbing fixtures.

The GHG emissions from building operation consist of carbon dioxide (CO$_2$), nitrous oxides (N$_2$O), methane (CH$_4$), and ozone (O$_3$) (TranSystems|E.H. Pechan 2012). The global warming potential factors that are developed by the Intergovernmental Panel of Climate Change (IPCC) can be used to represent all GHG emissions in terms of equivalent quantities of CO$_2$ emissions (Intergovernmental Panel on Climate Change 2007). The GHG emissions are quantified in the developed model based on the calculated (1) energy consumption of the building; (2) energy use during water extraction, treatment,
distribution, and waste water treatment; and (3) fugitive emissions of waste water, and solid waste. The GHG emissions of energy consumption are calculated based on the building electricity and natural gas consumption and the location of the building. This accounts for the types of plants that are used to generate energy for the building and associated average transmission losses. For major electricity grids in the United States, the Environmental Protection Agency provides energy emission factors and average transmission loss percentages, which can be used to estimate emissions of energy use in buildings (TranSystems (E.H. Pechan 2012). To estimate GHG emission of buildings, electricity and natural gas need to be calculated. The developed optimization model calculates electricity and natural gas consumption of the buildings using energy simulation software packages such as QUick Energy Simulation Tool “eQUEST” (U.S. Department of Energy 2013).

In addition to the GHG emissions that are created by the direct building energy consumption, the water consumption of the building create additional GHG emissions due to energy used in water extraction, conveyance and supply, treatment, and distribution. These emissions can be calculated based on annual building water consumption; and energy intensity of water extraction, water supply and conveyance, water treatment, and water distribution (ICLEI - Local Governments for Sustainability USA 2012). Similarly, the GHG emissions from wastewater treatment can be calculated based on annual building waste water; and energy intensity of wastewater collection, aerobic digesters for wastewater treatment, lagoons for wastewater treatment, attached growth of wastewater treatment, and nitrification or nitrification/denitrification of wastewater treatment (ICLEI - Local Governments for Sustainability USA 2012).

Another source of GHG emissions in existing buildings is calculated based on solid waste sent to landfill, combustion, composition, or recycling. The United Stated Environmental Protection Agency provides emission factors for each of these methods of managing solid waste (U.S. Environmental Protection Agency 2006). Accordingly, the annual equivalent carbon dioxide of solid waste in buildings can be calculated in the model based on the weight of each solid waste material and the associated emission factor calculated according to solid waste management method. According to all the aforementioned sources of GHG emissions, the model calculates the total equivalent emissions of existing buildings by aggregating all sources of GHG emissions.

Plumbing fixtures are responsible for the majority of water consumption in buildings. They include water faucets, showerheads, kitchen sinks, urinals, and toilets. Building water consumption can be calculated in the developed model based on type of building, type of plumbing fixtures, and number of occupants according the guidelines of the LEED rating system for existing buildings (USGBC 2014b).

3.2 Model Formulation

The decision variables of the optimization model are designed to represent all feasible alternatives of building fixtures and equipment that consume energy or water using integer decision variables such as lighting fixtures and bulbs, HVAC systems, water heaters, refrigerators, vending machines, hand dryers, and water plumbing fixtures. The model is also designed to integrate energy saving measures using integer decision variables such as motion sensors, solar panels, inverters, and percentage of renewable energy that can be generated at the building site. In addition, the model is designed to integrate plans of managing solid waste using integer decision variables that represents the disposal of each solid waste using landfill, recycling, combustion, or composition.

The objective function of this optimization model minimizes the negative environmental impacts of existing buildings by minimizing GHG emissions and water consumption. The model accounts for GHG emissions and water consumption of buildings using Building Environmental Performance Index (BEPI). This index ranges from 0.0 which represent a fully sustainable building to 1.0 which represent no reduction in negative environmental impacts of the building as shown in Equation (1).

\[
BEPI = W_{\text{GHG}} \times \frac{G_{\text{GHG}}}{G_{\text{GHG}}} + W_{\text{WC}} \times \frac{W_{\text{WC}}}{W_{\text{WC}}}
\]
Where: $BEPI$ is building environmental Performance index; $GHGE^R$ is building GHG emissions after implementing upgrade measures; $GHGE^E$ is existing building GHG emissions; $WC^R$ is building water consumption after upgrade measures; $WC^E$ is existing building water consumption; and $W_{GHG}$ and $W_{WC}$ are relative importance weights of GHG emissions and water consumption, respectively.

To ensure the practicality of this optimization model, it is designed to comply with two main constraints: (1) building performance constraints, and (2) upgrade budget constraint. The building performance constraint is integrated in the model to ensure that the required operational performance of the building will be maintained after replacing its fixtures and equipment, including space heating and cooling, water heating capacity, and light levels. The upgrade budget constraint is integrated in the model to ensure that the cost of upgrading the building fixtures and equipment, installing renewable energy systems, and managing solid waste will not exceed the specified upgrade budget.

### 3.3 Model Implementation

The computations of the optimization model are executed using Genetic Algorithms (Gas) due to its (1) efficiency in modeling the optimization problem with the least number of decision variables, (2) capability to model non-linearity and step changes in the objective function and constrains that are caused by replacing building fixtures and equipment, (3) capability of identifying optimal solution within reasonable computational time (Aytug and Koehler 1996; Goldberg 1989; Pendharkar and Koehler 2007).

The computation procedure of the developed model starts by searching an integrated databases in order to identify feasible replacements of HVAC systems and water heaters. The model then creates eQuest input files of feasible replacements and sends them to eQuest simulation environment to calculate their energy consumption. The model then stores the calculated energy consumption of HVAC equipment and water heaters in a database where it can be used during the optimization process. The GA computations start by generating random selection of building upgrade measures which represent the initial population. The fitness of this initial population is evaluated based on the index of negative environmental performance index and the model constraints. Solutions that satisfy all the constraints and achieve low values of negative environmental performance index are classified as solutions with high fitness values. On the other hand, solutions that achieve high values of negative environmental performance index or do not satisfy the model constraints are classified as solutions with low fitness values or infeasible solutions, respectively. Solutions with high fitness are then ranked based on their index of negative environmental performance index where the GA operators of selection, crossover, and mutation are applied to generate a new set of population. This process is iteratively repeated until no further improvements are achieved within a predefined number of iterations. It should be noted that the initial population of the model is set based on the GA string and possible values of the model decision variables (Reed et al. 2000; Thierens et al. 1998).

The developed optimization model is integrated with databases of building fixtures and equipment, components of renewable energy systems, and various types of building solid waste. These databases are designed to include general product data, cost data, energy and water characteristics, and physical characteristics of building fixtures, and components of renewable energy systems, including lighting bulbs and fixtures, motion sensors, HVAC equipment, water heater, hand dryers, vending machines, refrigerators, PCs, water coolers, solar panels, solar inverters, water faucets, urinals, and toilets. The databases also include data on energy intensity of water extraction, conveyance, treatment, distribution, and waste water treatment; and emission factors of energy consumption and solid waste according to the location of buildings in the United States. For example, the equivalent emission factors of electricity consumption, electricity savings, and average transmission losses of all electricity grids are stored in the model databases, as shown in Table 1.

4 CASE STUDY

A rest area building was analyzed and optimized by the developed optimization model in order to illustrate the model capabilities and demonstrate its use. This rest area building is located in Illinois and it was selected due to its high levels of negative environmental impacts caused by its continuous operation throughout the year and its inefficient energy and water fixtures. The building was built in 1989 and renovated in 1992 with a total area of 2500 square foot. This rest area building includes men’s and women’s bathrooms, lobby, vending area, travel information desk, storage rooms, mechanical room, attic, and detached small garage. The rest area also has parking lots for visitors that accommodate cars and semi-trucks. The major contributors of energy consumption in the building include interior and exterior lighting systems, water heater, HVAC systems, six vending machines, four hand dryers, five water coolers, PC, surveillance system, and five code blue emergency phones. The major contributors of water consumption in the building include eight toilets, two urinals, and six water faucets.

In order to minimize the negative environmental impacts of the rest area building, the optimization model requires input data of (1) building characteristics, including building size, construction materials, air infiltration, doors and windows, operational schedule, allocation of building activities, temperature set points, and airflow, as shown in Table 2; (2) characteristics of building equipment and fixtures which can be selected from the model databases, as shown in Table 3; (3) amounts of building solid wastes, as shown in Table 4; and (4) importance weights of building negative environmental impacts which were specified at 80% and 20% for GHG emissions and water consumption, respectively. It should be noted that the importance weights can vary from one decision maker to another, and the model enables them to specify their own weights accordingly.

The optimization model was used to minimize the negative environmental impacts of the rest area with various upgrade budgets that ranged from $10K to $100K. The model was able to identify the optimal upgrade decisions for all the specified upgrade budgets, as shown in Figure 1. For example, solution (a) in Figure 1 identified by the model as an optimal solution for an upgrade budget of $50K, and it provides a moderate reduction in the negative environmental performance index of (BEPI = 0.519) with an upgrade cost of $49,673. On the other hand, solution (b) is identified by the model as an optimal solution for an upgrade budget of $100K, and it provides minimum negative environmental performance index of (BEPI =
0.397) that caused reduction in GHG emissions by 58% and water consumption by 69%, as shown in Figure 1.

![Figure 1: Results of minimizing negative environmental impacts of the rest area building](image)

The model is designed to provide an action report for the generated optimal solutions which include detailed information of all the recommended building upgrade measures. For example, the model generated the recommended upgrade measures and solid waste management plans for optimal solution (a) in Figure 1 as shown in Table 5 and Table 6, respectively. The results of the model identify the optimal selection of building upgrades based on an identified upgrade budget which helps decision makers and building owners in their ongoing task of maximizing the sustainability of their building while complying with their available budgets.

5 SUMMARY AND CONCLUSIONS

This paper presents the development of an optimization model that is capable of minimizing negative environmental impacts of existing buildings by minimizing their GHG emissions and water consumption. The model is designed to identify the optimal selection of building upgrade measures while complying with a specified upgrade budget and preferred building operational performance. The model was developed in four main steps: metric identification step, model formulation step, implementation step, and evaluation step. The metrics identification step identified novel metrics for quantifying the negative environmental impacts of existing buildings in terms of GHG emissions and water consumption. GHG emissions were calculated based on energy consumption, energy use of water extraction, treatment, distribution, and wastewater treatment; and buildings solid waste. The formulation step identified the model decision variables, objective function, and constraints. The model is designed to include decision variables that have impact on GHG emissions and water consumption including building fixtures and equipment, renewable energy systems, and water plumbing fixtures. The objective function is designed to minimize GHG emissions and water consumption using an index that account for these impacts using importance weights. The model integrated a number of constraints to comply with specified upgrade budgets and building operational performance.

The model implementation step include the execution of the model computations using Genetic Algorithms (GAs) and the development of databases to facilitate input and output data of the model. The evaluation step validated the model performance using a case study of a rest area building. The model was able to identify the optimal selection of building upgrade measures for various budgets that range from $10K to $100K. The model is designed to provide detailed results for the identified optimal solutions which include an action report that lists the details of the recommended upgrade measures. The new and novel capabilities of the developed optimization model provide needed support for decision makers and building owners in their ongoing efforts to minimize the negative environmental impacts of their existing buildings while complying with their limited upgrade budgets. Future expansion of the model and more in-depth analysis are needed to further study the impact of feasible upgrade measures of the building envelope such as type of insulation, windows, and doors to consider their effects on reducing the building negative environmental impacts especially for buildings that have their energy consumption dominated by HVAC systems.

Abstract: This paper introduces a framework developed to automatically track the daily progress details of multiple small/medium construction projects, simultaneously. The framework has been designed with several features: Geographic Information System (GIS); cloud-based email/IVR services; activity-initiated communication to relevant supervisors; flexible user-revised email/IVR surveys; multi-project status reporting; and input/output to Microsoft Project scheduling software. The paper discusses the components of the proposed framework and comments on the performance of a prototype system on multiple simultaneous projects. A case study was used to demonstrate the usefulness of the timely collected data to improve the visualization of progress status and schedule updates, as well as project control decisions. The system can also collect data about the worker-related factors (e.g., morale) on projects. The developed framework supports efficient management of multiple projects for small/medium contractors. The proposed framework facilitates efficient communication between site and head office, to help construction companies work more cost effectively within the competitive business of construction.

1 INTRODUCTION

Timely and efficient progress tracking is a key issue for project payments, early warnings, and corrective action planning. One of the biggest challenges facing construction managers is to keep track of all actions that take place on site in order to detect potential problems and to select appropriate corrective actions. Progress tracking is even much more challenging in the case of managing multiple projects, which is a common case in construction where small/medium companies get involved in many jobs at the same time. Because progress information of each project are scattered in many formats like daily site reports, minutes of meetings, and correspondences, schedule updates are often problematic and the management of multiple projects can become a nightmare, ending with delays, cost overruns, and lost business.

While the Construction Industry includes many large companies, statistics indicate that over two-thirds of construction firms in the United States have less than five employees (Halpin 2006). The majority of these small firms are specialty subcontractors working with the general contractor. For those small players, the simultaneous management of multiple projects is an everyday situation. As reported in the literature, up to 90% by value of all projects occur in the multi-project context (Payne 1995). Generally, these projects are small and do not, therefore, have the luxury of dedicated resources, but must share at least some resources with other projects.

Commercial scheduling tools can help planners produce realistic baseline schedules that are suitable for planning purposes (Gould 2005). Due to rapid growth in Information Technology (IT) (Chen and Romano 2003), many systems have recently incorporated high level of communication and collaboration tools.
Because 25% to 30% of total project work is always spent on communication and collaboration (Helbrough 1995), the surge in IT-related features undoubtedly brings great benefits to the management of projects. On the other hand, however, the core scheduling, tracking, and control functions of commercial software remained mostly unchanged over the past four decades. For example, existing software tools still do not have functions for time-cost trade-off analysis, automated tracking, or schedule optimization.

While the management of individual projects is difficult, it's even much more complicated in the case of multiple ongoing projects (Dooley et al. 2005). Commercial project management tools are not efficient to handle multiple projects, particularly when it comes to project control (Evaristo and Fenema 1999). Despite the high rate of utilization in the industry, research on the management of multiple projects is also very limited (Patanakul and Milosevic 2009). Recent work (e.g., Besikci et al. 2015) focuses on optimizing the planning and resource management before construction, and none focuses on progress tracking and control.

Among the key challenges in project control for individual and multiple projects is the inability to track and utilize sufficient progress details in an easy manner. Currently, schedules represent progress in terms of activities’ actual start and finish times, and percentage complete, while keeping the important intermediate events (slow progress, rework, acceleration, etc.) hidden in other correspondences, daily site reports, or other paper-based documents. Thus, the low level of detail in progress tracking is considered inadequate to support corrective actions or the analysis of project delays (Hegazy and Menesi 2012). Without the mid-activity events of various parties recorded on the as-built schedule, forensic analysis of project delays becomes a complex task of sifting through mountains of scattered information and then trying to understand, a long time after the fact, how the progress events affected the schedule.

To enhance current project control for multiple projects, this paper proposes a new progress-tracking framework that has three key functions: (1) improved As-Built data representation; (2) user-defined system for email and voice tracking of progress and for verifying the quality of the progress data obtained; and (3) a visual reporting system to facilitate schedule analysis and corrective action planning. Each of these is discussed in the following sections.

2 AS-BUILT DOCUMENTATION ON THE SCHEDULE

As-built documentation has mainly been a manual process that is time-consuming and error-prone (Trupp et al. 2004), thus contributing to misunderstandings, incorrect assessment of project performance, and lack of early warnings. To facilitate project control decisions, enough details are required on how the progress events of all parties have evolved. Traditionally, the activities in existing commercial scheduling software, such as MS Project and Primavera, are represented as blocks of time (Left part of Figure 1). This representation, however, does not show the mid-activity events made by the various parties. As opposed to this representation, Hegazy and Menesi (2010) presented a rich representation of mid-activity events, called Critical Path Segments (CPS), as shown in Figure 1. In the figure, activity durations are divided into daily segments that can hold progress amount or other events made by any party on the specific timing of that segment, in addition to notes, hyperlinks to related documents, and explanations. Recording (or averaging) the progress percentage on the daily segments clearly conveys information related to speed of construction (actual vs. planned) and the evolution of events, not just the final status of each activity. The daily segments also can represent the events that are caused by the owner “O”, the contractor “C”, and/or neither “N” (e.g., weather). Rework amount is also represented as a negative percentage complete recorded on the relevant time segment. Such a generic activity representation clearly shows the evolution of all as-built events and allows a more granular level of detail at the segment level, which is general enough to facilitate corrective actions and schedule analysis. Due to its rich visualization and its usefulness for project control, the CPS representation has been used in this paper.

### 3 FRAMEWORK FOR MULTI-PROJECT PROGRESS TRACKING

Since the daily CPS details may require a large effort to manually collect data from site, this paper automates the data collection process using low-cost email and interactive voice response (IVR) tools. In the literature, many researchers examined different information technology tools for site data collection (e.g., Trupp et al. 2004; McCullouch 1997; Liu 2000; Egbu and Boterill 2002; and El-Omari and O. Moselhi 2009). Among these tools, email and voice-based systems have rapidly grown over the years as technology advances fast. Recently, the use of voice has matured and has incorporated advanced features such as voice recognition and voice commands (Sunkpho and Garret 2000; and Reinhardt and Scherer 2000). Previous work by the authors (Hegazy and Abdel-Monem 2012) used email and Interactive Voice Response (IVR) to automatically collect as-built progress details for single projects, which is extended in this paper for multiple projects.

In order to track the progress of multiple projects simultaneously, the proposed framework integrates several components (as shown in Figure 2): progress database; Geographic Information System (GIS); dynamic survey creation; communication tools; visual location tracking; and reporting for single/multiple projects. These are as follows:

1. Database: at the core of the framework is a relational Microsoft Access database that includes information about projects (location, start date, finish date, etc.), company accounts (email address, IVR account, etc.), personnel (Supervisors’ emails and phones as well as the contacts of the person(s) responsible for answering any requests for information), activities’ daily tracking details (progress percentage, delay reasons, quality control issues, photos, attachments, etc.), and activities’ digital drawing files;

2. Geographic Information System (GIS): GIS has been incorporated so that all projects can be represented visually on a map system. Such visual representation facilitates the management and tracking;
Figure 2: Multi-Project Progress-Tracking Framework

3. Survey Creation Tool: To collect progress details or any type of information, a survey creation tool (Figure 3) was developed to allow the user to easily customize pre-set questions an email or a voice (phone) survey. Survey questions are of two categories: typical progress queries (progress amount; events by different parties and their reasons; quality control/safety issues; and request for information); and other generic questions to be used for custom surveys (e.g., Yes/No; Multiple choice; and Comment message).

Figure 3: Add/Edit Interactive Voice Response (IVR) Survey.
The resulting custom IVR or email survey is dynamic in the sense that the sequence of questions is changed depending on the user's answer to a previous question (e.g., progress or delay). The customized surveys are saved in the system as templates to be used for tracking any project; 4. Communication tools: An IVR Cloud-Service, Ifbyphone server (Ifbyphone 2012), is used to collect progress details by phone from multiple participants simultaneously, according to a selected IVR survey form. It has high quality voice, unlimited parallel calls, customizability, and flexible send/receive features. For email, Jotform cloud server (Jotform 2014) is used to send emails to multiple supervisors, according to any selected email form; 5. Scheduling tool: Microsoft Project scheduling tool has been used to prepare projects for progress tracking, including the activities, relationships, and costs; 6. Work location visualization tool: In addition to IVR and email communications, better visualization of progress location on related drawing files enables project managers to better visualize the evolution of progress. In the proposed framework, the activity is first associated with an appropriate CAD or image file that refers to the location of that activity. This file is always attached to the email survey form for progress tracking to allow supervisors to indicate the elements that have been completed to date and to record pictures, sound, etc.; and 7. Custom reporting tool: provides a log of all communications, an updated schedule, CPS progress report, and overall summary of projects’ progress.

4 PROTOTYPE AND CASE STUDY APPLICATION

The developed system has been applied to a simple case study to track five projects simultaneously. The progress tracking process is shown in Figure 4. The main interface (top of Figure 4) shows the list of projects, the GIS map, and the setup options for company, projects, personnel, and surveys. The automated tracking process starts by the system identifying the running projects and the eligible activities for progress tracking. It then identifies their relevant supervisors and the predefined survey forms. The data collection process is all cloud-based to retrieve supervisor responses, verify responses, and update the schedule.

Project setup can be done through importing projects and all related information from MS Project as well as edit/add the date and time for progress tracking. Personnel can be added to the company personnel list of the supervisors who will respond to progress information requests and the persons who will respond to any request for information (RFIs).

To demonstrate the automated progress tracking process. Project 1 activities are used as an example. The project is expected to take 16 working days (22 days including weekends), starting from May 7th, 2014 and finish on May 28th, 2014. The developed system enables project activities to automatically request progress from their relevant supervisors, and all received information will be legibly visualized on the daily segments for each activity. The as-built tracking, as it applies to Project 1 summarized in Figure 4. Detailed step-by-step process is as follows:

**Identify Progressing Projects:** for each project, the system checks tracking date, tracking time, project % complete, project start and project finish. If current date is larger than or equal tracking date then check if the project's percentage complete is less than 100% then starting progress tracking process for that project. **Identify progressing activities:** for each of progressing project (e.g., Project 1 in this case study) the process starts by automatically identifying the activities that are planned to start (their predecessors are completed), or continuing on the current progress date. In the case study, activities 1 and 2 are the ones to start on the first day of the project;
**Identify progressing activities:** For each progressing project (e.g., Project 1 in this case study), the system automatically identify the activities that are planned to start (their predecessors are completed) or continuing on the current progress date. In the case study, activities 1 and 2 of project 1 were planned to start on the first day of the project;

![Diagram of multi-project progress tracking process]

**Figure 4:** Multi-project progress tracking process
Retrieve the communication list and IVR/email surveys: Upon identifying the eligible activities, the system retrieves the pre-defined project communication list (middle columns of Figure 5) and loads the supervisor's contacts, email surveys, the index number to the related IVR surveys, and visual files of the current eligible activities;

![Figure 5: Assign IVR/email surveys, and visual files](image)

Send Email/IVR progress request: In this step, according to the preset preference of each supervisor, the system automatically sends an email or a request to the IVR cloud-based service to initiates phone calls to the selected supervisors;

Read responses: Once the supervisor(s) reply to the phone calls or email requests, their responses, and any attachments, are collected by the cloud-based service and email system, which send these responses as email files to the project email account. The system then loads the latest email responses, saves the information into the project database along with other documents such as voice notes;

Update project information: Upon reading the new as-built information, the system updates the project schedule and saves all site events related to each activity, with any attached file(s) in the log of communications. In addition, two important reports are generated: an automated update to the MS Project file of the project with the cumulative percentage complete for each activity adjusted according to latest information; and a detailed CPS report of the schedule with the evolution of all as-built events, with all details shown as comments on their associated activities days. All visual files received with supervisor comments show the progress evolution for each activity. Such visual progress reports greatly facilitate understanding progress details, and facilitate decision makers' decisions. An example of a multi-project status update is shown in Figure 6 with the detailed CPS report of a sample project. The summery status of each project is also shown with color-coding to highlight the projects that have issues or require user attention; and
Respond to RFIs: After updating the project schedule with received information, the system automatically checks if there are any requests for information (RFI), quality control issues, or safety issues. Accordingly, the system automatically forwards the RFI emails/voice message to the responsible person’s email/phone predefined in the communication list. The answer to this RFI is then sent back automatically to the initiating supervisor.

5 CONCLUDING REMARKS

This paper proposed enhancements to the visual representation of a schedule, using time segments, to efficiently use the schedule as a decision support tool for project control. The proposed representation is coupled with an automated framework to legibly document full as-built events of multiple simultaneous projects directly on the schedule. The framework can accurately document all daily as-built detail using email and Interactive-Voice-Response (IVR) technologies. In addition, it allows supervisors to mark the elements accomplished for each activity, along with their location on digital plans. The visual progress files indicate the evolution of the progress of the activities, which helps project participants easily form a complete picture of the finished work to date. All the as-built details are thus saved automatically in a communication log and are attached to the relevant daily segments for each activity. The system has been uniquely designed for bidirectional voice/Email communication. It allows activity supervisors to initiate calls/Emails for progress updates; and allows eligible activities on the office server to automatically initiate contacts. In addition, the system automatically communicates any requests for information, and their responses, to the appropriate parties. The system’s flexible feature of allowing custom site surveys to be generated and communicated using email and IVR are currently being utilized to collect a new layer of site information related to workers’ stress level and morale. This information can be used to forecast realistic estimates of project completion time and cost, and can trigger warning signs. A prototype system has been applied to a simple case study to demonstrate its benefits. The paper contributes to improving multi-project tracking and control through enhanced bidirectional communication between site and head office to help construction firms collect timely and accurate as-built information for decision making.

MODELING SUBWAY RISK ASSESSMENT USING FUZZY LOGIC

Mona. Abouhamad\textsuperscript{1, 2} and Tarek. Zayed\textsuperscript{1}
\textsuperscript{1} Concordia University, Montreal, Canada
\textsuperscript{2} monabuhamd@yahoo.com

Abstract: According to the Canadian Urban Transit Association (CUTA 2012), 140 Billion CAD is required to maintain, rehabilitate, and replace subway infrastructure between the years 2010 and 2014. However, transit authorities are faced by a fund scarcity problem which is hindering them from addressing all the network rehabilitation requirements in an efficient manner. The solution according to the 2013 America’s infrastructure report card is to adopt a comprehensive asset management system to maximize investments. This research develops a risk assessment model for subway stations. Probability of failure of different subway elements are developed using Weibull reliability curves. Consequences of failure are measured against three predefined attributes these are financial, operational, and social impacts of failure. Finally, a criticality index measures the respective station criticality derived from its particular size, location in proximity to different attraction types, and, nature of use. A qualitative approach with the help of expert judgment is adopted to integrate the indices using the Fuzzy Analytic Network Process with application to Fuzzy Preference Programming. The three models are integrated into a fuzzy rule based risk index model to compute element and station expected risk index. The output of the model is a comprehensive risk index that can be used to prioritize elements across stations for rehabilitation. The model is verified through an actual case study comparing elements across six stations and computing probability of failure, consequence of failure, criticality and the risk index. This paper illustrates the general framework of the proposed methodology which will help decision makers prioritize stations and elements across stations for rehabilitation based upon their risk index.

1 INTRODUCTION

Subway systems failure is associated with consequences like multiple fatalities or injuries, partial or complete loss of service, major traffic disruptions, and, different socio-economic effects. A subway network is composed of diverse components and systems operating simultaneously to deliver the required service. The component diversity causes a level of complexity which complicates the process of assessing and maintaining the network at the desired level of service. In addition, the problem of fund scarcity faced by most public authorities converts it into a tough task. According to (Semaan 2011), “Société de Transport de Montréal” estimated a required amount of 5.1 Billion CAD for maintenance of its subway system for the next ten years. Different systems operating in a subway network compete for rehabilitation priorities while having various consequences of failure and multiple failure modes which turns the prioritization process into a tough task. Moreover, elements operating in a subway network pose diverse rehabilitation and maintenance needs based on their role in the network hierarchy and operation. The current method used for prioritizing subway stations is visual inspection. Hastak and Baim (2001) stated that in the subway stations context, inspections are used to identify the needed assessment for rehabilitation work. However, since no federal or state regulatory is used for inspections; the development and the implementation of the inspection standards in mainly the transit management responsibility
(Russel et al. 1997). This research aims at developing a risk assessment model on a network level based upon the visual inspection reports subway structural elements. This is a four-phased model in which sub-models for measuring the components of a risk equation, namely probability and consequence of failure, are first developed. The paper proceeds to suggest an addition to the classical risk equation to be better suited for the case of subway networks. The risk equation components are then combined using the fuzzy inference system.

The following section presents a background for the current practices adopted in addition to the available researches. The background is followed by the methodology section in which the developed models are explained in details. Finally, a case study is presented to demonstrate how the model works and its validation.

1.1 Background

1.1.1 Subway Assessment Efforts

The literature demonstrates research and industrial efforts to assess the condition of subway stations and rank stations for maintenance and rehabilitation. California transit authority developed an evaluation system for stations and ranked them on a scale from excellent to poor based on predefined criteria combined using a weighted average technique (Abu-Mallouh 1999). Whereas, Metropolitan Transit Authority of New York Transit developed a ranking system for condition assessment by assigning points to different functional factors (Abu-Mallouh 1999). London Transit developed the Key Performance Indicator to evaluate the performance of stations from its customers’ point of view using a direct evaluation of customer satisfaction through surveys and interviews. The Paris Rapid Transit Authority worked on developing a selection procedure for stations in need of rehabilitation, the model used a seven functional criteria selection procedure.

Subways domain was shyly researched in academia with only a handful models assessing subway stations. Abu-Mallouh (1999) developed a model to optimize the number of stations accommodated within a given capital program for full and partial rehabilitation. Semaan (2009) developed a condition assessment model to diagnose specific subway stations and assess their conditions using an index (0-10). In a corresponding effort, (Farran 2006) developed a model to address life cycle costing for a single infrastructure element with probabilistic and condition rating approach for condition state. And finally, (Semaan 2011) developed a model to evaluate structural performance of different components in a subway network using performance curves for components and the entire network using reliability-based cumulative Weibull function.

It is noted that the reported transit management practices adopted a qualitative functional perspective to inspect and prioritize subway stations for rehabilitation. On the other hand, the academia focused mainly on structural quantitative models through condition assessment and deterioration models. While these two perspectives of assessment are vital; none of the reported literature integrates the functional and structural aspects of a subway station into a single model.

1.2 Methodology

The developed methodology aims at combining structural and functional perspectives of a subway network into a single risk assessment model. The structural integrity is assessed through a probability of failure sub-model whereas the functional perspective is assessed through the consequence of failure and criticality index sub-models. The output of the three sub-models is then integrated into a risk index model using 30 rules extracted from experts’ knowledge. This section starts by presenting the network hierarchy used through the analysis and proceeds with the sub-models and model development.

1.2.1 Subway Hierarchy

A generic subway network hierarchy is presented in Figure 1. A typical subway line is composed of a number of station buildings. They operate by means of their composing systems such as electrical, mechanical, security and communication, and, structural. This research focuses only on the operational
risk failure derived from the structural systems in a network. Therefore, the structural system is identified as a composition of stations, tunnels and auxiliary structures. These are composed of the elements located at the lowest level of the hierarchy. This hierarchy will be the basis of calculations through model development and its associated sub-models.

1.2.2 Probability of Failure Sub-Model

The Probability of Failure (PoF) sub-model builds upon the performance model developed by (Semaan 2011). Semaan (2011) used reliability-based cumulative Weibull function to evaluate the structural performance of different components in a subway network and develop performance curves for subway components and the entire network. Reliability-based cumulative Weibull function takes a probabilistic approach that yields a reliability index, which is the inverse of the PoF. Therefore, PoF can be estimated as the inverse of the reliability and is shown in Equation [1]

\[ \text{PoF}_f = 1 - R(t) = 1 - e^{-\left(\frac{t-\delta}{\tau}\right)^\alpha} \]

Where,
\[ R (T) = \text{Reliability}, t = \text{Time}, \delta = \text{deterioration parameter}, \alpha = \text{location parameter}, \tau = \text{scale parameter}, \delta = \text{and} \ e = \text{exponential}. \]

Different system configuration requires different calculations for PoF values. The series-parallel reliability technique (Hillier and Lieberman 1972) entitles that any system is composed of components outlined in parallel, in series, or, in a combination of both. A system in parallel is a redundant system where components work simultaneously; hence, it can operate even if one of its components fails. This is the logic used to calculate the different PoF values. A subway network is composed of lines, stations, and auxiliary structures, the PoF is calculated for each system based on the configuration shown in Figure 2.
Station System (STA): In a subway station system, the slab and stairs are redundant systems and can be considered as a parallel system. The wall system is a series system in which if any wall “fails” to perform, the whole station becomes unsafe, and thus does not perform. PoF of a station system can be computed using equation [2]

\[ P_{STA} = 1 - \prod_{i=1}^{n}(1 - P_{STEi}P_{STII}) \left( 1 - P_{STIII} \right) \left( 1 - P_{WRI} \right) \left( 1 - P_{WELi} \right) \]

Where,
- \( P_{STAi} \) = Probability of station j failure,
- \( P_{STEI} \) = Probability of exterior stairs failure,
- \( P_{STII} \) = Probability of interior stairs failure,
- \( P_{STIII} \) = Probability of external slab failure,
- \( P_{STIV} \) = Probability of internal slab failure,
- \( P_{WRI} \) = Probability of internal wall failure,
- \( P_{WELi} \) = Probability of external wall failure, and, \( i = 1, 2 \ldots n \) = station floor.

Tunnel System (TUN): A tunnel system operates in series in which it fails if any of its components fail, therefore, PoF values are calculated using equation [3]

\[ P_{TUN} = 1 - \left( 1 - P_D \right) \left( 1 - P_w \right) \left( 1 - P_s \right) \]

Where;
- \( P_{TUN} \) = Probability of tunnel failure,
- \( P_D \) = Probability of Dome failure,
- \( P_w \) = Probability of wall failure,
- \( P_s \) = Probability of slab failure.

Auxiliary structures System (AS): These systems operate in series in which it fails if any of its components fail, therefore, PoF are calculated using equation [4]

\[ P_{Aux St} = 1 - (1 - P_{w}) \left( 1 - P_{TS} \right) \left( 1 - P_{BS} \right) \]

Where;
- \( P_{Aux St} \) = Probability of auxiliary structure failure,
- \( P_{w} \) = Probability of walls failure,
- \( P_{TS} \) = Probability of top slab failure, and, \( P_{BS} \) = Probability of bottom slab failure.

A Line System: is composed of all stations, tunnel, and auxiliary structure systems operating on the line. These systems together operate in series whereas; the composition of each system operates in parallel. The stations systems are redundant system, they operate in parallel and will fail to operate when all stations in a line fail. Likewise, a line failure occurs when all tunnels on the line fail to operate. Same applies for the auxiliary structure, operating is parallel in a line systems. On the other hand, the three systems operate in series. If any of the systems fails entirely that means the subway line is in a failure status and can no more function effectively. The line hierarchy is shown in Figure 2 (a) and is computed using equation [5]
Where:

\[ P_{\text{line}_i} = 1 - \left[ \left( 1 - \prod_{n}^{i=2} P_{\text{STA}_i} \right) \left( 1 - \prod_{n}^{i=2} P_{\text{TUN}_i} \right) \left( 1 - \prod_{n}^{i=2} P_{\text{AUX}_i} \right) \right] \]

**Subway Network:** A subway network is composed of all the lines operating in the network. It can be concluded that the lines in a network operate in parallel. Hence, the network only fails when all the lines operating in the network fail. This can be computed using equation [6] and concluded from Figure 2 (b).

\[ P_{\text{Net}} = \prod_{n}^{i=1} P_{\text{line}_i} \]

Where:

\( P_{\text{Net}} = \) Probability of network failure, \( P_{\text{line}_i} = \) Probability of line failure.

### 1.2.3 Consequences of Failure Sub-Model

A generic risk management system should identify PoF and Consequences of Failure (CoF) to be combined later to produce a representative risk index. A formal review of failure consequences diverts attention away from maintenance tasks having little or no effects and focuses on maintenance tasks that are more effective. This ensures the maintenance spending is optimized and guarantees the inherent reliability of equipment is enhanced (Gonzalez et al. 2006). Indirect impacts of failure of a subway station include, but are not limited to, service disruption, passenger delay, loss of reputation, loss of revenue in addition to other socio-economic impacts reflected as the extent to which the failure affects adjacent services and customers benefiting from the service and the ease of providing an alternative service. However, only a fraction of the expected CoF can be monetized whereas most of the expected indirect CoF are difficult to monetize and measure (Muhlbauer and W Kent. 2004). One way to overcome the difficulty inherent in these calculations is measuring CoF using indices, which facilitates comparing between expected CoF and highlights areas of higher failure impacts.

This research determined factors affecting CoF calculations in terms of tangible and intangible impacts using the Triple Bottom line approach. This revealed a wide spectrum of consequences occurring at element and station levels. A station is composed of a number of elements operating simultaneously; based on the location of the element and its nature, the element failure might cause total, partial, or no station closure. This suggests CoF are element-dependent, Figure 3 outlines the CoF model. Based on
literature and expert opinion, CoF are broadly grouped into financial, social, and, operational impacts of failure. It is noted that some factors could fall under two different perspectives simultaneously.

\[
CF_i = C_{wi} \times S_{si}
\]

**Figure 3: Consequences of failure model outline.**

The defined impacts of failure along different categories are interdependent; hence, the effect of a single impact cannot be measured independently without considering how other impacts affect and are affected by its occurrence. Therefore, Fuzzy Analytical Network Process (FANP) is selected to obtain relative weights of these factors. FANP addresses the interdependency inherent in the relation between these factors and accounts for the uncertainty caused by using expert opinions. The reader is referred to (Abouhamad and Zayed 2013a) for further model details. For each subway element, the consequence of failure index \( (C_{OF_i}) \) is computed using equation [7]

\[ [7] C_{OF_i} = C_{Wi} \times S_{Si} \]

Where;

\( C_{OF_i} = \) Consequence of Failure Index, \( C_{Wi} = \) Criteria weight obtained using questionnaire survey and FANP, \( S_{Si} = \) Severity score calculated from network data and inspection reports, \( i \) = elements operating per station.

Financial impacts are twofold; repair/replacement cost defined as the direct cost of repair or replacement and loss of revenue defined as the profit loss due to service interruption. Operational impacts is measured in terms of ease of providing alternative and time to repair. The ease of providing alternative is
measured by means of available bus stops and reroutes in case of no service whereas, the time to repair is the time required to return the component to a full functioning state. The social impacts are measured by user traffic frequency, maximum allowable interruptions per year per station and the degree of service interruption whether partial, total or no interruption at all.

1.2.4 Criticality Index Model

This research introduces criticality for the scope of subway networks as the Criticality index. The subway network breakdown structure is assessed differently, the element is selected such that its criticality level is dominant and diverse enough to prevail over other network components. Consequently, subway stations are selected to be the focus of criticality analysis. Systems and subsystems share the same major role of delivering the service; however, their criticality is derived from their respective locations in stations that vary in criticality according to several factors. From this discussion, the concept of criticality propagation is introduced; criticality level propagates upwards and downwards in a hierarchy of a subway network such that they acquire the same criticality level as stations where they operate. Similarly, a line criticality is computed as the sum of criticality indices of stations existing on this line. For interconnecting systems such as tunnels and auxiliary structures, CR is computed as the higher index of the two corresponding stations through which this system connects.

Factors contributing to station CR are identified through historical data, expert opinion and by consulting current structure and map of several subway networks. Station criticality is a complex decision based on different attributes defined as; number of lines, number of levels, station use whether end or intermodal, and station proximity to different attraction locations. CR factors defining a station differ in significance, thus, a weight component is introduced to the CR equation to accommodate the subjective variability in attributes weight. Attribute scores are computed based upon the network under examination and individual station information. Station criticality is defined in terms of three main factors and seven sub factors or attributes. Amongst attributes identified, the station location is the most diverse. For further details about this model, the reader is referred to (Abouhamad and Zayed 2013b). Station criticality attributes are strongly connected, hence, cause and effects loops flow between them. Therefore, FANP with application to Fuzzy Preference Programming is used to compute the attributes weight. The Criticality Index model is outlined in Figure 4.

![Criticality Index Model Diagram](image)

**Figure 4:** Criticality Index model outline.

Criticality Index per station \( C_{\text{R}} \) is computed using equation [8]

\[
C_{\text{R}} = \sum_{i=1}^{n} C_{\text{R}w_i} \times C_{\text{R}s_i}
\]

[8]
Where; $C_R$= Criticality Index per station, $c_{RW}=$ Criticality attributes weights calculated using questionnaire surveys and FANP, $c_{RS} =$ Criticality scores calculated using current network data, and $i=1,2, \ldots ,n$, $n=$ criticality attributes

1.2.5 Risk Index Model

Risk by definition is a combination of PoF and the severity of adverse effects (Lowrance 1967). When studying the risk level, it should be noted that elements with similar PoF might show wide variation in terms of consequences of failure and vice versa. In addition, critical elements with high consequences of failure usually compose a smaller portion of the overall network. Accordingly, focusing only on these elements would result in an unbalanced management practices since unexpected failures may occur in less-critical elements, which constitute the majority of the network. Furthermore, a comprehensive risk assessment should consider the relative importance of different components and systems of a subway network. A criticality index is introduced to measure the relative importance and consider it in the risk index development. Consequently, a new term is added to the risk equation, named as the criticality index ($C_R$). Several methods exist to compute the risk index value, ranging from simple straightforward multiplication to more sophisticated computation of risk matrix.

The Fuzzy Rule Based (FRB) technique was selected to compute the risk index in this research. This method permits users to integrate their experience into the decision support system through using “if-then” rules. Fuzzy sets allow for a more precise presentation of element’s membership particularly when it is difficult to determine the boundary of the set as crisp values. An FRB consists of a set of if-then rules defined over fuzzy sets (Masulli et al. 2007). The rules are usually created using “expert knowledge” (Castillo et al. 2008). The relationship between different fuzzy variables is represented by if-then rules of the form “If antecedent…… Then Consequent”. In cases where the antecedent has more than one part, the fuzzy operator is applied to obtain one number representing the consequence for the antecedents of that rule. This is the number used afterwards to obtain the output function. The Mamdani fuzzy inference system (Mamdani and Assilian 1975) uses the min-max composition as defined in equation [9]

$$\mu_{ck}(z) = \max\{\min[\mu_{Ak}(input(x)),\mu_{Bk}(input(y))]|k\}$$

Where;

$\mu_{ck}, \mu_{Ak}, \mu_{Bk}$ are the membership functions for output “z” for rule “k”, $x$ and $y$ are inputs.

Whereas in our case, the antecedent and the consequent are fuzzy propositions. The proposed model is performed using MATLAB® fuzzy logic toolbox. Mamdani algorithm based on experts’ knowledge is used to construct the rule base. The model combines PoF, CoF, and $C_R$ expressed as triangular membership functions. The min-max composition is used whereas the defuzzification was done using the Centre of Area method. The fuzzy risk equation solves equation [10] and is shown in equation [11]

$$\text{Risk Index} = \text{Probability of Failure} \times \text{Consequence of Failure} \times \text{Criticality Index}$$

$$R_i: \text{IF PoF is } X_i \text{ and CoF is } Y_i \text{ and } C_R \text{ is } Z_i \text{ then Risk is } L_i$$

Where, $i= 1, 2, 3 \ldots ,k$ , $X_i, Y_i, Z_i,$ and $L_i$ are linguistic constants as defined in model, $k =$ number of rules
The threshold for risk values are set based on the maximum allowable PoF and CoF values. This eliminates the major drawback of a risk matrix in differentiating between the two extreme cases of high PoF with low CoF and vice versa. It also ensures the highest priority is given to elements with most emerging rehabilitation need whether derived from high PoF or high CoF. Based upon feedback from experts, CoF is categorized into three levels based upon the combined effect of failure on financial, social, and operational levels. Criticality serves to define stations into normal stations with moderate importance and critical stations with higher criticality. All data incorporated in the risk index calculations is reserved for a detailed analysis of each station. The membership functions were selected based on literature review and unstructured interview with subway experts. A set of 30 rules (5 rules for PoF, 3 for CoF and 2 for CR) is generated to develop the Risk Index.

1.3 Case Study and Model Implementation

An actual case study was conducted on a sub network in Montreal metro to validate the model and proof its robustness. Montreal subway is one of the oldest networks in North America, with 68 stations spreading on four lines and covering the north, east, and centre of the Island of Montreal. Six stations (SEG 1 to SEG 6) on three different lines are analysed in the model with one station being the interconnecting station. SEG 1 to SEG 3 fall on the same line given the name Line A, SEG 4 and SEG5 both fall on the second line B. SEG 6 falls on line C whereas, SEG 2 is the interconnecting station for the three lines. Stations were selected from literature review (Semaan 2011) and based upon availability of inspection reports for different indices calculations.

1.3.1 Sub-Models output

PoF is calculated using year 2014 as the base for calculations. The subway system hierarchy together with the equations presented earlier were used to compute PoF values for elements at the lowest level of the hierarchy then aggregated upwards to compute the integrated PoF values for stations, tunnels and auxiliary structures, identified as a segment (SEG). Sample output PoF values are illustrated in Figure 5.

A questionnaire survey was launched to gather the required data for CoF and Criticality models' development. The questionnaire conducted pairwise comparisons between attributes, sub-attributes and goals for each of the two sub-models. It also contained open ended questions for experts to provide their opinion on model development and suggest any required modifications. The output of the questionnaires are local and global weights for attributes in CoF and CR models. Further details about the resultant weights can be found in (Abouhamad and Zayed 2014). FANP calculations are done using MATLAB® software and FPP as a prioritization tool.

Scores for CoF attributes were obtained from literature review (Farran, 2006) and current information of Montreal subway. Sample calculations for CoF index are seen in Figure 5. As stated earlier, CoF are calculated for elements at the lower level of the hierarchy then aggregated upwards. It is evident that CoF are highly affected by PoF value for each system since all the factors accounted for in the model are directly proportional with PoF value. Calculations for CR were done for the entire Montréal subway network (68 stations). Two stations with maximum and minimum criticality levels were set as thresholds for normalizing the index for the six stations under study. Criticality index is defined as the functional role a station plays and thus is calculated on stations level. A tunnel criticality index is taken as the higher value for the two connecting stations, while auxiliary structures acquire the criticality index of corresponding subway station. This explains the constant CR value per segment as seen in Figure 5. Unlike PoF and CoF where values are upwards aggregated, for an element level analysis, CR values for a given element are the same as the station where it operates.
1.3.2 Risk Index Model

The output of the preceding three submodels is used as the input for the risk index model. Using rules derived from experts as seen in Figure 5, each submodel is assigned a value based on the degree to which it belongs to its membership function. The risk Index is calculated on the elements level where PoF and CoF are calculated. The series-parallel technique is then used to aggregate the risk index to higher levels of the hierarchy based upon the scope of analysis. Figure 5 demonstrates the expected risk index calculated per elements and aggregated upwards per segments to the second level of the network hierarchy. Figure 6 shows a sample rules configuration used to develop the model. Figure 7 illustrates the resultant risk surface.

The station in SEG4 has the highest risk index. This is the complied effect of a high PoF and CR values despite somehow moderate expected CoF. It is noticed that the tunnel and auxiliary structure in the same segment share the same CR level yet their risk index is low. This is clearly due to the low probability of operational failure of the two elements derived from low PoF and CR. This resultant risk value is only available through a fuzzy risk index where the CR affects the risk index only in case of an existent risk value. The station in SEG 6 comes next with an expected risk index of 0.5. This risk index is mainly affected by the moderately high PoF in spite of low CoF and CR values. This also is attributed to the fuzzy risk model which triggers the expected risk index value based on interrelated criteria just like a human expert. The risk index for the remainder elements is considered within acceptable range since they all have low combinations of PoF, CoF and CR values.
1.4 Conclusion

This paper presented an overview of a network level risk assessment model. The risk index is developed using three sub-models and the fuzzy inference engine to incorporate experts’ knowledge. The illustrated case study verifies the model can be used for ranking element in a subway hierarchy based upon its risk index. Furthermore, the sub-models can be used as standalone models for ranking stations for rehabilitations based on one perspective (Structural or operational) only rather than the combined risk effect. The use of fuzzy logic facilitates incorporating experts’ knowledge into the model to account for the data scarcity and problem complexity. In addition, it overcomes the shortcomings of the conventional risk assessment techniques. The presented model is novel and expected to be of great benefits to academia, since the topic is poorly researched as well as industry, since the model is easy to use and straightforward.

Abstract: In the construction industry, auctions have long been used as a method for allocating contracts. Not addressed in the literature (engineering or economics) is the fact that most, if not all, large jobs are awarded to a general contractor who in turn subcontracts most, if not all, actual engineering services. Optimal bidding strategies in this setting require the general contractor to not only account for the optimal bidding strategies of rivals, but subcontractors as well. Because the true cost of construction is not known until after the completion of the contract, adverse selection occurs when the winner of the contract is the one that most has underestimated the true cost. Due to the multi-stage bidding environment, adverse selection may be compounded. Therefore, not accounting for the potential for adverse selection by bidders may result in requested change orders by the general and subcontractors or lower quality services. Either state ultimately results in an adversarial relationship between the subcontractor and general contractor, and the client as well. This paper uses game theory to determine to what extent the multi-stage aspects of large construction contract bidding may contribute to inefficient allocation of contracts. This should better help in creating an efficient and effective contracting environment that result in less conflicts, claims and disputes for all the associated stakeholders.

1 INTRODUCTION

Construction has long history since the beginning of human civilization. A great example is the Egyptian pyramids which had been constructed in 2600 before Christ. Nowadays, construction works are an integral part of everyone’s daily life. The construction industry is not only important for its final product, but also provides a numerous job opportunities. Therefore, understanding the basic processes within the construction industry is essential for contractors to maintain a competitive position within the market, and also for nations’ economy to operate effectively and efficiently.

According to Kuluanga (2001), the construction industry incorporated simple and straightforward processes in the early years. However, the construction industry is getting more complex and...
sophisticated in today’s world. Nowadays, one of the complicated areas in the construction industry is the contract allocation process. Competitive bidding has long been used as a method for allocating contracts in the construction industry (Seydel 2003). In the public sector, competitive bidding has been considered as a legal requirement. Furthermore, it is argued that one of the main factors that have a great effect on the success of construction projects is the firms’ bidding decisions.

Generally, in the construction bidding process, submitted bids are evaluated technically, and then the technically approved bids are evaluated financially or based on the submitted price. For the financial evaluation of the submitted bids, there are many methods such as the low bid method, the second lowest bid method, the average bid method, and the below average bid method. According to Ioannou and Awwad (2010), the low bid method is the most common method for construction contracts in the US. In the low bid method, which is applied in this paper, the contract is awarded the contractor who is technically approved, and has the lowest price among the submitted bids. Accordingly, the winning contractor is expected to construct the project based on the agreed price, schedule, and to provide, at least, the required level of quality.

The main difference between construction projects and other types of projects is the high level of uncertainty of events that may occur during the project’s life cycle. For instance, contractors must contend with inevitable and unforeseen input price increases, Labor issues, and construction conditions that must be accounted for when developing a bid for a long term project. Therefore, at time of submitting bids, contractors cannot know with certainty the actual project construction cost. As such, the construction industry relies on estimates of the project cost based on their current information, past experience, and utilizing methods such as RS means. The RS method is a construction cost estimation database based on historical data, that is used by professional estimators for calculating project cost, based on its type and region, prior to beginning of construction. Thus, in construction bidding, contractors, who underestimated project cost and bid less than the realized project construction cost, face the problem of adverse selection. Adverse selection results in what is known as the “winner’s curse”.

2 GOALS AND OBJECTIVES

The goal of this paper is to identify the degree of the winner’s curse in two common construction bidding settings. The authors aim to compare the construction bidding environments of “single-stage bidding vs. multi-stage bidding”. Furthermore, this research would provide an effective tool for contractors to mitigate the winner’s curse.

3 BACKGROUND INFORMATION

3.1 Construction Bidding and Common Value Auctions

Historically, auctions have been used over thousands of years to sell numerous types of goods and services. In our today’s world, auctions are of great practical importance because the value of goods being exchanged in auctions, in both public and private sectors, is relatively high (Kagel and Levin 2002). From the perspective of game theory, auctions are considered one of the most outstanding applications of games with incomplete information, because participants in auctions have different private information which is the main factor affecting their strategic behavior.

Generally, the same logic of auctions applies to construction bidding. Basically, contractors have two sources of incomplete information at time of submitting their bids; (i) actual project construction cost, and (ii) their competitors’ estimates of the project construction cost. In auction theory, auctions are classified into two types; (i) private value auctions, and (ii) common value auctions. In private value auction, the bidders know their own value of the item being auctioned with certainty, but they do not know other bidders’ values. On the other hand, in common value auction, the item being auctioned has the same value to everyone, but none of the bidders know this value with certainty. Each bidder generates different estimate about the true value, which is generally being observed after the auction is over (Kagel and Levin 2002).
According to Dyer and Kagel (1996), construction bidding is considered as a common value auction. This is due to the unknown true cost of construction projects which cannot be realized with certainty until completion of the project. Furthermore, the auction theory also refers to bidding for construction contracts as a reverse auction, where bidder usually wins the project, based on the low bid method, when they have the lowest estimate of the project cost.

3.2 The Winner's Curse

According to Kagel and Levin (2002), the story of the winner’s curse was firstly introduced by Capen, Clapp, and Campbell (1971). The three petroleum engineers claimed that oil companies had suffered unexpectedly low rates of return in early outer continental shelf (OCS) oil lease auctions. Thereafter, many researchers have claimed the same problem of the winner’s curse, such as in book publication rights (Dessauer 1981), in corporate takeover battles (Roll 1986), and in real-estate auctions (Ashenfelter and Genesore 1992).

The winner’s curse can be described in many ways. In construction industry, the winner’s curse can be defined as the situation when the bidder, with the most optimistic information and project cost estimate, wins the project contract based on a submitted bid less than the true project construction cost. Such a bidder, who fails to take the winner’s curse problem into account, ends up with negative or below normal profits.

According to Dyer and Kagel (1996), in construction bidding, US general contractors usually utilize one of the following three mechanisms to avoid the winner’s curse:

- One mechanism is that most states’ law allows low bidders to withdraw their bids for public projects in case of arithmetic errors, and without being subjected to penalty. The meaning of arithmetic errors is broad and not well defined, and contractors can benefit from this to escape from the winner’s curse by withdrawal of their submitted low bids.
- Second mechanism is depending on the relationship between general contractors and sub-contractors. General contractors can bid too high with the assistance of their sub-contractors to cover that. Usually, sub-contractors assist their general contractors in that in order to get the job, and for the usual long term work relationship between general contractors and sub-contractors.
- Third mechanism to avoid the winner’s curse is through change orders. Change orders refer to situations in which clients or owners adjust the original scope of construction of the project after signing the contract. Usually, the price of a change order is established through negotiations between associated stakeholders. Through tough negotiations, general contractor, who underbid a project, can recover at least his losses, and in some instances, make some profit.

Generally, the aforementioned mechanisms are considered ineffective, especially the third mechanism of change orders which is considered ineffective due to its many disadvantages such as the resulted adversarial between the sub-contractor and general contractor, and the client as well, and its potential legal costs. Therefore, in order to avoid the winner’s curse problem, and due to the relatively ineffectiveness of the aforementioned mechanisms, contractors must carefully consider all factors while preparing their bids such as market factors as location of the project, number of competitors, and time, and project factors as its size, type and scope. Being the case, the following section provides the contractors with guidelines in order to obtain the optimal strategic bid to submit and avoid the winner's curse.

3.3 The Symmetric Risk Neutral Nash Equilibrium (SRNNE) Bid Function

From past research in auction theory, Wilson (1977) developed the first Nash equilibrium solution for first price sealed-bid common value auctions. Thereafter, Dyer et al. (1989) presented the symmetric risk neutral Nash equilibrium bid function (SRNNE) for a sealed-bid first price common value auctions. Furthermore, Dyer et al. (1989) utilized this optimal bid function to analyze a series of laboratory sealed-bid common value auctions, in which bidders were competing for the right to supply an item of unknown
cost such as construction contracts. Dyer et al. (1989) focused primarily on analyzing and comparing the behavior of experienced executives in the construction industry with inexperienced students.

According to Dyer et al. (1989), it was found that both inexperienced students and experienced executives were almost similar in suffering from the winner’s curse. Furthermore, it was concluded that the use of SRNNE optimal bid function guarantee that bidders would not suffer the winner’s curse problem, subject to winning the project contract.

As aforementioned, the actual cost of construction project \( C \), is unknown at the time of submitting bids. Therefore, each contractor \( (i) \) has a different estimate of the project cost. Generally, the winner of the construction project contract expect to earn a profit which is equal to the difference between his bid and the actual cost of the project, as shown in the following equation 1:

\[
\text{[1] Profit} = \text{Winner's bid} - \text{Actual Cost}
\]

When the winner’s profit is negative or below normal profits, then the winning bidder is considered a prey to the winner’s curse. In deriving the SRNNE optimal bid function, the actual cost of project \( C \), is assumed to be randomly drawn from a uniform distribution on \([X_1, X_2]\). Furthermore, each bidder receives a private signal \( c_i \), about the true cost. This private signal is assumed to be randomly drawn from a uniform distribution on \([C-\epsilon, C+\epsilon]\). Moreover, it is also assumed that the uniform distributions of the actual cost \( C \), the private signal \( c_i \), \( \epsilon \), and the number of bidders \( N \), are a common knowledge to all participating bidders.

The SRNNE optimal bid function, as stated by Dyer et al. (1989), in the interval \([X_1+\epsilon < c_i < X_2-\epsilon]\) is as follows:

\[
\text{[2] } b(c_i) = c_i + \epsilon - Y
\]

Where \( Y = \left[2\epsilon/N+1\right] \exp\left[-(N/2\epsilon)(X_2-\epsilon - c_i)\right] \), and \( N \) is the number of bidders. The variable \( \epsilon \) represents the range of private signal around the true cost, and depends on the accuracy of bidder’s estimate. It is important to notice that the \( Y \) term diminishes rapidly as \( c_i \) moves below \((X_2-\epsilon)\). Also, the SRNNE implies that signals are just marked-up by a value equal to \( \epsilon \), which represents a strategic profit, just to avoid the winner’s curse problem of negative profits.

The main objective of SRNNE optimal bid function is to determine the optimal amount a bidder shall submit without being subjected to the winner’s curse problem, in case of winning the contract. It is logical that if the bidder bids based on estimating the project cost close to \((X_1+\epsilon)\), he may lose money in case of winning. This fact is expected to happen most of the times but not always. Sometimes, improbable things happen which turns bad decisions to be good. However, if this bidding competition is played many times and the bidder always estimates a project cost close to \((X_1+\epsilon)\), he will lose money eventually, in expectations, based on the winner’s curse concept.

## 4 RESEARCH METHODOLOGY

In this paper, the authors apply the aforementioned theoretical approach of SRNNE using some real projects dataset conducted by California Department of Transportation. Furthermore, the authors compare the results to those of the implemented model, which simulates the bidding procedure in reality. The main purpose is of the simulation model is to analyze the behavior of sub-contractors and general contractors towards the threat of the winner’s curse. Moreover, the authors aim to examine the effect of the nature of construction bidding environment (single-stage bidding vs multi-stage bidding) on the results from the winner’s curse perspective. As aforementioned, it is expected that multi-stage bidding will result in that the winner will suffer more losses, than in single stage bidding. To this end, this research uses a three-step research methodology in which the authors (1) design the single-stage and multi-stage bidding games; (2) set up the basic assumptions and considerations required for the simulation model; and (3) collect some real projects dataset to be utilized in the simulation model.
4.1 Design of the Single-Stage and Multi-Stage Bidding Games

In the single-stage bidding game, as shown in Figure 1, there are only three general contractors who are competing to win a similar project contract in each round. The contract is awarded to the general contractor who submits the lowest bid following the low bid method concept. The projects in SSG are designed to be the same as those in MSG.

![Figure 1: Single-stage bidding game (GC=General Contractor)](image)

On the other hand, in the multi-stage bidding game, as shown in Figure 2, there are three general contractors. Each general contractor receives bids from three sub-contractors for a symmetric part of the project. In MSG, it is assumed that the general contractor subcontracts up to 30% of the project work. Based on the low bid method, the winning sub-contractor for each general contractor is the one who submits the lowest bid. Thereafter, the three general contractors are competing in between to win the project and submit their joint bids to the owner. Eventually, the contract is awarded to the lowest of the three submitted joint bids by the general contractors, and consequently, his winning sub-contractor wins the project contract.

![Figure 2: Multi-stage bidding game (GC=General Contractor, SC=Sub-Contractor)](image)

4.2 Basic Assumptions and Considerations

In order to reduce the variability and facilitate the comparison between the two game types (MSG and SSG), there are some basic assumptions and considerations for each game type in each round. Those assumptions serve as the rules for the simulation model, which are as follows:

- In both SSG and MSG, there are six projects’ categories and each category is represented by 15 different projects.
- At each round in both SSG and MSG, each subcontractor and general contractor is randomly given a different private signal which represents his estimate of the true construction cost of his part in the project. All the given private signals, at each round, are within the range of the expected estimate’s error ($\epsilon$).
- The true cost is considered unknown for contractors at the time of submitting their bids.
- The simulation model is designed such that, at each round, the contractors would choose randomly to bid within the range of $\epsilon$, which is shown in table 1, around the given private signal.

For example, for general contractors who are bidding for one of the projects in category 1 in the SSG, the true cost is assumed to be randomly drawn from a uniform distribution with the range from $25,000 to $50,000. Furthermore, the private signals are randomly drawn within $750, which represents the value of $\epsilon$, around the true cost. This implies that, at each round, the true cost of the project would be within ±$750.
around the private signal. Figure 3 illustrates the distribution of the private signals and the true cost at a round for in category 1 in SSG as an example.

![Diagram showing distribution of private signals and true cost](image)

Figure 3: An example of the true cost and private signal distributions (C = True Cost, PS = Private Signal)

### 4.3 Simulation Model Dataset

As previously mentioned, the simulation is implemented using some dataset, which is based on real projects conducted by California Department of Transportation, to simulate the construction bidding process in reality. Either MSG or SSG is divided into six categories, based on the true cost of the project. Each category is represented by 15 projects in each game type in the simulation model. Furthermore, the value of $\epsilon$ is different from one category to another in order to be reasonable relative to the true cost of the project and simulate, as possible, the accuracy of contractors’ estimates in reality, e.g. 2%. The following Table 1 shows the six categories, and the value of $\epsilon$ for each category.

</table>

Note: (MSG = Multi-stage Bidding Game; SSG = Single-Stage Bidding Game; SC = Sub-Contractor; GC = General Contractor)

To this end, the simulation model of the single-stage bidding game, and multi-stage bidding game was implemented on NetBeans IDE 7.4 platform using JAVA programming language.
5 RESULTS AND ANALYSIS

5.1 Results of the SSG and MSG

In the single-stage bidding game, based on the results of the conducted simulation model, it was found that, in 75 projects out of the 90 projects in all the six categories of projects, the winning general contractor suffered from the winner’s curse, by winning the project contract with a submitted bid less than the actual true cost of the project, which represents 83.3% of all the projects being bid for.

Based on past literature, this result was expected according to the four experiments conducted by Dyer et al. (1989), in which the authors found that both inexperienced students and experienced executives suffered the winner’s curse by earning negative profits in three of the four experiments, and profits were not statistically different from zero in the other experiment. Figure 4 shows the winning general contractor’s actual bid and compares it to the actual true cost of the project for the 15 projects in category 1, as an example.

![Figure 4: Category 1: GC actual bid vs. joint project true cost (GC = General Contractor)](image)

Furthermore, in the multi-stage bidding game, the results indicated the winning sub-contractors, in their part of the project, suffered in 83 projects, out of the 90 projects being bid for, from the winner’s curse, which represents around 92% of the projects. On the other hand, the winning general contractors, also in their part of the project, suffered in 77 projects, out of the 90 projects being bid for, from the winner’s curse, which represents around 86% of the projects.

Moreover, the results indicated that in the MSG, all the projects, except one project, in which the winning general contractors earned some profits (13 projects) in the part of the project, their corresponding winning sub-contractors suffered from the winner’s curse and vice versa. Therefore, it is important to highlight that based on the characteristics of the construction competitive bidding and non-cooperative game theory, in the MSG, each of the winning sub-contractors or general contractors is considered liable to his submitted bid for his part of the project. In other words, the party who suffers some losses in his part of the project considered liable to them, while the other will earn the profits based on his submitted bid for his part of the project.

Furthermore, it is noticeable that the winning general contractors have avoided the winner’s curse more than the winning sub-contractors. This refers to one of the mechanisms stated by Dyer and Kagel (1996), in which the general contractors benefit from the low submitted bids by the sub-contractors to earn more profits and at the same time, submit low joint bids which guarantee them the winning of the project contract.

In the MSG, based on the low bid method, a general contractor must submit a joint bid less than the joint bids submitted by his competitors in order to win a project contract. In preparing the joint bid, a general contractor considers the bid of his winning sub-contractor plus the bid prepared for his part of the project. Based on the results of the conducted simulation model, it was found that in 85 projects out of the 90 projects, the overall winning joint bid is less than the joint true cost of the project, which represents...
around 94% of the projects. Despite that in some projects either the winning sub-contractor, general contractor, or both made some profits, this results is due to the high losses in part of one of them.

Figure 5 shows the joint actual bids of the winning general contractor and his winning sub-contractor, and the joint true costs of the 15 projects in category 1 as an example.

Figure 5: Category 1: the winning joint actual bid vs joint project true cost (MSG = Multi-Stage Bidding Game)

5.2 Case of Using SRNNE Optimal Bid Function in Bid Preparation for Both SSG and MSG

The SRNNE optimal bid function provides the contractors with a tool to avoid falling as a prey to the winner’s curse. Moreover, the SRNNE is derived to be used for symmetric bidders within the same stage. Thus, it is assumed that the SRNNE would be used separately at each stage of bidding for the MSG. Based on the results of both SSG and MSG; it was found that using the SRNNE optimal bid function gives positive profits in 100% of the projects. In other words, all optimal bids are more than the true cost of the projects. It is important to highlight that using SRNNE optimal bid function does not guarantee that the contractor will win the project contract. But, it guarantees that the contractor will not suffer from the winner’s curse in case of winning the project contract.

Furthermore, the optimal bids give only a strategic profit only to be above the project true cost. Based on the implemented model’s results, the average of the overall earned profits is 1.31% and 1.27% relative the joint project true cost for SSG and MSG, respectively. Figure 6 shows the comparison between the joint actual winning bids’ profits or losses and the earned joint optimal profits for the 15 projects in category 1 for both SSG and MSG. It is important to highlight that the X-axis (zero in Y-axis), in Figure 6, represents the joint true cost of the project.

Figure 6: Category 1: the joint optimal vs. joint actual profits or losses {(a) SSG = Single-Stage Bidding Game; (b) MSG = Multi-Stage Bidding Game}
5.3 The Comparison between Single-Stage Bidding Game and Multi-Stage Bidding Game

Based on the results of the implemented simulation model, it was found that the SSG is giving less losses as compared to the overall losses of the MSG. This result was observed to occur in 56 of the total 90 projects, representing approximately 62 percent of all projects, as shown in table 2.

In fact, this result was expected because in the MSG, the winner’s curse is expected to happen twice, one in part of the winning sub-contractors and the other in part of the winning general contractors. Not addressed in the literature is the fact that most, if not all, large jobs are awarded to a general contractor who in turn-subcontracts most, if not all actual engineering services. Therefore, due to the multi-stage bidding environment, adverse selection and the winner’s curse problem is compounded in most of the projects in the MSG. Being the case, the projects which incorporates multi-bidding environment, is expected, due to suffering more losses than those of single-stage bidding environment, to face more conflicts, claims, and disputes for all the associated stakeholders.

From the general perspective, the results indicated that the winning general contractors suffered, on average, approximately the same percentage of losses relative to the true cost of their part of the project, as shown in table 2. Therefore, the general contractors have no preference to either MSG or SSG from the winner’s curse perspective. They might prefer the SSG over the MSG due to the aforementioned increased amount of conflicts, claims, and disputes associated with the MSG. On the other hand, they might prefer the MSG over the SSG based on the size of the project. Figure 7 shows the comparison between the overall actual profit or losses of the MSG and those of the SSG for each project in category 1 as an example. Moreover, the X-axis (zero in Y-axis) in the figure 7 represents the joint true cost of the projects in category 1.

Figure 7: Category 1: overall MSG vs SSG actual profit or losses (SSG = Single-Stage Bidding Game; MSG = Multi-Stage Bidding Game)
6 CONCLUSION

The winner’s curse is a major concern associated with construction bidding. The results and analysis conducted in this study demonstrate that in construction bidding, the majority of the winning subcontractors as well as general contractors suffer from the winner’s curse in both single-stage and multi-stage bidding environments. However, the winner’s curse is more severe in the multi-stage bidding environment. A question which arises here is why contractors suffer from the winner’s curse in reality? Actually, this might happen for variety of reasons as follows:

- Inaccurate estimates of project cost.
- New contractors intend to enter the construction market.
- Minimizing losses in case of recession of construction industry.
- Strong competition within the construction market
- Opportunity costs which can affect the behavior of contractors towards the winner’s curse.
- The intention to win the project, then remedy the losses through change orders, claims, and other mechanisms.

Therefore, it is obvious the need for a tool which aids contractors in preparing more accurate bids to initially avoid the winner’s curse. It has been also demonstrated that the SRNNE optimal bidding methodology, in both bidding environments, provides the contractors with a tool to avoid the winner’s curse problem and gain strategic positive profits.

Furthermore, the aforementioned SRNNE optimal bid function considers only a strategic amount of profit to avoid the winner’s curse. For further research, the authors recommend the extension of the SRNNE optimal bid function to include more factors associated with bid preparation such as mark-up, overhead costs, contingency costs.

COMPARITIVE STUDY OF CURRENT PRACTICE IN BRIDGE CONDITION ASSESSMENT

Marwa H. Ahmed1,2, Anjan. Bhowmick1 and Osama. Moselhi1
1 Building, Civil, and Environmental Engineering Dept., Concordia University, Canada.
2 mar_ahme@encs.concordia.ca

Abstract: Bridges play a vital role in road infrastructure networks. According to Statistics Canada, bridges and overpasses accounted for 8% of total public assets in 2007. Ontario ranked as the third among provinces in terms of having old bridges. In 2007, Bridges in Ontario accounted for 7% of its public infrastructure, while in Alberta, bridges account for 9% of total public infrastructure. Bridge condition assessment is conducted to determine load rating capacity for bridge elements. The identification of current condition of each element provides early warning of necessary maintenance. Condition rating is performed during the inspection process. This paper provides a comparative study of current practices in bridge condition rating worldwide, with emphasis on the United States and Canada. The study includes 4 main criteria: inspection levels, inspection principles, inspection frequencies and numerical ratings for 4 provinces in North America: Alberta, Ontario, Quebec and state of Oregon and 5 countries outside North America: United Kingdom, Denmark, Portugal, Sweden and Australia. The Limitations of current practices are discussed and recommendations for improved inspection are provided. The study is expected to assist professionals and inspectors in selecting feasible method/s for effective bridge condition assessment.

1 INTRODUCTION

Bridge Management System (BMS) is the process of monitoring, inspection, repair and replacement of deteriorated bridges. All bridge management decisions require inspection data to identify current condition of bridges. Moreover, it provides decision making with tools to select the appropriate solution, such as bridge rehabilitation or replacement. BMS is facing imbalance between the need for repairs or replacements and many challenges due to incorporating of multi objectives; structural safety, serviceability, optimum maintenance and economic considerations. Therefore, BMS cannot make decisions without accurate and detailed data of bridge conditions. Thus, decision makers can avoid the worst consequences of underestimating the degree of deterioration and avoid the costly consequences of overestimating the degree of deterioration. The main goal of BMS is to gain the maximum performance with using minimum cost and this can be achieved by efficient techniques and technologies that can be automatically updated. Consequently, the service life of bridges can be increased within effective cost. (Rens et al. 2005; Steart et al. 2002, Wang et al.2007). Structural health monitoring, inspection process and condition assessment are considered main components of BMS.

Bridge condition assessment is conducted to determine load rating capacity for bridge components. The main components of bridges are deck, superstructure and substructure. Each component has different role in bridge structure with specified relative importance. Bridge condition assessment defines the
structural importance of each bridge element. The identification of current condition of each element provides with early warning of necessary maintenance. The main difficulty in bridge condition assessment is the large number of bridges in the network which requires regular inspection. However, condition rating is performed using the inspection data. These collected data are converted to a rating to assess bridge condition (Xia and Brownjohn, 2004; Yehia et al. 2007). This paper presents a detailed comparison of current practices of condition assessment of bridge structures in different countries.

2 CURRENT PRACTICE IN BRIDGE CONDITION ASSESSMENT IN NORTH AMERICA

According to Federal Bridge Inspection Standard (FBIS), the levels of service deficiencies are based on comparisons of the actual load capacity of bridge with the level of service. The evaluation of bridge condition deficiency (BCD) includes an assessment of the condition of each of the three primary elements of the bridge: Super structure (SPD), Substructure (SBD) and bridge deck (BDD). After the total deficiency has been established for all bridges, costs associated with replacement and rehabilitation should be determined (FHWA, 2012; Branco and de Brito, 2004).

\[
BCD = SPD + SBD + BDD \tag{Eq.1}
\]

Condition ratings for each element of the bridge are assigned every two years and are then aggregated into overall condition ratings for super, sub structure and deck, the ratings are numerical values from 0 to 9. Bridges are considered structurally deficient if any of deck, substructure or superstructure is equal or less than 4 (poor). If the structural evaluation is equal or less than 2, then the bridge is having high priority for replacement (FHWA, 2012; Branco and de Brito, 2004). According to the manual for maintenance inspection, AASHTO describes two basic load rating procedures: (1) the allowable stress, (2) Load rating, LR. In the United States, bridges are periodically rated according to their structural capacity. The rating can actually increase with time in bridges inspected regularly with maintenance programs, where the live load limits are checked by traffic police.

2.1 Bridge Condition Assessment in Alberta Transportation

According to Bridge Inspection Manual of Alberta Transportation, the condition rating system in Alberta consists of a numerical rating range of 1 to 9 (BIM 2004; Branco and de Brito 2004). This rating applies to all inspection elements as well as the general rating for each category. The rating is representative of the condition of the element and the ability of the element to function as originally designed. Bridge can be rated 9 if it is in excellent condition. Additionally, the rating of the element also reflects any safety concerns and maintenance priority. The rating of an element is determined by the rating of the worst item within the group. The inspector should describe, and explain the condition, why the post has a low rating and where it is located.

The rating of the element is visual inspection and based on what the inspector can see. The inspector should be able to see enough of the element to be comfortable assigning a rating. If the element is inaccessible or is not visible for the inspector to assign a rating, the element is rated ‘N’. If a particular element does not apply to the structure being inspected, the element is rated ‘X’. In situations where an element does not exist but is required in the judgment of the inspector, the element is rated ‘X’ with a comment provided in the ‘Explanation of Condition’ section which illustrates within a maintenance recommendation (BIM 2004). The general rating for each category is determined by the ratings assigned to critical load carrying elements or members of the structure. The general rating must also reflect any safety concerns related to the function of the structure. The general rating is not an average of the element ratings; as the general rating cannot be higher than the lowest critical element rating.

All bridges are to be inspected in accordance with the following intervals to ensure an appropriate level of safety: major bridges, Standard bridges, in highways with numbers less than 500 or greater than or equal to 900 are within 21 months interval. Major bridges, standard bridges in highways with numbers equal to or greater than 500 but less than 900 are within 39 months interval. Major bridges in parks that carry pedestrian traffic only are inspected within 57 months interval. All new bridge structures are to be inspected immediately after construction is complete and within 24 months after completion. All bridge
structures are to be inspected immediately after any significant maintenance or rehabilitation is completed. The inspector may specify shorter intervals depending on the age, traffic characteristics and known deficiencies (BIM 2004; Branco and de Brito, 2004).

Most major bridges, standard bridges, are inspected by a certified bridge inspector on a routine basis which is known as Level 1 inspection. However, certain major bridges or components of standard bridges require inspection with specialized knowledge, tools and equipment. Almost all bridges will require specialized inspections which are known as Level 2 inspections. Specialized inspection includes ultrasonic tests on steel bridges, CSE tests on deck concrete, coring test. Level 2 inspections are essential for high load and overload damage, or where critical or significant deficiencies are determined (BIM 2004; Branco and de Brito, 2004). Level 1 is a general inspection which requires completion of the BIM report and use of basic tools and equipment. This level of inspection must be undertaken by certified bridge inspectors. Level 1 inspections are general visual inspections conducted using standard tools and equipment. This level must be performed at time intervals not exceeding those specified by Department policy. Level 1 inspection rate the worst part of each element and do not take the overall element condition into account.

Level 2 inspection is an in-depth inspection which requires completion of the BIM report, and use of specialized tools, techniques, and equipment. Level 2 inspections are quantitative inspections conducted using specialized tools. This level of inspection gathers detailed information on the condition of a particular bridge. In Alberta, concrete deck inspections are currently performed on approximately 120 bridge sites per year throughout Alberta on a 4 to 5 year inspection cycle. Additional Level 2 deck inspections may be completed as part of a bridge assessment that identified in a previous Level 1 inspection. The quantified condition data that are collected provide information on the element and this condition can be monitored over time. The condition rating for Level 2 inspections are grouped together into categories. Therefore ratings from 9-7 are grouped as very good condition ratings, and then ratings 6 and 5 are grouped as adequate ratings. Ratings of 4 and 3 are grouped as ratings that are the most critical and give priority of the element. Ratings of 2 and 1 are grouped as these ratings are required immediate maintenance or repair. The inspector should rate the general condition and not just the worst case. The inspector should note that if the damage is significant to the structural capacity.

Level 1 rating should be used to reflect the worst damage to the element. A rating of 5 or higher is for elements that are functioning as designed. For a rating of 5 an element may have minor structural flaws, but these flaws should not impact the structural capacity of the member. A rating of 4 is a low maintenance priority, and these elements would generally be scheduled for repair in more than 3 years. A rating of 3 is a medium priority for maintenance, as repairs would typically be scheduled from 6 months to 3 years away. A rating of 2 is a high priority for maintenance and repairs would likely be less than 6 months away. A rating of 1 requires urgent and immediate action.

The Chloride Test is a field test to determine the chloride content of concrete. It is most often performed on a deck because these are the areas of the bridge that are commonly exposed to the de-icing salt. This test is performed in level 2 inspection. Chloride testing is destructive because holes are drilled into the component that is being tested. This testing is also time-consuming as the samples must be extracted and tested. The destructive and time-consuming nature of the test means that only a limited number of samples can be gathered and tested. Copper Sulfate Electrode (CSE) test is a repeatable, non-destructive field test. Alberta Transportation remains one of the few agencies that use CSE testing as a predictive tool for preventative maintenance programs. CSE testing, also referred to as half-cell testing is used to determine the potential of corrosion in reinforcing steel, but they do not indicate a corrosion rate. Test results from one year to another are compared to assess the advancement of corrosion and predict the future deck condition. The CSE data are used to develop prediction models and to determine the ideal time to rehabilitate a deck. CSE data is also used to evaluate the effectiveness of various rehabilitation methods. CSE testing is quick, and cost-effective. The limitation of CSE testing is that, suddenly the readings become higher, lower, as the ground connection may be broken, the voltmeter connections may have worked loose, or the grounding wire may be broken. In this case, inspector should stop and verify the validity of the ground connection or check if the deck is not wet enough for accurate results.
2.2 Bridge Condition Assessment in State of Oregon, USA

The Oregon department of transportation (ODOT) considers the routine inspection report to be the primary tool for reporting the condition of a structure. The routine inspection report is a summary of condition assessment data that is generated via a number of more detailed types of inspections. A Routine Bridge Inspection is a regularly scheduled inspection that generally consists of visual observations that are needed to determine the functional condition of the bridge, and Recommend any repairs or other services that may be needed. Standard routine inspection frequency is two years. However, the NBIS requires inspections be performed annually when conditions rating of bridge is 3 or less or the bridge has an operating load rating factor of less than 1.0 for any of the legal load types (ODOT 2012). In depth evaluation of bridge is needed to supplement the visual inspection. The bridge inspector may employ either nondestructive testing techniques or destructive techniques such as chipping, drilling and core drilling which are the most common in-depth exploratory methods. Nondestructive methods need expertise that is required to interpret the results in the field. The steps for in-depth evaluation of a concrete structure are:

1. Visual Inspection with the last bridge inspection report in-hand.
2. Revision of engineering data, design, construction documentation, operation and maintenance records.
3. Revision of inspection reports and then mapping of the various deficiencies.
4. Monitoring and using nondestructive evaluation methods.

The steel location and depth of cover can be determined non-destructively using a device called a pachometer. This device measures variations in magnetic flux caused by the presence of steel. If the size of reinforcement is known, the amount of concrete cover can be determined. In general, these devices can measure cover to within ¼ inch at 0 to 3 inch from the surface. The accuracy of the devices is dependent on the amount of reinforcing steel that is present in the concrete. The more congested the reinforcing, the less accurate the device becomes. In some cases, when other bars interfere, the device cannot identify either location or depth of cover. Other techniques, such as ground-penetrating radar (GPR) or x-ray, can be used for locating steel rebar which the pachometer fails to provide the necessary information. Between GPR and x-ray, x-ray is more accurate in locating steel rebar. The corrosion of steel rebar can be determined by using the CSE methods (ODOT 2012).

The state of Oregon uses destructive in depth testing such as chloride content test, depth of carbonation and core test to determine the compressive strength of concrete. Hammer sounding and chain dragging are used to determine delamination in concrete. While these methods are not expensive, they are time consuming to perform. Petrographic analysis is a detailed examination of concrete to determine the formation and composition of the concrete and to classify its type, condition, and serviceability. Petrographic examination helps determine some of the freeze-thaw, sulfate attack and alkali-aggregate reactivity. Petrographic examination is a highly specialized practice requiring skilled and well trained technicians. The most common defects encountered in steel superstructures include corrosion, fatigue cracking, heat damage, and overload damage. One of the primary methods to mitigate corrosion is painting with an acceptable coating. Dye penetrate and ultrasonic are used as non-destructive evaluation methods for fracture critical members bridge inspection (ODOT 2012; FHWA 2012).

2.3 Bridge Condition Assessment In Quebec

Bridges in Quebec are managed by MTQ (Manuel d’entretien des structures). Bridge condition inspections in Quebec are classified to visual examination which can be used to document and record the severity and overall condition of bridges. A photographic record of this information is essential. Some testing can supplement observations and measurements. Some of the techniques that can be used during ordinary inspections are: acoustic impact (hammer sounding, chain dragging) for detection of delamination, debonding, voids, and other defects underneath the surface; rebound hammer to evaluate the concrete strength and quality on a comparative basis. NDE methods are used for advanced
inspection. However, these methods still need more development regarding data interpretation. Using combination of visual inspection half-cell potential, acoustic methods and coring are the most widely used techniques in bridge inspection practice.

There are currently three types of bridge inspection Practice in Quebec. These are as follows:

- Routine inspection: It is a visual inspection and is done once a year where defects are observed and recorded. Routine inspection provide inspector with general knowledge about the condition of the bridge.
- General Inspection: This type of inspection is more accurate type and is performed by an engineer or technician who has been trained by a regional bridge engineer. It remains a visual examination, that is supplemented by hammer sounding, general dimension measurements and crack measurements. The frequency of this inspection varies from 3 to 6 years depending on the bridge type; concrete bridges are inspected every 5 years.
- Special inspection: This type of inspection usually follows the general inspection where significant deterioration is found and when the inspector has difficulties to assess the condition. This type of inspection is carried out as requested and can be done with the help of a structural engineer. The bridge condition rating index in Quebec ranges from 1 to 6, where 1 is the lowest value and 6 is the highest: 1-critical, 2-defective, 3-mediocre, 4-acceptable, 5-good, 6-excellent and for elements that don’t exist, the index value is 0.

2.4 Bridge Condition Assessment In Ontario

Ontario structure inspection management systems (OSIMS) was developed to store and manage the inspection data that is collected during the detailed structure inspections. OSIM is capable of creating, updating and storing inspection rating data for structures owned and maintained by the ministry of Transportation. The data are stored in data base and then can be used to generate reports on condition rating. The general information for a structure is obtained from Ontario structure inventory system (OSIS). In the past, inspectors relied on their background and experience in reporting bridge condition. OSIM sets standard for detailed routine inspection and condition rating for structures and their components (OSIM, 2000; Branco and de Brito, 2004). In order to classify defects, severity level should be illustrated. As an example, severity is considered light when delamination area measured is less than 150mm in any direction; medium when delamination area is between 150mm to 300mm; severe when delamination area is within 300 mm to 600 mm and very severe when area is more than 600mm. The defects are divided into material defects and performance defects. OSIM presents the material defects that are found in concrete and steel bridges and it is related to building materials regardless of any consequences to the structure. Performance defects are problem that may impact the structure as a whole. The material and performance condition rating are numerical systems in which a number from 1 to 6 is assigned to each component of the structure. Number 0 is assigned to a component when it doesn’t exist and number 9 is assigned to a component that is not visible at the time of inspection. In some cases, performance defect exists as a result of defects in design or construction. The lowest performance condition rating of primary component should be the performance condition rating of the structure (OSIM 2000; Branco and de Brito, 2004).

The inspection system in Ontario is classified into general inspection, detailed inspection and condition survey. General inspections are based on visual inspections; routine general inspection can talk place daily, monthly or annually for bridges within span over 6 m. Non routine general inspection is performed when inspection is needed for specific problem. Detailed Inspection can be routine or non-routine inspection and should be done by using measurement tools, tabs, camera and thermometers. Inspectors should review all previous inspection reports, details and all records. The inspectors should take sketches and photographs. Condition Survey inspection requires measurements and documents of all areas of defects and deterioration. It requires access to all area of the structure. Routine condition survey can be done every 5 years on selected number of structure and it incorporates the load carrying capacity assessment. For bridge deck condition survey, assessment can be done using GPR and thermograph.

3 CURRENT PRACTICE IN BRIDGE CONDITION ASSESSMENT OUTSIDE NORTH AMERICA

3.1 Bridge Condition Assessment In United Kingdom

In United Kingdom, bridges are subjected to general inspection every 2 years and to more principal inspection every 6-10 years. These inspections are visual inspection that record only damage or deterioration that are seen. Defects that have main concern are inspected within special inspection, such as half-cell potential and cores sampling are examined to check the presence of alkali reaction. Special inspection measures the depth of concrete cover, carbonation, chloride, sulfate contents. The condition of each element is given a rating on scale of 1 to 5 at the time of inspection based. Each element is given a location factor based on its structural importance. The overall condition rating of bridge is given using the equation 2.
BCI = \(100 - f_1 \times \left[ \frac{F_2 \times (E_{fp} \times S_f)}{N_p} + F_3 \times \left( \frac{E_{fs} \times S_f}{N_s} \right) \right]\) \hspace{1cm} \text{EQ2}

Where, \(E_{fp}\) is element factor from 1 to 10 of primary element, \(E_{fs}\) is element factor of secondary elements, \(S_f = \text{The extent of damage} / \text{Severity factor} 1 - 10\). \(N_p\) is the number of primary elements, \(N_s\) is the number of secondary elements and \(F_1, F_2\) and \(F_3\) are the severity factors. Superstructure and substructure are both divided into a number of elements and receive score of 1 to 8. The element rating percentage can be calculated from EQ2. The overall condition rating for substructure and superstructure is taken as the lowest element rating. Bridge condition assessment in UK has some shortcoming as there is little use of nondestructive evaluation methods and there is no relationship between bridge age and maintenance cost. Current practice with countries outside North America are illustrated in Table 2

### 4 SUMMARY AND CONCLUSION

The current practice for bridge condition assessment and inspection in Alberta has some limitations. For example their Level 1 inspection is visual and the rating is subjective and depends on the inspector experience. Level 2 inspection, the overall rating might not be accurate as the areas that are not visible cannot be accurately assessed. In Level 2 inspection, chloride test is used to determine the chloride content in concrete. This test is time consuming and destructive test. When CSE test is used in level 2, the inspector should stop when reading is getting so high or low, and verify the validity of the ground connection or check if the deck is not wet enough for accurate results. CSE test can determine the presence of corrosion but cannot determine the corrosion rate.

The state of Oregon still rely on destructive methods where samples should be taken in specific positions from the bridge to perform in depth inspection such as chloride content test, depth of carbonation and core test. Hammer sounding and chain dragging are time consuming. Pachometer that used for depth of cover measurements sometimes fail to give accurate information. Petrographic examination is a highly specialized practice requiring skilled and well trained technicians.

The current practice in Quebec has some of shortcoming. The condition rating values cannot be used to evaluate the structural capacity of the element. These values are used for general condition of the structure and for evaluation of deterioration. Also, the special inspection is not clearly defined and the system that is followed for reporting is not provided. Inspectors and engineers should be well trained; they should increase their knowledge regarding the material behavior. General inspection is still visual inspection without condition evaluation for specific elements. Special inspections should include in-depth condition evaluation including load-carrying capacity evaluation.

Inspection system outside North America is based on number of visits to the bridge at fixed time interval which is called periodic; the other type of inspection that is not based on interval is called non periodic inspection. The general system of inspection is classified into: superficial inspection that usually done every one year; it is visual inspection with portable support measurements. Through inspection which is called detailed inspection and usually done within period equal to a multiple of the superficial inspection; it is checkup of the structure with detailed visual inspection and usually done with inspector with high
experience. Special inspection is usually not periodic inspection; it is done based on specific defects that was detected; this inspection usually done using specialized equipment and test with the use of NDE methods. Bridge condition assessment in other countries is almost the same. Bridge inspection levels are classified according to inspection interval where the inspection intensity varies with inspection interval. There are three levels of inspection that are defined based on the interval: Short interval check of safety, medium interval of maintenance needs and long intervals, in depth assessment. Identifications of repairs needed are identified during the inspection within medium interval. Inspection with less interval are used together with the inspection of long interval. There is less use on non-destructive evaluation methods in the special inspection. However, MRWA Australian manual is incorporating the use of many NDT methods.

Abstract: Understanding project complexity is crucial for determining—or designing—the tools, methods, and skills required to effectively deal with interface issues in a construction project. However, understanding project complexity is not an easy undertaking; the concept of project complexity is composed of many interrelated sub-concepts, and thus is complex in itself. Given this background, this research aimed to define the dimensions of project complexity based on empirical data focusing on the variations in the project complexity factors between projects. To achieve this research objective, data for project complexity factors were collected via semi-structured interviews from 45 large-scale construction projects, and were analyzed using principal component analysis. As a result, 6 interpretable principal components were extracted from the dataset: ‘unclear scope of work for multiple stakeholders in the definition and design of projects with new technology’, ‘the uncertainty in boundaries and communication relative to other complexity factors’, ‘unfamiliarity with other project participants’, ‘the multiplicity of stakeholders relative to the amount of cost pressure and execution risks’, ‘the relative multitude of engineered items’, and ‘the high-level program/project administration’. These complexity dimensions can help with understanding sources of project complexity and determining the skills, tools, and systems to effectively cope with the sources of project complexity. Additionally, the analysis results hint that organizational interfaces should be effectively managed to prevent project failure in construction projects, and therefore support the need for advanced interface management in complex projects.

1 INTRODUCTION

Interface management (IM) is an emerging practice in the construction industry. In a broad sense, IM is defined as “the management of communication, relationship, and deliverables among two or more interface stakeholders” (CII 2014). IM usually involves formalized ways of communication and coordination between parties involved in a project—e.g., formal procedures for interfacing between parties involved, designated interface managers/coordinators, and software systems for IM (Shokri et al. 2014). In traditional construction projects, interfacing between parties have mostly relied on informal and less organized means, such as verbal communication in face-to-face meetings, memos, phone conversations, and emails. However, these ways of dealing with interfaces become insufficient and ineffective for managing a complex project, and IM has recently emerged as an approach to better cope with complexity in construction projects (Shokri et al. 2014).

Therefore, understanding project complexity is crucial for determining—or designing—the tools, methods, and skills required to effectively deal with interface issues—i.e., level of systematization of practices for
IM—in a construction project. In other words, a better understanding of project complexity can give us an insight into how IM practices can help prevent—or, at least, mitigate—the adverse impact of complexity on performance in construction projects. In more general terms, understanding the sources of project complexity, the interrelationships between the sources, and to what extent the sources are salient and important for effectively managing a complex project might help with determining the tools, methods, and skills for not only IM but also for effectively dealing with project complexity in general (Remington et al. 2009; Maylor et al. 2008; Baccarini 1996). Project complexity has been known as one of the greatest factors of difficulty of project management (Remington et al. 2009; Baccarini 1996; Gidado 1996), and project failure (Parsons-Hann and Liu 2005), in the construction industry.

However, understanding project complexity is not an easy undertaking; the concept of project complexity is composed of many interrelated sub-concepts, and thus is complex in itself. Project complexity is multifaceted (Maylor et al. 2008), and it has many sources (i.e., dimensions)—“Not all projects are complex in the same way” (Remington et al. 2009). Due to this nature of project complexity, it is not clear which specific dimensions of project complexity can be addressed by IM, and how IM practices can help in dealing with those particular dimensions.

A number of researchers have attempted to define the dimensions of project complexity, and to assess the impacts that each of the project complexity dimensions has on project performance. Several research approaches have been proposed and used in this line of attempts, including framework development by aggregating the complexity factors found in the literature (Bosch-Rekvedlt et al. 2011; Vidal and Marle 2008), Analytic Hierarchy Process (Vidal et al. 2011), workshops with industry practitioners (Maylor et al. 2008), surveys via interviews (Remington et al. 2009), and surveys and statistical analysis (Tatikonda and Rosenthal 2000 (factor analysis)).

In most of these proposed methods, complexity factors and dimensions were directly identified and assessed by research participants’ perceptions and evaluations. Therefore, the complexity dimensions that are defined by these methods are essentially a result of a human perceptual phenomenon (Liu 1999). This approach would be most useful in studying the subjective aspect of project complexity (e.g., perceived difficulty of project management). This view of project complexity is echoed in Fioretti and Visser’s (2004) statement that “complexity matters only because of the cognitive problems it gives rise to” (p.12), and Remington et al.’s (2009) statement that “[what matters is] how it is understood by the people who are affected…. [therefore] complexity is most usefully conceptualised in cognitive terms.” However, this approach has limitations in producing objective knowledge about the interrelationships between project complexity factors and the levels of project complexity that may vary between different projects.

With this background in mind, this research aims to identify the dimensions of project complexity by looking at the main sources of variations in the project complexity factors in an empirical dataset. In other words, this research suggests that project complexity dimensions can be statistically defined based on empirical data for various project complexity factors.

In the next section, a literature review on the definitions and factors of project complexity is provided. Then, the methodology and results of this research are presented in the following section. Subsequently, the implications of the results for IM as well as for general project management are discussed.
2 LITERATURE REVIEW ON PROJECT COMPLEXITY

2.1 Definitions of Project Complexity

Table 1 shows several selected definitions of project complexity found in the project management literature. As shown in this table, some disagreement and different—but, inter-related—perspectives exist in the definitions of project complexity in the literature (Bosch-Rekveldt et al. 2011; Vidal et al. 2011; Remington et al. 2009; Vidal and Marle 2008; Gidado 1996). One perspective to project complexity seems to be centered on managerial complexity (i.e., difficulty of management), which means that project complexity is the property of a project that makes managing the project difficult, and therefore requires more sophisticated managerial skills and systems. And, the other perspective seems to be more focused on the nature of the multitude of inter-related and interacting entities in projects (e.g., stakeholders, disciplines, trades, resources, processes, technologies etc.) and uncertainty. The concept of project complexity of interest in this research is in line with the latter view.

2.2 Project Complexity Factors

A large number of various sources—i.e., factors—of project complexity also have been discussed in the literature, and researchers have often attempted to categorize them. Table 2 shows several classifications of project complexity found in the project management literature. As shown in this table, many researchers have categorized and analyzed project complexity factors in different ways, while the most commonly used categories were organizational factors and technical factors. The project complexity factors that were looked at in this research can be categorized into these two groups from a broad perspective.

3 RESEARCH METHODOLOGY

3.1 Data Collection

A survey questionnaire was developed as a tool for collecting empirical data for project complexity factors. (This survey questionnaire was developed as a part of a larger survey conducted by Construction Industry Institute Research Team 302 (CII RT 302). More information about this CII research project can be found in CII 2014.) Table 3 shows the project complexity factors included in the questionnaire. These factors were selected based on the result of the literature review and discussions with sixteen experienced project engineers/managers who participated in the questionnaire development process. The project characteristic factors that can be identified at a project’s onset were focused on in this research, and thus dynamic factors such as change orders and changes in the economic environment were excluded. As mentioned above, the complexity factors included in this research cover the organizational aspect as well as the technical aspect of project complexity, and are, especially, in line with the project complexity factors identified in Bosch-Rekveldt et al. 2011, Geraldi and Adlbrecht 2007, and Vidal et al. 2011.

</tbody>
</table>

Then, the surveys were administered directly by the authors. The authors had either a face-to-face meeting or a web conference call with project engineers/managers/interface managers representing a project. The interviewees were asked to rate the project complexity factors on a 10-point scale by the question, “How much does this factor contribute to the complexity of your current project? (1 for the lowest and 10 for the highest)?” Also, the interviewees were asked to give responses solely based on their current project, or their most recently completed project if there was no current project to which they belonged.

The survey was conducted during 2013. In total, 46 projects owned or managed by US- or Canada-based organizations were studied in this survey, and the data that was valid for the analysis presented in this paper were collected for a total of 45 projects. The average rating of complexity factors ranges from 1.94 to 7.76 with a mean of 5.21 in the sample. This distribution of average complexity score shows that the sample included a wide range of projects in terms of project complexity. More detailed description of data collection method as well as the sample is available in Shokri et al. 2014.

3.2 Data Analysis

The collected data were analyzed by principal component analysis (PCA). PCA is a widely used statistical method used for reducing the dimensionality of a dataset while retaining the variations in the dataset as much as possible. In PCA, the original data are transformed into a smaller number of new variables called principal components (PCs). Although there are several variants of the analysis method, one of the most common methods to define PCs is finding the eigenvectors of the correlation matrix of the original variables (Jolliffe 2002), which is the method used in this research. If the original variables are interrelated, the first few PCs—i.e., those with a large eigenvalue—retain most of the variations that were distributed over the original variables. If an appropriate number of PCs are selected, therefore, the PCs can retain most of the ‘information’ in the dataset, and that is why PCA can be used for reducing the number of dimensions in the dataset. In this research, PCs were used to define the major dimensions of project complexity extracted from the empirical dataset.
4 RESULTS

As mentioned in the previous section, selecting a suitable number of PCs is crucial in PCA, because PCA has two conflicting goals; they are reducing the number of PCs and maximizing the variances accounted for by the PCs. Many rules-of-thumb for this process are available in the literature, but there is no single best rule (Jolliffe 2002). Among these rules, one of the most common criteria, called Kaiser’s rule, was used in this research. According to this criterion, only the PCs whose eigenvalue is greater than 1 are selected, and as a result, a total of 6 PCs were extracted from the dataset.

Figure 1 shows the total variance that is accounted for by each of the PCs, and the cumulative percentage of total variance of the 6 PCs. As shown in this Figure, the percentage of total variance that is accounted for by each of the 6 PCs is 27.76%, 10.83%, 10.53%, 8.61%, 6.76%, and 6.25%, and the cumulative percentage of total variance accounted for by the PCs is 70.73%.

![Figure 1: Percentage of total variance and cumulative percentage of total variance of the principal components of project complexity](image)

Table 4 shows the loadings for the 6 PCs. Interpretation of PCs is primarily done by looking at the general pattern of the loadings (i.e., coefficients for the original variables) for the PCs (Jolliffe 2002). As shown in this table, the first PC has positive loadings for all original variables, and especially has a high level of loading for ‘unclear responsibilities between involved parties’, and ‘unclear requirements between involved parties’, ‘new technology’, and ‘extended/uncertain scope’, all of which are related to either the clarity of scope or the newness of technology in the design. Therefore, this PC can be interpreted as ‘unclear scope of work for multiple stakeholders in the definition and design of projects with new technology’.

*Note. In bold type are the loadings whose absolute values are greater than half the maximum loading for the PC.

The second PC has negative loadings for the variables such as ‘unclear responsibilities between involved parties’, ‘unclear requirements between involved parties’, ‘unclear geographical boundaries within project’, ‘not-aligned software/design standards between parties’, ‘multiple languages’, ‘unfamiliar partners/collaborators’, all of which are related to either the clarity of boundaries or communication between parties. In the meantime, the second PC has positive loadings for many other variables such as ‘cost pressure’, ‘schedule pressure’, ‘execution risks’, ‘large number of suppliers/subcontractors’, ‘government rules/regulations’, and ‘large number of engineered items.’ Therefore, the second PC contrasts the uncertainty in boundaries and communication with the rest of the complexity factors, and implies that after the issues of the clarity of scope and of the newness of technology in the design have been accounted for, the main source of variation in the dataset is the uncertainty in boundaries/communication relative to the rest of the complexity factors.

The third PC has an outstanding loading for ‘multiple languages’, and ‘unfamiliar partners/collaborators’ follows in term of the size of loading. These two variables are thematically inter-related in general, and reflect that there are project participants with unfamiliar backgrounds. Therefore, this PC can be interpreted as ‘unfamiliarity with other project participants’.

The fourth PC has negative loadings for the variables such as “multiple engineering centers”, ‘multiple general contractors/EPCs’, and ‘Large number of suppliers/subcontractors’, whereas it has positive loadings for ‘cost pressure’ and ‘execution risks’. Therefore, the fourth PC contrasts the multiplicity of stakeholders with cost pressure/risks, and implies that after the variances that are accounted for by the first three PCs, the main source of variations in the dataset is the multiplicity of stakeholders relative to the amount of cost pressure and execution risks.
The fifth PC has a relatively high level of negative loading for 'large number of engineered items' while having positive loadings for 'cost pressure', 'multiple owners', and 'multiple general contractors/EPCs'. Therefore, the fifth PC contrasts the multitude of engineered items with cost pressure and the multiplicity of owners/general contractors, and implies that after the variances that are accounted for by the first four PCs, the main source of variations in the dataset is the multitude of engineered items relative to cost pressure and the multiplicity of owners/general contractors.

The sixth PC has the highest positive loadings for 'government rules/regulations' and 'multiple general contractors/EPCs', while having negative loadings for 'extended/uncertain scope', 'large number of suppliers/subcontractors', and 'new technology'. Government rules/regulations and multiple general contractors/EPCs are related to the high-level program/project administration, and the sixth PC contrasts these factors with lower-level scope and technology factors.

5 DISCUSSION

As shown in the previous section, PCA was used in this research for finding the main sources of variations in the dataset, which can be defined as major dimensions of project complexity. As a result of this method, 6 interpretable PCs were defined, and these PCs combined to explain more than 70% of the total variance in the dataset. In other words, the number (17) of original variables was reduced to the smaller number (6) of new variables by PCA, while 30% of the total variance was sacrificed. One should not take from this that the 30% of the total variance excluded in the 6 PCs are not important, but, given that the data were collected by surveys, and that the data are under the influence of random errors as well as the sample size, it seems acceptable to say that the 6 PCs capture the majority of the sources of variations in the dataset.

An interesting finding from this analysis is that the complexity factors that were highly rated for most of the projects, such as 'cost pressure', 'schedule pressure', and 'execution risks', did not have much variations in the dataset, and therefore contributed to the first few PCs relatively less than other factors. This shows that PCA is useful for distinguishing the complexity factors that actually vary between projects from the factors that are shared by most of the construction projects studied. Therefore, the results of PCA might be useful for specifically developing the managerial approaches to address the complexity factors that vary between projects and the managerial approaches to address the complexity factors that are common among projects.

The fact that the first PC is positively related with every original variable tells us that all of the original variables are inter-related to some extent, and the first PC can serve as a kind of composite indicator of the level of overall project complexity. This implies that some projects in the dataset are more complex in general than others, and that the score for the first PC can tell us overall how complex a project is. Therefore, this PC might be useful for determining the level of systematization of project management system required in a project. The project complexity dimensions defined by later PCs indicate more specific aspect (i.e., source) of project complexity and explain a smaller variance in the dataset.

Notably, complexity dimensions defined by the PCs are related to organizational interactions (e.g., unclear scope of work for multiple stakeholders in the definition (1st PC), uncertainty in boundaries and communication (2nd PC), unfamiliarity with other project participants (3rd PC), and the multiplicity of stakeholders (4th PC)). These results hint that organizational interactions (i.e., interfaces between parties involved) are a major source of complexity in many projects. This implication is in line with observations/findings in previous research works. Vidal et al. (2009) reported that 11 project complexity drivers (i.e., factors) identified from their survey belong to the family of "project interdependencies", and this takes up 61.1% of the entire project complexity drivers they identified. From this result, they also argued that their result helps justify the tools and methods that been recently developed to deal with interactions and interdependencies in projects.

Vidal and Marle (2008) stated that classical tools and methods of project management are not sufficient in dealing with the level of complexity in modern projects, and therefore, the current level of project complexity justifies the need for a new project management approach that can assist the existing ones,
such as IM. Similarly, Baccarini (1996) argued that project complexity should be treated by more efforts for integration such as coordination, communication, and control. Therefore, more advanced managerial skills and tools for interface management would be required to effectively manage complex projects, and in particular, it seems that such development of advanced skills and tools for project management should aim at those projects that have complex organizational structure and a large number of interfaces in it. An efficient implementation of managerial functions can influence the impact of project complexity on project performance (Gidado 1996), and therefore is expected to mitigate the adverse impact of complexity on performance in many construction projects. More research is strongly warranted in this area.

6 CONCLUSION

Although many researchers have attempted to define project complexity and have investigated various factors that would affect complexity in construction projects, it is unclear what the dimensions of project complexity are and how they can be measured. This lack of knowledge about project complexity has been one of the main reasons that the construction industry has displayed great difficulty in effectively dealing with complexity in projects. Given this situation, this research aimed to define the dimensions of project complexity based on empirical data. To achieve this research objective, a questionnaire was developed as a tool for collecting data for project complexity factors, surveys were administered in semi-structured interviews, and the collected data for 45 major construction projects were analyzed using PCA. As a result, 6 interpretable PCs were extracted from the dataset: ‘unclear scope of work for multiple stakeholders in the definition and design of projects with new technology’ (1st PC), ‘the uncertainty in boundaries and communication relative to other complexity factors’ (2nd PC), ‘unfamiliarity with other project participants’ (3rd PC), ‘the multiplicity of stakeholders relative to the amount of cost pressure and execution risks’ (4th PC), ‘the relative multitude of engineered items’ (5th PC), and ‘the high-level program/project administration’ (6th PC). These dimensions of project complexity defined by the PCs tell us not only what the possible dimensions of project complexity are, but also which dimension explain the most variations in the dataset. Therefore, these complexity dimensions can help with assessing the level of complexity of a project at its onset and with determining the skills, tools, and systems that will be required to effectively cope with the sources of complexity in the project. Additionally, the analysis results hint that organizational interfaces should be effectively managed to prevent project failure in construction projects, and therefore support the need for IM in complex projects.

This research has several limitations that can be addressed in future research. First, the complexity factors included in this research are limited. More research efforts to investigate a broader set of project complexity factors are strongly warranted to gain a comprehensive view of various complexity factors that may play an important role in construction projects. Secondly, the sample size used in this research is modest. Since PCA is a data-driven method, a larger sample size may be required to gain a greater confidence with the PCs extracted in this research. Thirdly, the impacts of the project complexity dimensions identified in this research on project performances, such as cost and schedule, are yet to be investigated. Therefore, more future research efforts are strongly warranted to relate the levels of project complexity with project performance measures, and to investigate the effectiveness of approaches to address project complexity in this relationship.

INVESTIGATION ON CONSTRUCTION WORKERS’ SOCIAL NORMS AND MANAGERS’ DESIRED NORMS REGARDING ABSENCE: PRELIMINARY RESULTS FROM A NORM ELICITATION STUDY

Abstract: Researchers have found that construction workers’ absence behavior is under the influence of social norms existing in work groups. Although the previous research efforts on social absence norms in construction have significantly expand our understanding of how they might develop in work groups and exert on workers’ absence behavior, we have limited knowledge about what the absence norms actually existing in construction work groups are. Given this background, the objective of this research is to measure the absence norms shared by construction workers in their work groups as well as the norms desired by construction managers. To achieve this, a novel approach to elicit norms in organizations that were developed by Krupka and Weber (2013) has been used in this research. In this approach, experiment participants are asked to evaluate several hypothetical actions plausible in a given situation using their understanding of what a typical member of their team would think about the actions as well as their own opinions on the actions. The elicitation of social norms is facilitated by a coordination game structure and monetary incentives in the experiment. Using this method, construction workers’ social norms and personal standards, managers’ belief about workers’ social norms, and managers’ desired norms, regarding worker absence behavior were elicited at a construction site. Analyses on the differences between workers’ social norms and managers’ desired norms reveal that there is a general pattern of alignment, but also a measurable difference, between workers’ social norms and managers’ desired norms regarding absence at the site.

1 INTRODUCTION

In their influential paper published in 1982, Johns and Nicholson defined absence culture as “the set of shared understandings about absence legitimacy in a given organization and the established ‘custom and practice’ of employee absence behavior and its control......” Since they introduced the concept of absence culture in organizational behavior research, many researchers have investigated the impacts of such social aspects on employees’ absence behavior in organizations, and have demonstrated that absence behavior is indeed subject to social norms in organizations. Among those researchers, some have looked at construction workers’ absence behavior, and have found that construction workers’ absence behavior is also under the influence of social norms existing in their work groups (Ahn and Lee 2015; Ahn et al. 2014; Ahn et al. 2013; Sichani et al. 2011; AbouRizk et al. 2010). Given that construction work groups are known to have a high level of social identity and solidarity in general, social absence norm is an important subject for studying and improving workers’ attendance at jobsites.
Although the previous research efforts on social absence norms in construction have significantly expanded our understanding of how they might develop in work groups and exert on workers’ absence behavior, we have limited knowledge about what the absence norms actually existing in construction work groups are. For example, some previous research has investigated to what extent construction workers’ absence behavior are influenced by their social awareness (c.f., Ahn et al. 2014), but few research attempts have been made to measure what the actual absence norms (i.e., collectively held opinions and beliefs regarding absence) are. Given this background, the objective of this research is to measure the absence norms shared by construction workers in their work groups as well as the norms desired by construction managers. To achieve this, a novel approach called norm elicitation technique has been used in this research.

An overview of this technique is provided in the following section. Subsequently, the results from a preliminary study using this technique are provided, and a discussion on the results will follow.

2 RESEARCH METHOD

2.1 Norm Elicitation Technique

Researchers have tried to measure the social norms in work groups in several ways, and among them the most common is survey questionnaire. Although survey questionnaire is a cost-effective and scalable means to collect real world data, one of the main weaknesses of this method is the difficulty in measuring group-level latent variables such as collectively held norms (Burks and Krupka 2012). To address this issue, Krupka and Weber (2013) developed a novel method for measuring social norms in organizations using hypothetical vignettes and a coordination game structure, called norm elicitation technique. In this method, vignettes describing a situation with which experiment participants will be familiar—because it is a situation that they can observe or experience in the workplace on a daily basis—are provided. A vignette is given along with a range of actions a person might choose from in the situation. Then, participants are asked to rate each alternative action for each vignette using a 4-point Likert scale, each of which means ‘Very inappropriate’, ‘Somewhat inappropriate’, ‘Somewhat appropriate’, and ‘Very appropriate’.

In the experiment, participants are asked to repeat the rating task several times for each vignette. First, participants are asked to try to match their ratings to those of a typical member of a group—either a group they belong to or another group, and they are told that their responses will be compared with the responses of a randomly selected respondent from the group, and that they will be paid if their responses match the responses of the target respondent (i.e., a coordination game structure with monetary incentives). Second, participants are asked to provide their personal opinions (i.e., ratings based on their own personal standards) without trying to match their responses with anybody else’s.

This technique has been used in this research for identifying social norms of construction work groups (i.e., crews) and personal standards regarding absence. As a first step to do this, a list of behaviors regarding absence with which construction workers will be familiar was developed. A focus group discussion with three construction managers was used in this process. Table 1 shows the list of behaviors regarding absence used in this study, sorted in order of appropriateness as identified by the focus group’s ex-ante ranking. (The behaviors were re-sorted in the experiment, and therefore these behaviors were not presented in this order to participants.)

2.2 Participants

For conducting the experiment, a building construction site (“Site A”) in Ann Arbor, Michigan, US, was approached. Site A was a large-sized engineering research complex building construction site located on the University of Michigan campus. At the time the site was contacted, the project was in the final phase of construction, and therefore many on-going processes were for the finishing work. The number of workers operating daily at this site was about 40–50 with some variation.

With an agreement with the construction managers to conduct the experiment at this site, construction workers to participate in the experiment were recruited. The purposes and processes of this experiment were explained to the foremen in a weekly meeting at the site, and the foremen verbally advertised the experiment to their team members. In this way, the construction workers were informed when and where the experiment was going to take place, and the workers voluntarily participated in our experiment. As a result, a total of 26 workers (of 9 different trades and of 10 different companies) participated in the experiment. In addition to this, the 3 construction managers of the general contractor participated in the experiment.

2.3 Experiment Procedure

Participants among workers were asked to provide their evaluation of these behaviors twice. On the first pass, the participants were asked to match their ratings with those of a typical member of their own crew; on the second pass, they were asked to provide their personal opinions. As mentioned above, the elicitation of social norms is facilitated by a coordination game structure and monetary incentives in this experiment. The participants were informed that a subset of all of the participants in this experiment will be randomly selected, and their responses on the first pass will be compared with the responses of another randomly selected participant from their crew, and they will be paid $10 for each of their matching responses. This incentivizing method was clearly explained before the experiment began.

Participants among construction managers (of the general contractor) were also asked to provide their evaluation of the behaviors twice, but in a slightly different manner. On the first pass, the participants were asked to match their ratings with those of a typical construction worker working at the site, and on the second pass, they were asked to match their ratings with their fellow managers at the site. The
construction manager participants were also informed that their responses on the first pass will be compared with the responses of a randomly selected worker participant, and their responses on the second pass will be compared with a randomly selected manager participant.

The experiment was taken during crews’ breaks during work hours (e.g., morning break, lunch time, afternoon break) to avoid interrupting the construction work. Construction workers voluntarily visited the area where the experiment administrators were, and participated in the experiment. When a worker or workers arrive at the experiment place, the experiment administrators briefly introduced the experiment’s purpose and processes, including the information about the incentives. Then, a consent form, the evaluation sheet, and pens were provided to the participants. The experiment administrators gave an instruction, then participants provided their response in each pass. In total, the experiment took approximately 20–25 minutes. Every participant was paid a $10 participation fee at the end of the experiment.

3 RESULTS AND DISCUSSION

The participants’ evaluations of the behaviors were converted into numerical scales: -1, -1/3, 1/3, and 1, for “Very inappropriate,” “Somewhat inappropriate,” “Somewhat appropriate,” and “Very appropriate,” respectively. Tables 2 and 3 present a summary of the evaluations for the absence behaviors provided by the workers and the managers, respectively. Each row in these tables corresponds to an absence behavior that was evaluated by the participants, and these tables separately summarize the participants’ evaluations made during the first pass and the second pass (Workers’ evaluations during the first pass and the second pass are labeled as “Workers’ social norms” and “Workers’ personal standards” in Table 2, and managers’ evaluations during the first pass and the second pass are labeled as “Managers’ desired norms” and “Managers’ belief about workers’ social norms” in Table 3.) The columns of these tables present the mean (M) and the standard deviation (SD) of the responses, and then the number of responses for each option (N(-1), N(-1/3), N(1/3), and N(1)), for each behavior in the list.

</tbody>
</table>

**Note. The numbers in bold type are the mode of responses for each behavior.

The fact that the modal response for any behavior received more than 46% of the responses when the task is matching their responses with the responses of a peer shows that there is a general consensus in the belief about the normative evaluations made by the members of their groups, whether it is workers or managers. Also, the fact that a relatively high level of consensus in the normative evaluations exists among all the workers at this site means that to some extent the crews at this site have similar social norms when it comes to which absence behavior is acceptable and which is not.

Tables 2 and 3 show a general pattern of alignment, but also a measurable difference, between workers’ social norms and managers’ desired norms regarding absence. The mode of responses from workers and from managers were identical for four behaviors, while the mode of responses for the other three behaviors was measurably different. To visualize the degree of alignment between workers’ social norms and managers’ desired norms, the mean of the responses from these two groups for each behavior was plotted, as shown in Figure 1. Then, each line in this figure can be seen as a profile of norms held by workers or managers. As shown in this figure, workers’ social norms and managers’ desired norms regarding worker absence behavior shows a complete agreement as to valence (i.e., whether a behavior is in the “appropriate” side or in the “inappropriate” side); both groups agreed that absence behaviors 1–4 are considered inappropriate, whereas behaviors 5–7 are considered appropriate. However, the two groups show some disagreement in the intensity of the evaluations. For absence behavior 3, “James takes absence when he has a hangover, and he informs his foreman of the absence early in the morning,” for example, all of the managers said that this behavior is “very inappropriate,” whereas workers were more likely to say that it is just “somewhat inappropriate.” This shows that there is a subtle but measurable misalignment between workers’ social norms and managers’ desired norms about absence caused by alcohol.
Another interesting, measurable misalignment between workers’ social norms and managers’ desired norms was observed for absence behavior 6, “James takes absence when he feels too sick to work well, and he informs his foreman of the absence early in the morning.” All of the managers said that this behavior is “very appropriate”, while a majority of workers said that it is just “somewhat appropriate”—4 workers even said that it is “somewhat inappropriate.” This result shows that many workers believe that being sick may not be an excuse for an absence that his/her peers would approve of, although managers think that absence due to sickness is perfectly OK.

Although measurable misalignment between workers’ social norms and managers’ desired norms was observed for specific behaviors, managers were found to have a fair understanding of workers’ social norms. Figure 2 compares workers’ social norms with managers’ belief about workers’ social norms. As shown in this figure, the average distance between the two lines is much smaller than that of Figure 1. This supports the idea that the social norms regarding absence actually exist in the workers’ group, and they are even visible to out-group members such as managers—although it may not be as clear as to the in-group members.
4 CONCLUSIONS

To address the lack of our understanding of what the absence norms are in construction work groups, this research aimed at measuring and quantifying actual absence norms shared by construction workers as well as norms desired by managers. To accomplish this goal, a norm elicitation technique developed by Krupka and Weber (2013) was used to collect and analyze empirical data for social norms and personal standards regarding absence.

Using the norm elicitation technique, construction workers’ social norms and personal standards, managers’ belief about workers’ social norms, and managers’ desired norms, regarding worker absence behavior at a construction site were elicited, and they were visualized as a profile represented by a line connecting 7 points in the plots (e.g., the lines in Figures 1 and 2). Analyses on the differences between workers’ social norms and managers’ desired norms revealed that there is a general pattern of alignment, but also a measurable difference, between workers’ social norms and managers’ desired norms regarding absence.

Although this paper demonstrates that the norm elicitation technique is effective for measuring social norms regarding absence in construction projects, more research efforts are warranted to produce more generalizable knowledge in the subject. The greatest weakness of this paper is the small sample size included in the analysis. Therefore, obtaining more data is strongly required in order to generalize the findings from the results presented in this paper. Another, and related, weakness of this paper is that the data used in the analysis were from a single site. Therefore, obtaining more data from multiple projects from different regions or of different types, or of different phases is strongly required to improve the representativeness of the sample. This is crucial because different construction projects may have different characteristics in terms of project environment and context, which can affect absence norms in the projects. As the title of this paper suggests, this paper presents only a pilot study, and therefore, these weaknesses of this paper will be addressed in our future research.

Abstract: To implement BIM in a construction project successfully, all the project participants as BIM users must have minimum BIM capabilities. Before any project starts, assessing BIM capabilities of project stakeholders is a concern for construction clients. The main problem of public clients regarding BIM is that they have no mechanism to ensure that the key participants, they hire for a BIM project, have the minimum capabilities (i.e. BIM Infrastructure, processes and qualified resources) to participate in design and delivery of the project. The high variability of firms’ readiness to work with BIM may impose a high cost for the client and other mature members of the supply chain. Therefore, construction clients need a way to ensure minimum BIM maturity of participants, such as a maturity audit to assess BIM competency of potential project team members. From a client’s perspective, “minimum BIM qualification” means “minimum capability to use BIM”. The current BIM maturity models try to assess BIM capabilities level of firms, but lack BIM uses assessment. This research proposes a prototype that focuses on capability of firms in specific BIM uses, while measuring their general BIM capabilities. The research methodology is based on an iterative literature review followed by focus group discussions. Through literature review, the researchers propose BIM platform maturity model. Then, BIM experts discuss on possible improvements. It is expected that by using this model, construction clients may achieve more BIM benefits, i.e. reduced cost, time, and increased quality of project, through selection of BIM-qualified project team members.

1 INTRODUCTION

The construction industry has been facing many problems and barriers, such as cost overruns, time delays, prolonged contractual claims (Liberda et. al., 2003), disputes (Musonda, 2011), and labor productivity decline (Teicholz, 2004), leading to low performance and productivity. In addition, the project-oriented nature of the construction industry and the uniqueness of every project (Wegelius-Lehtonen, 2001), multi-disciplinary, cross-organizational, and changing make-up of Architectural, Engineering, and Construction (AEC) project teams (Liston, 2009) with fragmented supply chain (Cox and Ireland, 2002) increases the complexity of working on large construction initiatives. To improve productivity of the construction industry, different solutions, such as digital construction, are observed. Digital construction aims to address the growing fragmentation problems and improve productivity by using technologies such as Building Information Modeling (BIM) for integrating processes throughout the entire lifecycle of a construction project. BIM proposes a consistent digital information platform to be used by the
stakeholders throughout the lifecycle of the project. To date, many construction projects have reported benefits from the use of BIM technology and recommended it as a remedy for productivity issues (Mihindu and Arayici, 2008). According to McGraw-Hill (2009) the most notable reported BIM benefits of a project, include: reduced conflicts during construction, improved collective understanding of design intent, improved overall project quality, reduced changes during construction, reduced number of RFIs (Requests for Information), and better cost control/predictability.

To implement BIM successfully, in a project, and fully get the benefits, all the project members, as users of BIM should demonstrate minimum BIM capabilities. However public clients have no mechanism to measure the minimum BIM capabilities (i.e. BIM Infrastructure, processes and qualified resources) of the key suppliers to participate in the design and delivery of the project using BIM technology. High variability of BIM maturity level of project members may result in high cost for the client and the most mature members of the supply chain. Therefore, having members who obtain and provide an independent BIM maturity certificate beforehand would help in solving this issue.

This paper reviews the current BIM maturity models, which are developed for the purpose of BIM qualification assessment in project team selection. Since there is a lack in development of maturity levels of BIM Uses in the current BIM maturity models, it proposes a practical BIM maturity model in order to evaluate both general BIM capability and specific ‘BIM Uses’ capability of firms, which are two main concerns of construction clients. Finally a hypothetical sample part of this model, namely 3D Coordination, is developed at maturity level 1, to demonstrate the potential evaluation process used with the proposed maturity model.

2 BIM CAPABILITY MATURITY ASSESSMENT FOR PROJECT TEAM SELECTION

A “maturity model” can be defined as “... a conceptual framework, with constituent parts, that defines maturity in the area of interest. [...] In some cases, [...] a maturity model may also describe a process whereby an organization can develop or achieve something desirable, such as a set of Capabilities or practices” (OPM3, 2003). The term 'BIM Maturity' refers to the quality, repeatability and degrees of excellence of BIM services (Succar, 2010b). Current BIM maturity models in construction were developed for different purposes. Reviewing three of these models, which were developed for the purpose of BIM qualification assessment in project team selection stage (i.e. BIM Indiana University, 2012; CIC, 2012; Sebastian and Van Berlo, 2010), can help researchers in a) understanding what the construction client expects from a BIM maturity assessment tool during the project team selection and qualification, b) what BIM topics should be assessed for such a process, and c) how a BIM maturity assessment should be done in practice. The authors believe that an industry guardian (evaluator) can alleviate burdens from the client by independently conducting such a process beforehand.

Sebastian and Van Berlo (2010) developed the BIM Quick Scan tool to benchmark current BIM performance level of AEC organizations for the Dutch construction industry. The purpose was to justify qualification of project parties to be involved in projects and to “… raise awareness and establish a common strategy for innovation through BIM” (Sebastian & Van Berlo, 2010). In this approach, a certified BIM consultant carries out the assessment upon request of an organization and produces an assessment report. This approach combines quantitative and qualitative assessments of the ‘hard’ and ‘soft’ aspects of BIM at a) corporate level, b) ICT infrastructure level, and c) model/modeling level. Four main chapters of an organization, including organization and management, mentality and culture, information structure and information flow, and tools and applications, are assessed by the BIM Quick Scan tool. Each one of these chapters contains a number of Key Performance Indicators (KPIs) “… in the form of a multiple-choice questionnaire. (KPIs). […] With each KPI, there are a number of possible answers. For each answer, a score is assigned. Each KPI also carries a certain weighting factor. The sum of all the partial scores after considering the weighting factors represents the total score of BIM performance of an organization” (Sebastian & Van Berlo, 2010, pp. 258 and 259). KPIs are assessed using a percentile scale and the chapters are assessed in a five-level scale of 0 to 4 (Sebastian & Van Berlo, 2010). The tool asks about presence of ‘BIM Uses’ in the firm, but there is a problem associated with categorization of BIM Uses. While some of these BIM Uses are specific, such as planning (4D) and quantities/costing, the others are very general, such as simulations, design, architectural, construction, etc. In addition,
although it asks for presence of a BIM Use, the maturity level of a specific BIM Use is not evaluated by the tool. For example, if a firm has BIM 4D planning, this assessment tool cannot assess how well the firm is using BIM for planning (4D) in a scale.

According to CIC (2012), it is suggested that the BIM maturity level of applicants must be evaluated during the team selection stage, namely during Request For Qualification (RFQ) and Request For Proposal (RFP). At the project team selection stage, to enable the owner to assess the BIM maturity level of applicants, a BIM capability and maturity model is needed. The owner asks about BIM experience and expertise of applicants in RFQ. Applicants must provide proof of qualifications they claim to have. In RFP, the applicants must propose the BIM services that they can provide for the project. After reviewing the BIM qualifications and BIM proposed services of all applicants, they will be scored in a BIM maturity matrix. Considering the results of BIM maturity assessment, the owner selects the applicants who best match with the required criteria. The categories in "BIM Qualifications Scoring Matrix" and "Proposal Scoring Matrix" are shown and presented in Table 1, according to CIC (2012).

Although this model (CIC, 2012) considers the proposed BIM Uses of applicants, it fails to measure the maturity level of a firm in performing specific BIM Uses, such as 3D Coordination, 4D Modeling, etc. The BIM assessment categories of ‘BIM tools’, ‘Technical Capabilities’, and ‘Deliverables’, are general in BIM maturity assessment. The authors of this paper believe that clients should not have to expend effort on a case-by-case basis to do this assessment every time. Having an independent certification body where BIM maturity certification is obtained, managed by independent certified assessors (i.e. like ISO) would be simpler for the clients and would better control quality of assessment for the whole industry.

Another BIM maturity model, in form of a matrix, was developed by the Indiana University (IU) to evaluate BIM expertise and experience of construction project participants (consultants) (BIM Indiana University, 2012). “IU BIM Proficiency Matrix” must be submitted to Indiana university by the design team before the contract award for its construction projects of $5M or greater and for the construction projects which have already used BIM. For other projects, it is encouraged but not required to submit. The consultant scores the matrix based on the examples of previous projects with use of BIM. The IU can understand the BIM level of expertise and experience of design team by evaluating the maturity matrix. Interested contractors can submit an “IU BIM Proficiency Matrix” to the university at the bid submittal stage (BIM Indiana University, 2012). This matrix contains eight categories, comprising of four sub-categories. A total of thirty-two subcategories are scored with a score ranging from 0 to 1. A maximum total score of thirty-two can be achieved based on this mechanism. The achieved total score locates the BIM maturity level of firm on a defined range: total score of 0 to 12 is assigned for “Working Towards BIM” category, 13 to 18 for “Certified BIM”, 19 to 24 for “Silver”, 25 to 28 for “Gold” and 29 to 32 is assigned for “ideal”. The problem with this scoring system is that for each subcategory a value from 0 to 1 is earned based on subjective judgement from maturity level. This approach is not very accurate. For example, although a score of 0.45 represents a higher maturity level than a score of 0.4, it is not defined clearly how to justify this scoring
and its performance measurement. This model considers some BIM Uses, such as ‘Design side collision detection’, ‘Coordination modeling’, in maturity assessment. However, lack of development of capabilities within different maturity levels, is a deficiency. According to Succar (2010a), “the matrix focuses on the accuracy and richness of the digital model (as an end-product) and has less focus on the process of creating that digital model”. In addition, the matrix has very little consideration for BIM resources. For example, the sub-category of “Model managers role defined” asks about the presence of a model manager for each discipline. However, the level of BIM expertise, experience, and knowledge of model managers are not considered in the scoring. The matrix also has other weaknesses, for example in BIM technological resources assessment. Although delivering a rich and accurate digital model is the focus point of this model, the required technological infrastructure was not considered in maturity assessment.

It is important for construction clients to measure how well a potential project member can use a specific BIM application. All the reviewed models have a common problem, which is lack of development of capabilities in maturity levels of BIM Uses. There is a need to address this issue.

3 PROPOSED BIM MATURITY MODEL FOR INDEPENDENT CERTIFICATION

As mentioned in section 1, construction clients need a way to ensure that the participating firms of project meet minimum BIM requirements in order to qualify for a project. From the perspective of a client, “minimum BIM qualification” can be translated to “minimum capability to use BIM” and this is practically what is wanted by a certification: ‘how well does this participant uses BIM technology in a construction project’. This is accepted as as a principal assumption of this study. Clients want to know whether a firm is capable of using BIM, and if yes, to what level. This perspective offers an opportunity to adapt existing BIM maturity models to reach that goal. There is a lack, in the current BIM maturity models, to look at BIM through this lens. The existing BIM maturity models provide a rich base of information to achieve this goal. However, no model has focused on development of maturity levels of ‘BIM Uses’. “A BIM Use is a unique task or procedure on a project which can benefit from the integration of BIM into that process” (CIC, 2011). This paper proposes a new approach in assessing BIM capability maturity of firms in performing specific BIM uses, while measuring their general BIM capabilities at the same time. This approach represents the clients’ expectation of a maturity model. They want to know how well a project stakeholder uses BIM to delivers a BIM product or service. Therefore, the authors propose a BIM platform maturity model that provides information about maturity of BIM Uses that will meet clients’ expectation.

Client perspective in maturity assessment

The software industry has considerable experience in adopting capability maturity model from quality management field to software industry processes (i.e. Capability Maturity Model Integration (CMMI)). Although processes in the software industry are quite different from processes in the construction industry, but the notion of process maturity is the same. To develop our proposed model in this study, we have studied a maturity model from the software industry, namely Software Maintenance Maturity Model-S3m (April, 2005), which is based on the client perspective and is designed from using both industry references, and national and international standard practices. This model helps software “maintainers identify their process maturity level and guide them to higher maturity processes…. The maintenance maturity model was developed to address the uniqueness of software maintenance” (April, 2005, p. 143). S3m uses the architecture of the CMMI (SEI, 2010a) and draws practices from two international software standards: ISO12207 and ISO 14764. The reason that S3m is studied is that the relation of our proposed maturity model to the other BIM maturity models (i.e. IU and CIC) is a similar relation of S3m to CMMI. S3m maps practices from CMMI and ISO standards in the same way our proposed model maps to several BIM maturity models (i.e. Succar, 2010a,b; Succar et al., 2012; Sebastian and Van Berlo, 2010; CIC, 2012; BIM Indiana University, 2012; NIBS, 2007, 2012) to cover unique expectation of client (BIM uses).

3.1 Proposed architecture of the BIM Platform Maturity Model (BIMPMM)

April (2005) organized software maintenance activities in a hierarchical architecture from the most general definitions to most specific practices. The first level of this hierarchy (less specific) to fourth level (most specific) includes respectively “process domain”, “Key Process Areas (KPAs)”, “Roadmaps”, and
“Practices”. Our proposed BIM platform maturity model is inspired from S3™ architecture while using the processes and activities that are BIM specific, as shown in Table 2.

Table 2: Proposed architecture of the BIM Platform Maturity Model (BIMPMMD)

3.1.1 BIM domains

Various domains are defined for BIM in the literature. This first study just focuses on the domains of “BIM Process” domain and “BIM Resources” domains as they pertain to the construction industry to address the construction clients concern regarding assessment of minimum BIM capabilities of applicants in their project. The “BIM Process” domain considers BIM capabilities regarding specific “BIM Uses” and the maturity level of BIM project management. This domain is very important as a client wants to know how well a firm is using and managing BIM technology in this area. The “BIM resources” domain evaluates the required resources to perform the BIM Processes in general. The available resources of applicants are an important factor for project team selection from the perspective of the construction clients.

3.1.2 Key Process Areas (KPAs)

In this study, KPAs of the “BIM Process” domain include BIM uses and project management. BIM uses are about specific applications of BIM in construction projects. Top three most frequent uses of BIM, which include “3D Coordination”, “Design Reviews”, and “Design Authoring” according to Kreider et al. (2010) study, are selected to introduce example of BIM Use specific KPAs in the proposed BIM platform maturity model. The proposed ‘project management’ KPA refers to the quality of management in using BIM. We know that BIM project management can include various activities, such as designing BIM execution plan in project, defining and procuring required BIM resources, defining BIM collaboration processes, etc. The proposed “BIM Resources” domain includes KPAs related to BIM “infrastructure” and “human resources”. In the other words, the allocated infrastructure and human resources to BIM at the organization/project levels will be assessed in this domain and within these KPAs. The proposed maturity model, considers BIM infrastructure as the technological aspects of BIM (i.e. software, hardware, network, ...). We also know that human resources relates to the personnel roles and responsibilities, and the level of knowledge, skill, and experience that they posses, in using BIM technologies. The training and educational programs of an organization to improve BIM competency of personnel will be evaluated in this category. In the proposed maturity model, KPAs are also categorized according to their general and specific BIM capabilities. Since a ‘BIM Use’ is about specific application of BIM in a doing a task in a project, KPAs of ‘BIM Uses’ are considered as specific BIM capabilities. But KPAs of “Project management”, “Infrastructure” and “Human resources” don’t reflect any specific BIM application and are defined, in the proposed maturity model, to be part of a ‘General BIM capability’ category.

3.1.3 Roadmaps and practices

A Roadmap is defined “… as a set of linked practices that can often cover many levels of maturity” (April 2005). Each KPA contains a number of roadmaps. Practices are defined within the roadmaps. “In a given
roadmap, the sequencing of the practices is organized based on the sequencing of the pre-requisites required to move from an initial beginner's implementation of a process up to its mastery. Practices required to initiate the implementation process are positioned at the initial level (e.g. level 1), while more sophisticated practices are ordered progressively up to level 5." (April, 2005). In the proposed BIM platform maturity model, the practices are mapped from current BIM maturity models (Succar, 2010a,b; Succar et al., 2012; Sebastian and Van Berlo, 2010; Computer Integrated Construction Research Program, 2012; BIM Indiana University, 2012; NIBS, 2007, 2012) and other relevant resources. Finally, the practices that represent capabilities with the same topic, construct a roadmap. BIM experts meet to discuss the position and the rationale of each practice in the maturity levels, and possible improvements. Based on the obtained feedback, an iterative development of the proposed maturity model (iterative model development/improvement and experts’ feedback) is carried out by the researchers.

3.2 Proposed maturity scale

As many maturity models use five-level scale of maturity (see Succar et al., 2012, p. 134), our model also proposes a five-level scale. We adopted the maturity scale of BIM Planning guide for facility owners (CIC, 2012), which used BIM maturity level definitions inspired from the Capability Maturity Model Integration (CMMI) for Services (Forrester et al., 2011) (Figure 1). Each KPA can be assessed by a maturity scale of five level (levels 0-5). Reaching a maturity level requires the achievement of all practices of that level.

<table>
<thead>
<tr>
<th>Maturity Level</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>(0) Non-Existing</td>
<td>At this maturity level, a process has not yet been incorporated into current business processes and does not yet have established goals and objectives.</td>
</tr>
<tr>
<td>(1) Initial</td>
<td>At this maturity level, a process produces results in which the specific goals are satisfied, however, they are usually ad hoc and chaotic. There is no stable environment to support processes with the ability to repeat such and possible abandonment in time of crisis.</td>
</tr>
<tr>
<td>(2) Managed</td>
<td>At this maturity level, a process is planned and executed in accordance with policy; employs skilled people having adequate resources to produce controlled outputs; involves relevant stakeholders; is monitored, controlled, and reviewed; and is evaluated for adherence to its process description.</td>
</tr>
<tr>
<td>(3) Defined</td>
<td>At this Maturity level, a process is tailored to the organization’s standard processes according to the organization’s guidelines; has a maintained process description; and contributes process related experiences to the organizational process assets.</td>
</tr>
<tr>
<td>(4) Quantitatively Managed</td>
<td>At this maturity level, a process is managed using statistical and other quantitative techniques to build an understanding of the performance or predicted performance of processes in comparison to the project’s or work group’s quality and process performance objectives, and identifying corrective action that may need to be taken.</td>
</tr>
<tr>
<td>(5) Optimizing</td>
<td>At this maturity level, a process is continually improved through incremental and innovative processes and technological improvements based on a quantitative understanding of its business objectives and performance needs and tied to the overall organizational performance.</td>
</tr>
</tbody>
</table>

Figure 1: BIM Maturity levels (CIC, 2012)

However, a BIM maturity assessment measurement is inspired from ISO15504 recommendation in four categories: N,P,L and F. The S3" (April, 2005) and many other maturity models conform to this ISO recommendation that defines partial maturity of a practice, when it is not fully achieved or not achieved (ISO/IEC15504):

N: Not reached – 0 to 15%

P: Partially reached – 15%-50%

L: Mostly reached – 51%-85%

F: Fully reached – 85%-100%
3.3 Evaluation process of proposed BIM platform model

To make it easy to assess the BIM maturity level of a participant, an assessment tool can calculate the threshold rating, and a BIM entry level to be eligible to participate in a construction project. The applicants must be eligible in BIM and show their maturity certificate to apply in a construction project bidding. A certified BIM maturity assessor (i.e. an assessment body) would issue the certificate using a class 1 assessment process (this will be presented in another paper). The BIM maturity assessment could take place at any time independently from projects. Based on the type of firm, i.e. architect, engineer, contractor, the KPAs and questions of a questionnaire are filtered and adapted by the assessor to be included in assessment of that firm. For example, within a project an engineer may not be evaluated in KPA of ‘Design reviews’, because the client doesn’t expect the engineer to perform ‘Design reviews’ in that project. The independent assessor would plan the assessment and then distribute a questionnaire to the interested firms. The results of their questionnaire will be evaluated based on their specialty. The questions ask the firms if they have the practice in their organization. As shown in section 3.2, based on utilization level in the firm, a respondent can choose an answer from four options of “Not reached”, “Partially reached”, “Mostly reached”, and “Fully reached”. For a Class 1 assessment, a minimum of four process instances shall be identified for each process within the scope of the assessment. To achieve a maturity level, all practices of that level must be “fully reached” where process attributes are assessed and validated. Finally, the third party reports the BIM maturity assessment results and can issue a certificate.

To describe the evaluation process of the proposed model, the first part of this model is presented in the next section. This portion of the proposed model only presents the “3D Coordination” KPA, its roadmaps and practices, and questions that are asked at maturity level of one. The description of the two other mentioned BIM uses, namely ‘Design Authoring’ and ‘Design Review’ are quoted from CIC (2011) in Table 3.

Table 3: ‘Design Authoring’ and ‘Design Review’ BIM Uses description (CIC, 2011)

<table>
<thead>
<tr>
<th>BIM Use</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Design Authoring</td>
<td>A process in which 3D software is used to develop a Building Information Model based on criteria that are important to the translation of the building's design. Two groups of applications are at the core of BIM-based design process: designs authoring tools, and audit and analysis tools. Authoring tools create models while audit and analysis tools study or add to the richness of information in a model. Most of audit and analysis tools can be used for Design Review and Engineering Analysis BIM Uses. Design authoring tools are a first step towards BIM and the key is connecting the 3D model with a powerful database of properties, quantities, means and methods, costs and schedules</td>
</tr>
<tr>
<td>Design Reviews</td>
<td>A process in which stakeholders view a 3D model and provide their feedbacks to validate multiple design aspects. These aspects include evaluating meeting the program, previewing space aesthetics and layout in a virtual environment, and setting criteria such as layout, sightlines, lighting, security, ergonomics, acoustics, textures and colors, etc. This BIM use can be done by using computer software only or with special virtual mock-up facilities, such as CAVE (Computer Assisted Virtual Environment) and immersive lab. Virtual mock-ups can be performed at various levels of detail depending on project needs. An example of this is to create a highly detailed model of a small portion of the building, such as a facade to quickly analyze design alternatives and solve design and constructability issues</td>
</tr>
</tbody>
</table>

4 3D COORDINATION KPA

CIC (2011) describes BIM Use of ‘3D Coordination’ as “a process in which Clash Detection software is used during the coordination process to determine field conflicts by comparing 3D models of building systems. The goal of clash detection is to eliminate the major system conflicts prior to installation”. The
The design team must check collision against architectural, engineering and MEP models of the project. The collision reports must be prepared, and then the project team or responsible members review the collision report and address the issues in the models (BIM Indiana University, 2012, category A.3). This process includes several activities, which must be mapped with their relationships in a detailed process map. The capabilities in a ‘3D Coordination’ process are defined under four roadmaps of ‘Process map’, ‘Information requirements’, ‘creating, transferring, and compiling information’, and ‘collision detection and solving’. These capabilities are explained as follows.

4.1 3D Coordination process map Roadmap

The responsible organization for performing ‘3D Coordination’ must be capable to develop a detailed process map of this BIM Use. The detailed map must contain all necessary activities and connect them properly. The responsible party of each activity must be determined. According to CIC (2011), Eastman et al. (2011), BIM Indiana University (2012), the main activities of 3D Coordination can be concluded as defining information requirements, performing collision detection and solving collision problems. The required capabilities and questions are as follows:

4.1.1 Process map capability in Maturity Level 1

**Practice 1.** The firm is capable to develop a process map in order to identify 3D Coordination activities and their relation, responsible parties, and information requirements (CIC, 2011, p. 20&21).

Explanation: To initiate 3D Coordination in a project, the responsible firm needs to define the process map. The firm must identify the required activities, the relation and dependency of activities, responsible parties for the activities, and the required information and information exchanges for 3D Coordination in the project (CIC, 2011). Without a process map, the firm cannot carry out the process.

**Question 1.** Does your firm develop a process map in order to identify 3D Coordination activities and their relation, responsible parties, and information requirements? (Choose answer from: No, Partially, Mostly, Yes)

4.2 Defining 3D Coordination information requirements Roadmap

Clash check is between specified building systems, i.e. mechanical and structural systems, because model components belong to a specific type of system (Eastman et al., 2011). Clash detection also can be done within one discipline. Therefore, 3D Coordination information requirements define intended building systems for conflict detection, including structural, mechanical, engineering, plumbing systems, and civil systems such as storm water systems, buried electrical systems (e.g. duct banks), rails, sewer systems, etc. After defining the required building systems’ model, the level of detail of models must be defined for each model. The contractor must make sure the suitable Level of Detail (LOD) (Eastman et al., 2011). To define LOD at the beginning of the project, the clash detection information requirements must be considered for future 3D coordination during the project.

4.2.1 Information requirements capability in Maturity Level 1

**Practice 2.** The firm carries out clash check for Architectural, Structural, and Mechanical, Engineering and Plumbing (MEP) building models (Eastman et al, 2011, p. 273; BIM Indiana University, 2012, category B.2).

Explanation: At this maturity level, the firm initiates to do clash check of Architectural, Structural, and Mechanical, Engineering and Plumbing (MEP) building models, against each other and within the disciplines, irregularly. At this level it is expected that the firm be capable of clash check for various building models and even irregular clash check satisfies meeting maturity level 1.

**Question 2.** Does your firm carry out clash check for Architectural, Structural, and Mechanical, Engineering and Plumbing (MEP) building models? (Choose answer from: No, Partially, Mostly, Yes)
4.3 Performing collision detection and solving collision problems Roadmap

The location and schedule for 3D Coordination meetings must be defined. In the meetings, the conflict problems must be addressed. Therefore, a protocol to address collisions is required before beginning coordination process (CIC, 2011). Clashes can be categorized into two groups. A group of them, which are small errors, can be defined as minor clashes. Minor clashes can be ignored in design phase and can be addressed during construction, on the site (Amiri, 2012). However, major clashes must be defined and be addressed during the 3D Coordination meetings.

4.3.1 Clash detection and solving capability in Maturity level 1

Practice 3. The firm defines the schedule and location of clash detection meetings in order to review and discuss on the clash problem and address it (BIM Indiana University, 2012, A.3; Succar, 2010a, p. 90).

Explanation: The organization assigns a responsible person to arrange a meeting to address the problem. In each meeting, the assigned responsible person prepare a collision report and the other involved project members review and discuss on the clash problem and how to address it. There is no protocol to address the clash problems in this level.

Question 3. Does your firm define the schedule and location of clash detection meetings in order to review and discuss on the clash problem and address it?

5 CONCLUSION

Construction clients need a qualifying mechanism to ensure that the participating firms of a project meet minimum BIM requirements. From the perspective of a client, “minimum BIM qualification” can be translated to “minimum capability to use BIM”. This perspective offers a new opportunity for a novel BIM maturity model and its independent certification process. The authors observed that there is a lack, in the current BIM maturity models, to look at BIM through this lens. This research, which is still in progress, focuses on the “BIM Process” and “BIM Resources” domains of the construction industry to address the construction clients concern regarding assessment of minimum BIM capabilities of potential project participants. This research proposed a new BIM platform maturity model presenting a hierarchical architecture, from most general definitions to most specific practices, namely ‘BIM domains’, KPAs, Roadmaps, and practices. The main contribution of the proposed maturity model is to focus the BIM maturity assessment of key ‘BIM Uses’. BIM Uses are considered as KPA in the proposed model, additional to general KPAs, namely ‘BIM project management’, ‘Infrastructure’, and ‘Human resources’. This BIM platform maturity assessment proposal, which is currently a prototype at concept of operation, proposes to set a threshold, a BIM entry level, to be eligible to participate in a construction project involving BIM. The interested firms to be eligible to participate in a construction project bidding, where BIM is required by the client, would need to be certified at certain BIM maturity level beforehand. A recognized third party assessment body would issue the BIM maturity certificate. By employing more BIM-qualified or BIM-certified firms in the construction industry, the industry will advance more rapidly and should gain more competitive advantages. BIM benefits, which bring most value to a project, include ‘Reduced conflicts during construction’, ‘Improved collective understanding of design intent’, ‘Improved overall project quality’, ‘Reduced changes during construction’, ‘Reduced number of RFIs (Requests for Information), ‘Better cost control/predictability’ (McGraw-Hill, 2009).

Abstract: Constructability means finding ways to construct effectively. It minimises disputes, cost overrun, and schedule delays. However, constructability program adoption in construction projects differs from one corporation to another, and the level of implementation (measured in two levels: corporate and project level) extends from highly sophisticated to none at all. Despite its benefits, many construction companies are reluctant to fully implement it due to many barriers (e.g. complacency with status quo and lack of expertise for design firms). In order to improve the effectiveness of constructability programs in construction projects, identification and mitigation of constructability program barriers using gap analysis techniques should be done. This paper illustrates research done with a partner company to measure degree of implementation of constructability in the company. We used CII constructability evaluation matrix to evaluate the degree of implementation of constructability program in both corporate and project levels. ASCE survey and two case studies of existing projects were also used to provide a clear picture of current practices of constructability in the company. The analysis showed that the company constructability program ranged from informal to formal and the percentages of implementation of the program in planning and execution phases were 63% and 67%, respectively. We introduced recommendations for the six missing concepts in the partner company practice.

1 INTRODUCTION

Construction projects are unique in terms of their goals and values, and different projects with different natures normally encumber systematically applying the same construction, communication, procurement or contracting methods. Defining projects major elements such as overall project plan, planning and design, construction schedule, cost estimate, and major construction method is a normal procedure applied by any construction company. The integration and optimization of project major elements enhance project objectives for achieving owner’s expectations in terms of schedule, cost and quality of the final product, and normally it is done by including expert knowledge in the project. Implementing constructability concepts is one way to achieve maximum inclusion of construction expert knowledge in any construction project.

Construction Industry Institute (1986) defined constructability as "the optimum use of construction knowledge and experience in planning, design, procurement, and field operation to achieve overall project objective," and in 1991, presented by the Construction Management Committee, ASCE divided constructability into two terminologies: constructability and constructability program. The ASCE defined
constructability as “the capability of being constructed” and defined constructability program as “the application of a disciplined, systematic optimization of construction related aspects of a project during the planning, design, procurement, construction, test, and start up phases by knowledgeable, experienced construction personnel who are part of a project team. The program’s purpose is to enhance the project’s overall objectives.”

Constructability programs are not fully implemented in projects due to many reasons (e.g. lack of communication between project participants starting from the conceptual design stage). Type of project, contract type, availability of experienced construction personnel and many other barriers affect the implementation of constructability programs in construction projects. For example, in public services projects, design bid built type of contracts are used. This type of project limits the involvement of contractors in the conceptual design phase of any project and normally it is mitigated by adding design services as part of the contract. Lack of understanding of the benefits of applying constructability programs is another example of barriers. Understanding benefits of applying constructability concepts on construction projects can motivate project parties on applying formal, explicit constructability knowledge bases. For example, it was found that the owner saving on project cost and schedule when applying constructability was 4.3% and 7.5%, respectively (Russell, et al., 1992b). Delivering these research outputs to project participants or stakeholders can enhance the adoption of constructability programs in construction projects.

The level of implementation of constructability programs varies from highly sophisticated program to none at all. These levels of implementation of constructability programs are controlled by barriers which limit the effectiveness of constructability concepts in the construction industry. The existence of constructability barriers extends from corporate to project levels and its mitigating process involves a three-phase cycle: identification, mitigation and review (O’Connor & Miller, 1995). Conducting surveys administered to projects parties is one way to show the gap between the formal constructability program and what is actually implemented in reality. For example, ASCE, represented by Construction Institute’s Constructability Committee, conducted a survey to address the current state of constructability best practices in the architecture, engineering and construction industry (Pocock, et al., 2006).

This paper will illustrate the gap analysis of constructability program implementation in a construction company located in Alberta. We used two approaches to study the gap: reviewing historical projects and surveys. These two approaches complement each other as the first method focuses on project level, the later focuses on corporate level. The paper also proposes a recommendation for the partner company to further enhance their constructability program implementation.

2 LITERATURE REVIEW

Based on the definition of constructability program by ASCE, the optimum use of construction program concepts in any project can be achieved by the involvement of construction personnel in the project team starting from the conceptual design stage. This point depends on the understanding of constructability program capabilities by all project parties, which can result in a corporate commitment for applying such a program. The level of implementation of constructability is controlled by many barriers such as complacency with the status quo and lack of expertise for design firms, and overcoming such barriers is important to create a solid constructability program structure. The following section discusses capabilities, implementation and barriers of constructability program.

2.1 Capabilities

Implementing constructability leads to more owner satisfaction and contractor profit. Jergeas and Put (2001) introduced an example of implementing constructability profit: Trans Canada saved 40% in building a compressor station compared to historical similar projects when they applied constructability concepts. Another example on constructability program capability was presented by Russell, et al. (1992b). He found that the owner saving in project cost and schedule when applying constructability was 4.3% and 7.5%, respectively.
2.2 Implementations

The implementation of constructability programs varies from one corporation to another. The level of implementation or existence of constructability program extends from extremely sophisticated, excellent programs to none at all (Construction Management Committee of ASCE Construc, 1991). CII also concluded that constructability program implementation in the construction industry lacks structure and is progressing slowly (1993). This section provides description of the implementation of constructability programs in the construction industry.

2.2.1 Constructability methods

According to Raviv, et al. (2012), constructability methods can be grouped under seven family categories according to different approaches or methods of implementation:

- Formal corporate policy statement
- Checklists covering corporate procedures, lessons learned, and technical issues
- Organization measures
- Contractual measures
- System modeling and analysis methods
- Reviews
- Advanced technology methods like building information technology (BIM)

Raviv, et al. (2012) found that a construction engineer with full authority and responsibility for constructability is the best, most effective way to achieve constructability, while contract incentive clauses, brainstorming, owner’s involvement, and formal company constructability procedures are the least effective methods. Criticizing this point, the author disagrees with Raviv. The effectiveness of mentioned factors is almost of the same weight. Indeed, the integration of all these factors can produce a solid constructability program structure.

2.2.2 Constructability knowledge transfer

Typically, contractors have more expertise in constructability than engineers; therefore, transferring contractors’ expertise to engineers during the design process will increase efficiency. However, the right information must be available for engineers at the right time. Unfortunately, transferring expertise is done on an ad hoc basis. O’Connor and Miller (1994) introduced the Conceptual Product/Process Matrix Model (CPPMM) which can be used to organize constructability knowledge based on appropriate timing and level of details (Pulaski & Horman, 2005). CPPMM is a kind of matrix, where the vertical axis represents level of details and the horizontal axis represents project phase. According to the current project phase, the relevant information will be introduced. For example, during steel structure design, the model might suggest using shop welding instead of bolting in site. Pulaski and Horman (2005) introduced a case study on using CPPMM in a Pentagon renovation project.

2.2.3 Constructability in design firms

Constructability starts from the design stage; engineers must bear in mind how the contractors will execute the job, otherwise schedule delays and claims are inevitable. A new contracting systems like design-build push design companies to implement constructability as a procedure in the design process. According to Arditi, et al. (2002), many design firms have a formal (explicit) constructability program that is launched as early as the conceptual planning stage of the project. They reviewed constructability implementation during the design phase in a construction project. They focused on existence of constructability programs, timing implementation, and factors that improve or hinder constructability implementation. Arditi, et al. (2002) showed that peer reviews and feedback systems are the most prevalent tools used to achieve high levels of constructability.
2.3 Constructability Implementation Barriers

Constructability tries to improve construction companies’ performance; however, implementing it faces many barriers. A barrier to constructability can be defined as any significant inhibitor that prevents effective implementation of the constructability program (O'Connor & Miller, 1994). O'Connor and Miller (1994) categorized barriers into general, owner, designer, constructor, organized labor, vendor, code authority, and researcher barriers. These barriers affect corporate and project level.

Jergeas and Put (2001) designed a survey to identify constructability barriers in Alberta; they found a large gap in the following constructability concepts:

- Up-front involvement of construction personnel during design stage. This is mainly due to using the traditional contract (design-bid-build), especially in the public sector.
- Construction efficiency, which can be achieved by modularization and pre-fabrication. However, modularization is specific to certain projects.
- Using innovative construction methods.

Goodrum, et al. (2003) discussed the implementation of constructability on highway construction projects. They surveyed 19 state transportation agencies to identify implementation barriers. Lack of time, lack of available manpower, lack of available experience, and contractor reluctance were the main stated barriers.

2.3.1 Barrier mitigation

O'Connor and Miller (1995) suggested identifying barriers then mitigating or overcoming these barriers using barrier breaker tactics. Construction Industry Institute (CII) introduced a list of barrier breakers (O'Connor & Miller, 1995); this includes seven steps to mitigate complacency with status quo:

- Designate a strong program champion
- Report constructability program benefits regularly
- Make constructability the responsibility of younger, more energetic individuals, who more frequently confront the status quo
- Establish funded programs that promote creativity and intelligent risk-taking
- Establish monetary awards for rewarding innovation and intelligent risk-taking
- Conduct training programs in shifting paradigms, promoting creativity, and promoting critical thinking
- Screen out personnel who regularly support the status quo

3 GAP ANALYSIS

We performed a gap analysis of constructability program implementation in a construction company located in Alberta. Identifying the constructability gap is a crucial step to reaching a full constructability implementation. We used two approaches to study the gap: reviewing historical projects and surveys. These two approaches complement each other as the first method focuses on project level, the later focuses on corporate level.

3.1 Methodology

The data used in this study were obtained by two means: 1) reviewing historical projects and 2) surveying a construction manager working with the partner company (a construction company in Alberta). The survey covers two project case studies, which have been built by the partner company. The survey contains two parts: constructability program evaluation matrix, provided by CII, and a survey questionnaire prepared by ASCE Construction Institute’s Constructability Committee (1991). The constructability program evaluation matrix is further divided into two sections: corporate constructability evaluation matrix and project constructability evaluation matrix, as shown in Figure 1. The corporate constructability evaluation matrix shows 13 parameters identified by CII for assessing the level of implementation of the constructability program at the corporate level. The level of implementation is
classified into five levels; level 1 represents no program implementation and level 5 represents comprehensive formal program. In project constructability evaluation matrix, 10 parameters were identified to assess the implementation of the constructability program at the project level and the classifications of implementation levels are the same as for the corporate level. This survey allows the determination of areas where improvement of constructability program is required and also identifies areas where the constructability program is successful.

The second part of the survey is used to provide a clear picture of current practices of constructability in the construction company, which is achieved by describing the following points (ASCE, 1991):

- Project phases at which constructability efforts usually begin.
- Constructability methods used during design and construction.
- Who requires constructability and who performs it.
- The major benefits of constructability and problems it could prevent.
- The major obstacles to implementing constructability.
- Progress in constructability practice and where improvement is needed.

![Constructability Survey Structure](image)

**Figure 1 Constructability Survey Structure**

### 3.2 Case Study

The gap analysis is done on two projects that have been built recently by the partner company. The first project (Project A) involves replacing four existing cyclones and associated ancillary equipment in the Raw Meal Preparation Area with two larger cyclones. The scope of the project included civil, structural, and mechanical works. The partner company tried to include constructability concepts in the project, especially in the early design phase. These attempts included:

- Brainstorming to identify stakeholders’ expectation and opportunities.
- Inspecting “lessons learned” from previous projects.
- Assessing safety considerations like site congestion and critical rigging and lifting.

The Generator Replacement – Evaporator Modernization Project (Project B) for Pulp and Paper Companies is the second case study we considered in the constructability gap analysis. In this project, the partner company applied constructability concepts in different project phases, as follows:
• Conceptual design phase:
  • Optimize layout and routing by assessing equipment locations to minimize handling and reduce crane requirements.
  • Set up an effective communication plan to minimize the impact of delays for all project stakeholders.

• Design and procurement phases:
  • Assess severe winter conditions in the design phase (e.g. use domed tents).
  • Consider three different design options to see which one is better from the constructability prospective.
  • Discuss vessels’ design with constructability personnel.

3.3 Result

By reviewing constructability concepts in the company’s historical projects and surveying, we were able to assess how constructability concepts have been implemented in the partner company. Analysis of Part A of the survey shows that constructability implementation in the company lies between informal and formal program. Table 1 summarizes the results of constructability implementation in the partner company. We included 13 CII constructability principles (Jergeas & Put, 2001) with the corresponding degree of implementation. We used a scale from 1 to 5 for degree of implementation, where 5 means fully implemented and 1 means missing concept, in the partner company practice.

These 13 concepts can be grouped into two general categories: 1) planning phase and 2) executing phase. Figure 2 and Figure 3 show percentage of implementation for each group separately. These figures show that the partner company used concepts like constructability in early project planning and considering adverse weather; however, they are behind in using modularization, preassembly and standardized elements.

Table 1 Constructability concepts and degree of implementation (5 means fully implemented and 1 means missing concept).

4 RECOMMENDATION

This section discusses the missing constructability concepts in the partner company and tries to fully implement them.
4.1  **Constructability in Contracting Strategy**

The ultimate use of constructability program concepts in construction is affected by the selection of the type of contract. For example, in design-build and cost reimbursable contracts, the owner and contractor teams work together, while in design-bid-build contracts, the owner and contractor teams work individually, which results in less integration of construction experience in the design stage. The construction management committee of ASCE summarized the factors affecting the selection of the type contract as the following (1991):
• Owner’s corporate policy on contracting.
• Availability of in-house experienced personnel.
• Time available to get the project designed and constructed.
• Desire of owner to control elements of project.
• Importance of cost to owner.
• Amount of risk owner wants to contract out.
• Availability of contractors.
• Local construction climate.
• Experience or confidence in contractor or design builder.

Constructability concepts can be formulated in the contracting strategy by the following points:

1. Including the help of experienced construction personnel in choosing the right contract for the right project for the owner.
2. Adding design services as part of fixed price contracts.
3. Achieving mutual trust with the owner to maintain the use of cost reimbursable type of contracts in the future.
4. Documenting success stories when using constructability programs and delivering them to owners.

4.2 Constructability Team

Constructability process involves the integration of construction knowledge and experience prior to the beginning of the actual design. This process is achieved by the formation of a constructability team that includes construction experts. The application of constructability team in the construction industry differs based on the motivation and the attitude of project participants on applying constructability programs in their projects. For example, the owner is required to expand his front-end planning and invest more time and money in forming a constructability team to better address the interrelationship between construction method, material, equipment, and construction trades. In the contractors’ point of view, constructability teams are always formed while tendering and prior to construction to break down the project to allocate required labor, equipment, materials, etc. for the project. The maximum effectiveness of constructability programs in terms of forming constructability teams can be achieved when constructability teams of the owner and the contractor work together in harmony. This concept can be achieved by considering the following points:

1. Consider forming constructability teams as part of the project roadmap.
2. Establish formal commitment to the idea of constructability.
3. Highlight the importance of early involvement of constructability.
4. Establish constructability specialist’s position in the company.

4.3 Standardized Design Elements

Projects are unique and different projects have different design elements. It is difficult to standardize design elements that can work in any project because the design is controlled by the design firm. However, it is possible to standardize the design elements for big projects with repetitive features such as high rise buildings and residential compounds; therefore, constructability in the form of standardized design elements can be applied in only certain types of projects. Maximizing the use of standardized design elements can be achieved by the following points:

1. Deliver the fact of saving time and money by using standardized design elements to the owner.
2. Enforce the use of standardized design elements in projects of repetitive nature.
3. Provide in-house training in BIM technology.

4.4 Modularization and Preassembly

Prefabrication and preassembly have doubled in the last 15 years (Haas, et al., 2000). However, some companies fail to implement this concept due to barriers like “it is specific for certain projects” (Jergeas & Put, 2001). However, modularization and preassembly are very effective to overcome severe weather and uncontrolled quality on site. It improves productivity and reduces project duration. The following guidelines will help in implementing this concept:

1. Form constructability team early and make sure they are involved in design stage.
2. Use BIM technology.
3. Realize that using modularization and preassembly will be very useful for schedule-driven projects.
4. Perform further analysis for modularization and preassembly cost benefit.

4.5 Design and Procurement Schedules are Construction Sensitive

Construction sensitive schedules are defined by CII as ones that consider project completion date and the requirements of the construction phase to optimize the project cost and schedule (Rusell, et al., 2004). This concept tries to balance the time allocation for each activity in the schedule. To avoid this concept’s barriers:

1. Develop a detailed schedule in the design phase.
2. From the early start, assign considerable time allocation for planning, design, procurement, and construction (Rusell, et al., 2004).
3. Avoid unnecessary changes to the main schedule.
4. Make sure late procurement will not affect the schedule.

4.6 Design Facilities Turnover and Start-up

This concept ensures integrating facilities turnover and start-up in the design stage. This is an important concept to avoid facilities start-up problems and design/construction changes. In order to utilize this concept:

1. Contractors should be involved in the design stage with owners and designers.
2. Prefer new contracts (e.g. design-build) over traditional ones (design-bid-build).

5 CONCLUSION

This paper discusses constructability concepts implementation in the partner company, starting from the gap analysis. The study concluded that use of constructability concepts by the company lies between informal and formal constructability program classification. The degree of implementation of constructability concepts was further divided into two phases: planning and execution phases. It was found that the degree of implementation of constructability concepts in both phases were 63% and 67%, respectively. We found that there are six concepts that need more work within the partner company. Three of them are related to planning phase while the other three are related to execution phase. This paper states specific recommendations for each concept in order to mitigate their barriers and implement them smoothly.

Abstract: The United States and Canadian construction markets are facing a shortfall of skilled craft workers in the face of increasing labor demands. There are initial indications that the shortages are already having a significant impact on project performance in the industrial construction sectors. While there are many demographic aspects of the shortage, the authors focus on the shift in aging of the United States and Canadian construction workforce and the effects this is having on the availability of craft workers, especially on highly skilled craft trades such as pipefitters and electricians. Also, the authors examine immigration policy and its influence on the qualifications of the construction workforce. The authors use multiple US and Canadian data sources to examine the trends on both sides of the border, including the US Bureau of Labor Statistics’ Current Population Survey, Statistic Canada, and the Build Force Canada datasets. The findings show that while both the US and Canadian construction markets are experiencing an aging workforce, the aging of the US workforce is occurring at a much faster rate.

1 INTRODUCTION

Construction is one of the largest economic industries in the United States and Canada. In 2010, construction accounted for 3.5% of the U.S.’s Gross Domestic Product (GDP) (CPWR 2013), and for 6% of Canada’s Gross Domestic Product (GDP) (Statistic Canada 2014). Construction in 2012 employed approximately 9 million workers in the United States (Dong et al. 2014), whereas Canada employed 1.3 million (Statistics Canada 2014).

The Bureau of Labor Statistics (BLS) estimates that the US construction industry will be the fastest growing industry over the next decade, which will create an estimated 1.6 million jobs (Glavin 2013; Gonzales 2013). The growth of construction projects will increase the demand for skilled craft workers, (Wilder 2013; Shelar 2013). Industrial construction on the Gulf Coast has contributed 1,100 projects and $44 billion in revenue, effectively increasing hours worked from 99.7 million to a projection of more than 121 million by 2016. Likewise, Canada has a vast number of oil and gas projects that are on an upward trend (Wilder 2013), although the authors note current dramatic fluctuations in oil prices will likely significantly temper the demand for workers. According to the Construction Sector Council of Canada, the Canadian construction industry will need 319,000 new workers to replace retiring workers and to also fill new job openings—219,000 and 100,000 respectively between 2012 and 2020. The Construction Sector Council estimated that graduates of vocational schools could fill almost half of these jobs, but the other industries like manufacturing and migrant workers will have to fill the remaining jobs (Komarnicki 2012).
Because of the high demands for construction, companies are losing money from the lack of skilled craft workers. According to Stephen E. Sandherr, the Associated General Contractor’s (AGC) Chief Executive Officer, 74% of construction companies in the U.S. are having difficulties finding workers to fill job openings (Gonzales 2013)—specifically in the Gulf Coast region (Wilder 2013). The Bank of Canada’s Business Outlook Survey in 2012 claimed that 29% of Canadian firms face labor shortages, an increase from 2009 and 2010 (Komarnicki 2012).

The skill shortages in the construction industry are not new, and are a cyclic problem (Castaneda et. al. 2005). A shortage of skilled, qualified craft professionals has been an unfortunate recurring trend in the US and Canadian construction industries for the past three decades. In the early 1980’s, the Business Roundtable predicted that a shortage of skilled craft workers would hamper the growth of both open shop and union construction sectors by the late 1980s (BRT 1983). The prediction was confirmed by a 1996 Business Roundtable study that found that 60% of its surveyed members were experiencing a shortage of skilled craft workers; 75% of the respondents indicated that the shortage had worsened in the five years prior to the study (BRT 1997). The shortage of craft workers apparently has further worsened in recent years. In 2001, the Construction Users Roundtable (CURT) conducted a survey in which 82% of the respondents reported shortages on their projects. In addition, 78% of the same respondents indicated that the shortage had worsened in the three years prior to the study (CURT 2001). In 2007, that number had risen to 86% (Sawyer and Rubin 2007).

Higher skilled trades in construction (e.g. electricians and pipefitters) are experiencing greater shortages in comparison to lower skilled trades (e.g. laborers and roofers). Electricians, pipefitters, welders, boilermakers, millwrights, and ironworkers are among the skilled crafts with the greatest demands among construction industry trades in the U.S. (Wilder 2013; Shelar 2013; Gonzales 2013). Yet electricians will be the trade in demand in Canada between 2011 and 2020, as predicted by the Canadian Occupational Projection System (COPS). While COPS believes there will be a higher demand for electricians, this timeframe could also experience a surplus of carpenters, plumbers, pipefitters, and gasfitters. Nevertheless, a surplus in some regions may hide skill shortages in other regions (Komarnicki 2012).

1.1 Reasons for the Shortage

Many agree that the skills shortage issue is multifaceted (Watson 2007; Healy et. al. 2011). Two reasons for long-term shortages are a lack of training and an inability to attract new talent. There are also reasons for short-term shortages, such as an increasing demand within the workforce and the retirement of the Baby Boomer generation of workers (born between 1946 and 1965). A significant reason for the craft worker shortage is the aging, “greying,” population. In 2010, 39% (3.5 million) of the U.S. construction workforce were Baby Boomers, many of whom had already reached the normal retirement age which varies from age 65 to age 67 (SSB 2014; GOC 2014b; CPWR 2013). Just a decade earlier, 49% of the construction workforce were Baby Boomers (4.6 million) (CPWR 2007). The average age of the U.S. construction workers was 40.2 years in 2010. In comparison, union workers are on average five years older than non-union workers. In 2010, union workers average age was 42.4 years and non-union workers average age was 37.7 years (CPWR 2013). Shigeru Fujita (2014), believes the Baby Boomers’ retirement is a main contributor to the workforce shortage, which started around 2010 and became much more problematic at the beginning of 2012. However, 30 % of the total decline in the participation rate, which was measured from the beginning of the great recession up to the end of 2011, is due to discounted workers, who stop looking for employment. R.E. Parker, president of Repcon, Inc., a mechanical contractor based in Corpus Christi, Texas said “Due to the aging of the ‘baby-boomer’ workforce and the tremendous amount of construction planned for the next several years, our current labor shortages are going to become a crisis” (Wilder 2013). However, the major contributor to the construction workforce shortages as a result of baby boomer retirements is a continuance of two actions within the workforce during the last couple of decades. First, more and more existing workers have been leaving the construction industry for other industries, especially during the great recession. Second, there has been a lack of new workers entering the construction industry (Druker and White, 1996). While the current rapid decline in oil prices has diminished the demand for oil service projects, especially in the upstream, it is also having a positive effect of increasing craft demand for construction projects in other
sectors designed to take advantage of cheap energy prices, such as projects related to manufacturing. Table 1 is a list of reasons of construction workforce shortages from previous studies.

1.2 Research Objectives

The main objective of this study is to understand the influence of demographics on the construction industry's workforce availability, focusing on the shift in aging of the United States and Canada. In addition, the study examines the influence of immigration policy on the educational attainment of construction craft in both the U.S. and Canada.

2 RESEARCH METHODOLOGY

The authors use multiple US and Canadian data sources to examine the trends on both sides of the border, including the US Bureau of Labor Statistics’ Current Population Survey (CPS), Statistic Canada, and the Build Force Canada datasets. This study includes only craft workers in the construction industry, filtering out manager, superintendents, foreman workers, inspectors, and engineers.

3 RESULTS OF ANALYSIS

3.1 Average Age

3.2 Construction Industries vs. All Other Industries [United States]
An increase in the average age of construction craft workers is one of the reasons for the shortages. Craft workers in the construction industry are younger than craft workers in all other industries. From 1994 to 2006, the aging rate for the construction industry was 0.092 and the aging rate for all other industries was 0.260, Figure 1. However, the aging rate for the construction industry has increased almost four times (4.4 times) from 2007 to 2014 and became 0.405, while the aging rate for all other industries has decreased by 0.7 times to became 0.185. Yet, the average age for all industries is older than the average age for construction industry. In 2014, the average age for all industries is 42.9 while the average age for construction industry is 40.8.

3.2.1 Average Age at Trades Level [United States]

The authors observed the average age among four high skilled trades, including carpenters, electricians, pipelayers-plumbers-pipefitters-steamfitters, and construction equipment operators [except crane], Figure 2. In general, the average age in each these trades is above the average in all skilled trades in construction. The equipment operators’ trade has older workers than other trades, and the carpenters’ trade age has increased sharply since 2006.

3.2.2 Construction Industry’s Average Age [United States vs. Canada]

The writers compared the U.S. construction industry's average age with the Canadian construction industry's average age. The Canadian dataset is relatively limited in that it did not go back earlier than the year 2006. In 2006, the average age in Canada was 39.5 and in the U.S. it was 37.4. However, the U.S. working age increased in 2014 to 40.8 years on average, while the Canadian average age for construction workers stayed almost the same, at 39.8 years, Figure 3. Therefore, the overall outcome summary from this analysis is that the US construction industry is aging at an alarmingly rate, which puts it at risk, especially during the current high demand period.

3.2.3 Age Distribution

The writers examined the age distribution in 2007, just before the great recession, and compared it with the age distribution in 2013. For all craft workers, the average age in 2007 was 37.4 and in 2013 it increased to 41. As shown in Figure 4, the percentage of young workers in 2007 was higher than the
percentage in 2013, but the percentage of the workers who were 70 years old or older was almost the same at years 2007 and 2013. Therefore, the construction industry lost more craft workers than it gained over this six year period. On the other hand, the authors used Statistics Canada to observe the age distribution for the Canadian side. Instead of including each worker’s raw age, Statistics Canada reports data on age classified by groups. In order to examine the age distribution on a similar time scale, the probability distribution for Canadian construction workers was examined for 2006 and 2011, Figure 5. In 2006, the first mode was the age group from 20 to 24 years, and the second mode was the age group from 40 to 44 years. And in 2011, the first mode was the age group from 25 to 29 years, and the second mode was the age group from 20 to 24 years. Therefore, the Canadian construction workers in 2011 were younger than construction workers in 2006.

Figure 4: U.S. All Craft Workers [2007 vs. 2013]  
(Data Source: Current Population Survey)

Figure 5: Canadian All Craft Workers [2006 vs. 2011]  
(Data Source: Statistics Canada)

In a further detailed analyses, the authors examined the age distribution for the electricians and pipelayers-plumbers-pipefitters-steamfitters trades in the U.S., since they represent the industrial construction trades that are currently in high demand. For US electricians, the average age in 2007 was 38.7 and in 2013 it increased to 41.4. As shown in Figure 6, the percentage of young workers in 2007 was higher than the percentage in 2013. However, the percentage of the workers who were 70 years old and older was higher in 2007 than 2013. Therefore over this time frame, the U.S. construction industry lost more electricians than the average loss of all craft workers. For the pipelayers-plumbers-pipefitters-steamfitters trade, the average age in 2007 was 39.7, and it increased to 41.5 in 2013. As shown in Figure 7, the percentage of young workers in 2007 was higher than the percentage in 2013. However, the percentage of the workers who were 70 years old and older was almost the same at years 2007 and 2013.

(Data Source: Current Population Survey)
3.3 Immigration

There are other differences between the Canadian and the U.S. construction workforces. For example, the majority of white workers in the United States are U.S. citizens, while a large number of the white workers in Canada are not Canadian citizens, but rather from Europe and the U.S. However, the Canadian government utilizes a Temporary Foreign Worker Program (TFWP) that “allows Canadian employers to hire foreign nationals to fill temporary labor and skill shortages when qualified Canadian citizens or permanent residents are not available” (GOC 2014a). The workers in this program have flexibility to become permanent residents if their skills are needed (GOC 2014a). The U.S. H-2B Visa, which is equivalent to Canadian TFWP program, is not flexible (Wilson 2013). Therefore, the authors looked at the immigration in the both countries differently. In Canada, the authors looked at the workforce population by their citizenship (Canadian by birth, Canadian by naturalization, and not a Canadian citizen) to study immigration, which is equal to the “not a Canadian citizen” category. In the U.S., the authors focused only on the Hispanic population, since this has been a historically faster growing demographic population in the U.S. construction industry, while other populations have been shrinking (Goodrum 2004).

3.3.1 Canadian Citizenship [Construction vs. All Other Industries]

The authors examined the Canadian construction workforce by their citizenship. Almost 80% of craft workers are Canadian by birth. In 2011, the percentage of the workers who were not a Canadian citizen was almost similar in construction and all other industries with the rate of 4.5%, Figure 8. However, the construction industry has a lower percentage of Canadian citizens by naturalization. In 2011, the percentage of naturalized citizens in the construction industry was 11.13%, while the percentage in all other industries was 15.6%.

![Figure 8: Canadian Citizenship vs. All Other Industries](Data Source: Statistics Canada)

![Figure 9: High School Graduates or Higher](Data Source: Statistics Canada)

3.3.2 High School Graduates or Higher in Construction Industry [By Canadian Citizenship]

The writers took an additional step and observed the educational level of Canadian construction craft workers by citizenship. The educational level varies by citizenship type for the year 2001 and years before, Figure 9. In 1991, the percentage of construction workers who had at least a high school diploma was 55.9% for those who were “Not a Canadian citizen”; 59.9% for those who were “Canadian by naturalization”; and 63.3% for those who were “Canadian by birth”. However, the rate of high school graduates increased for all citizen types. In 2011, the craft workers who had at least a high school diploma were around 80% for both citizens and non-citizens, which is in many ways in stark contrast to the high school graduation rates among Hispanic and non-Hispanic construction workers in the U.S. (Figure 13).
One of apparent influences of the increasing educational level of foreign workers in Canada was the weight applied to an immigrant's educational attainment through the old immigration entry system. The education category constituted around 25% of the old weighting system. The Canadian government focused more on educated (talented) foreign workers, Figure 10. However, the weighting system changed in 2015 to an express entry system, which places significantly more weight on having a job offer (50%), and decreases the weight related to educational attainment to only 10%. The influence of the new weighting system on the educational attainment among immigrant workers in the Canadian construction industry is yet to be seen.

3.3.3 Hispanic Workforce in the United States [Construction vs. All Other Industries]

The authors also looked at the rate of Hispanic employment in the U.S. and found that the rate has grown significantly over time for construction and all other industries, Figure 11. However, the Hispanic population rate was lower for the construction industry in the mid-90s, and it has grown very fast since the beginning of 2000s. In 2014, the Hispanic population rate was 26.9% in the construction industry, and 17.4% in all other industries, while it was 9.9% in 1994, in both construction and all other industries.

3.3.4 U.S. Construction Hispanic workers at Trades Level

The writers examined the employment rate of the Hispanic population among specific U.S. construction trades. The highest employment rates of Hispanic workers within specific construction trades were typically related to the residential sector, Figure 12. In fact, most of these trades did not require an education background (high school degree or higher) (BLS 2014). Less than 20% of Hispanic workers were in higher skilled trades (which are below the all craft trade's average) that require unique training or certification (e.g. electrical and pipefitter).
3.3.5 High School Graduates or Higher in the U.S. Construction Industry [Hispanic vs. Non-Hispanic]

The researchers studied the educational level among U.S. Hispanic craft workers and compared it with non-Hispanic craft workers. The sampled Non-Hispanic workers reported having higher educational levels, measured by high school graduation rates, as compared to the sampled Hispanic workers, with an approximate gap of 37% in 2014, Figure 13. In 1994, 42.1% of Hispanic workers had a high school degree, while 77.4% of non-Hispanic workers had the same degree. In 2014, the rate of educated Hispanic workers increased to 50.3%, while the rate of non-Hispanic educated workers also increased to 87.3%.

4 DISCUSSION

The aging of the workforce indicates that the retirement of baby boomers is having a significant impact on the current workforce shortage. The entire workforce’s average age has increased over the time, but the age of the U.S. construction industry grew very fast in recent years, almost four times faster than in the previous decade. Age distribution results show that the construction industry in the U.S. is losing more workers than it gains, especially electricians and pipefitters. Losing experienced skilled workers will create a gap, since skilled trades require unique training and certification, which for new workers takes time usually measured in years. Therefore, most of the highly skilled trade workers in the U.S., including electricians, and pipefitters, are older than the average craft trade workers in the construction industry. However, the average age of Canadian construction workers was also been growing steadily. However, the average Canadian construction worker in 2014 was still younger than the U.S. construction worker. Moreover, the Canadian age distribution shows that more young workers entered the construction industry in recent years.

It appears that Canadian immigration policy, which has placed a significant weight on an applicant’s educational attainments, has influenced the overall educational level of the Canadian construction workforce. The educational attainment of Canadian foreign-born workers was nearly equal to that of Canadian natural born worker. As part of a growing immigrant workforce in the U.S., the same cannot be said for the U.S. Hispanic construction workforce when compared to the non-Hispanic workforce. A significant educational gap between Hispanic and non-Hispanic construction workers exists in the U.S. This gap limits the abilities of the Hispanic workforce to enter into higher skilled and higher pay construction jobs. In a time when the U.S. construction market is experiencing severe workforce shortages among higher skilled jobs, structural changes in the education and training of the Hispanic workforce is needed.

5 CONCLUSION

Using the previously mentioned data sets (CPS, Statistics Canada, and Build Force Canada), this research primarily examines the influence of demographics on skilled workforce shortages, comparing the U.S. construction industry with Canadian construction industry. Additionally, the authors focused on the trades that are more related to the industrial projects. The following findings were identified:

- There is a “greying” of the workforce, especially in the U.S., and the rate is increasing. All other industries craft workers in the U.S. are older than the construction craft workers. However, in the last decade, the rate of aging among U.S. construction workers is almost four times higher than the growing rate from the previous decade.
• High Skilled trades in the U.S. (i.e. electricians, and pipefitters) are older than the construction industry average age.
• The construction industry in the U.S. is losing more craft workers than it is attracting.
• The Canadian construction foreign workers percentage has not increased over time, but their level of education has increased sharply.
• The percentage of Hispanic craft workers in the U.S. has increased sharply over the time while their level of education has not.

The analysis showed that the aging of the construction workforce plays a significant role in the current craft shortage, especially in the U.S. Outside of revamping a U.S. immigration policy that considers the educational attainment of foreign born workers, the U.S. needs to critically examine how to improve the educational attainment of Hispanic construction workers both for the personal benefit of the individual worker and the industry’s needs.

INTEGRATING 3D CAD AND COST ESTIMATING AT THE CONCEPTUAL DESIGN STAGE OF BRIDGE PROJECTS

Bashar Al-Dosary¹, Ahmad Jrade²
¹ Graduate Student, Civil Engineering Department, University of Ottawa, Ottawa, Canada
² Assistant Professor, Civil Engineering Department, University of Ottawa, Ottawa, Canada

Abstract: Bridge Information Modeling (BrIM), as a concept, has been introduced to enhance the procedures of the whole phases of a bridge life-cycle starting with concept and design, through construction and operation, and ending with maintenance and rehabilitation. Integrating BrIM and design tools would help improve the methods used in designing and constructing bridge projects at early stages taking into considerations their cost and time constraints. The main objective of this research is to develop an integrated model that helps owners, designers and construction managers visualize bridge projects in a 3D mode and accordingly automate the process of generating preliminary cost estimates during the conceptual design stage. To achieve the abovementioned objective, a proposed methodology will be applied where all the aspects needed to develop an efficiently integrated model are realized. Thus, this paper describes the proposed methodology that incorporates three modules, which will be the core of the integrated model. These modules are: a knowledge based system module, which is used to generate conceptual dimensions and parameters depending on algorithmic and heuristic knowledge gathered from codes, guidelines and design experts; a conceptual cost estimation module, which is used to generate conceptual cost estimate based on the results of the first module; and a 3D visualization module, which is integrated with the previous modules where users will visualize the proposed bridge in 3D based on the results of the knowledge based module. The integrated model will be validated through an actual case project to test its workability and output.

1 INTRODUCTION & LITERATURE REVIEW

Significant advancement and Development in automation and communication technologies occurred in recent years, but bridge engineering and its construction management did not fully adapt and integrate these developments (Chen and Shirole, 2008). According to Chen and Shirole; (2008), Bridge Information Modeling (BrIM) has weighty potential efficiencies and reasonable advantages to be gained by developing integrated approaches. The concept is the same as Building Information Modeling (BIM) but it is closely related with an axis for road or railway design (Katz, 2008). Bridge Information Modeling (BrIM) widely is becoming an effective tool in the bridge engineering and construction industry. Bridge Information Modeling (BrIM) methodology is being used increasingly in the design and construction of complex and large bridges, also (BrIM) aspects such as visualization, detailing, bridge operations management and project delivery are being used in infrastructure projects through the use of AASHTO Ware (Shirole et al. 2009). Integrated approaches of BrIM aspects will not only result in costs reduction, faster delivery and improvement of quality, but also will pave the way towards different project delivery models such as design/build delivery model. However, lots of engineers and researchers are still unaware of the economic benefits of utilizing such technologies in cost estimation at the conceptual design phase.
of bridge projects (Shirole et al. 2009). Many researchers studied and applied BrIM on stages of bridge projects such as on the detailed design, construction and maintenance. However, BrIM aspects were not implemented at the conceptual stage of a bridge project. This research proposes a methodology to integrate part of the BrIM, which is the 3D CAD, with cost estimation at the conceptual design stage of bridge projects.

Integrated design and construction of bridges was addressed in many studies and pieces of research, which gave manufacturing industries excellent results and provided improvements. Lee et al (2012) developed 3D models for specific construction methods used in prefabrication of concrete bridges. The proposed model was needed to enable engineers to make cost-effective decisions. Also, the model ensured adequate collaboration between CAD systems that is not available in 2D drawings, because 2D drawings need additional effort to correct constructability problems due to insufficient information delivery between different engineers. Lee’s 3D proposed models not only increase the efficiency of collaboration between different engineers but are also useful for communication between project parties. The CATIA-V5 CAD engine was used in their model to support the 3D geometry models. Their model was based on digital mock-up (DMU) computer-based information technology. The model was validated by utilizing a precast concrete box girder bridge construction project by a general contractor. Concrete segment components were modeled and assembled, where the DMU technology improved the quality of the concrete segments and reduced their time and construction cost. Bill of Materials (BOM) conducted to provide information concerning the product parts and the correlation between the parts. The huge sophistication and complexity of construction and fabrication of the reinforced concrete structure was accelerated using this technology. A lot of researchers have been studying and discussing the operation of construction equipment using computer-aided design software and modern technologies for very complex and complicated bridge projects. Park, et al (2009) applied 3D CAD for effective derrick crane operations in a case project concerning cable-stayed bridge construction. In this case project, a 3D CAD model was applied during the operation stage, wherein it showed, in detail, the movement of the equipment and materials throughout the construction operation. The operation stage requires more in-depth knowledge of the whole construction operation. The case study presented the application of a 3D CAD model to show the operation of a derrick crane in constructing the Cheongpoong Grand Bridge which is a cable-stayed bridge. The derrick crane was the major piece of equipment used in the project. However, analyzing the safety of using the derrick crane in installing objects was crucial. Thus, analysis of the crane operations was conducted using the 3D CAD model. The entire path of the crane, when in motion, was visualized during the envelope analysis before the physical construction starts. Using a 3D CAD model in the case project led the authors to conclude that this technique can prevent reworks, while improving the productivity of bridge construction.

Technology developments that have occurred during recent decades have encouraged many researchers to develop modern methods to improve productivity in different fields of construction. Modern technology and bridge information modeling (BrIM) were used in many bridge projects during both the project and operational stages. Other researchers are currently looking at the application of BrIM project tasks such as planning, scheduling, safety, construction operations and maintenance. Most BrIM applications have been implemented on projects after their design stage where the related information and data are available. However, applying and using the BrIM concept during the project conceptual stage has not captured the attention of researchers. Applying the concept during this stage will lead to developing effective and powerful applications and models that will save time and cost. However, this research will focus on integrating the 3D CAD part of BrIM with conceptual cost estimating; thus, the conceptual design stage is the focus of the research study.

According to Miles et al (1994), the conceptual design area has been resistant to the introduction of computer systems. However, developers were enabled by the development of the KBS to provide systems that undertake conceptual design needs. According to the definition of the KBS, it consists of two main parts: the knowledge and the interface engine. Two types of knowledge are used in the KBS: algorithmic and heuristic. The algorithmic knowledge represents equations based on Newtonian physics, while the heuristic knowledge represents rules of thumb which are based on experience. On the other hand, the interface engine presents the knowledge via logical statements and IF-THEN rules. Manos et al (2011) proposed a methodology for implementing KBS for the preliminary design of the seismic isolation
of bridges. The proposed methodology is based on the current design provisions of Eurocode 8, but is complemented by additional criteria, set according to expert judgment, laboratory testing and recent research findings, while using a combined cost/performance criterion to select from a database of available bearing products on the international market. The methodology is also implemented in software whose efficiency is validated through parametric numerical analyses as well as by using the case of a real bridge. Miles and Moore (1989) proposed another example of implementing KBS for conceptual design. They proposed implementing KBS for conceptual design of road bridges. They developed a system which is intended for inexperienced young civil engineers and aims to assist young civil engineers in gaining more understanding of conceptual bridge design process. Miles and Moore (1989) suggested to include graphics and to build more interaction with other computer system such as CAD systems and intelligent databases.

2 METHODOLOGY

The proposed methodology that integrates bridge information modelling and cost estimation for bridges at the conceptual design stage requires following the steps used to design the bridge at the conceptual stage. This can be achieved by identifying all the necessary bridge-related parameters and information needed for the conceptual design. The integrated model consists of the following three main modules (1) knowledge-based system; (2) cost estimation module; and (3) 3D visualization module. The knowledge-based system is used to generate preliminary dimensions/parameters, and to recommend bridge type alternatives. The cost estimation module consists of a comprehensive cost database that is used to generate cost estimates for the selected alternatives. The visualization module utilizes three-dimensional (3D) drawings in modeling bridges.

2.1 Knowledge Based System

The main purpose of utilizing the Knowledge-Based System (KBS) is to generate preliminary dimensions and parameters which can be used in the conceptual cost estimating module. The main procedure of the KBS involves three steps, (1) user's input variables; (2) knowledge base analysis; (3) KBS output variables. The first step requires the user to identify objective variables rather than subjective variables. The reason behind this is that objective evaluation criteria require objective feedback or measures, which are available to both experienced and inexperienced designers. On the other hand, subjective criteria require subjective feedback or experience judgment, which can be available only for the experienced designer. The objective variables, which should be identified by the user, are bridge length, road type, required number of lanes, location and overpass object information. The second step is to use the user's input variables in consulting the system's stored knowledge base. Two types of knowledge are to be consulted, algorithmic knowledge and heuristic knowledge. The algorithmic knowledge is based on highway geometric design guidelines, navigational waterway guidelines and bridge structural design code, while the heuristic knowledge is based on rules of thumb gathered from bridge design experts and engineers. The knowledge base is consulted and restored though the interface IF-THEN rules. Finally, the third step is to present the output variables to the user, and to provide flexibility to the user in case any changes are desired. These variables are bridge cross-sectional dimensions, element dimensions and span arrangements. These variables are then used in the process of bridge type selection, will be used later in the conceptual cost estimating module and visualization module. Figure 2.1 illustrates the process flow of the knowledge-based system.

2.1.1 Knowledge Base

Transportation Association of Canada Geometric Design Guideline 1999 (TAC 1999) is used by designers in Canada as a source of a highway geometric design guideline. The purpose of using this guideline is to get assistance in generating conceptual road features and dimensions considering all the highway design factors such as mobility, environmental impacts, safety, capital cost, aesthetics, maintenance cost and vehicle operational cost. Sample of the road features and dimensions are lane width, left shoulder width, right shoulder width, median width, bike path width, transit lane width, pedestrian path width and parapet width. This guideline assists designers in applying the design domain concept by providing numerical guidance, in the form of tables and graphs. In addition, it provides a
commentary on the nature of the design domain and quantitative evaluation data of safety performance. After gathering all this information, logical relationships and IF-THEN rules are ready to be created.

The Navigable Waters Protection Act (NWPA), established by Transport Canada, is responsible for protecting the public right of navigation in all navigable waters in Canada. Any company or government agency that proposes to construct or repair any work within the limits of navigable waterway must obtain approval through the NWPA (TAC 1999). A document developed by the Transport Canada Navigational Waterways Protection Division (TC NWPD) in 2006 is used as a guideline in determining minimum navigational clearances. This guideline insures the provision of minimum required navigational clearances that allow safe passage under bridges and culvert structures for all types of vessels. If the bridge crosses a navigational waterway, it is important to know the minimum required navigational clearances in order to be able to identify bridge span arrangements. After gathering all this information, logical relationships and IF-THEN rules are ready to be created.

Little structural design information is available at the conceptual design stage. In addition, there is no specific formula or unique solution the designers have to follow -- structural design is based mainly on the designer's experience and knowledge. Thus, collecting information from bridge design experts is the only source for developing the structural design knowledge base. The research authors decided to interview two bridge design experts to elicit information and knowledge for developing the structural design knowledge base. The reason for selecting multiple experts in developing the knowledge base is that it has been found that interviewing multiple experts is highly beneficial and is recommended for knowledge base development (Moore, 1991). Interviewing multiple experts has been found to provide less chance of missing vital information, and to reduce the length of the overall knowledge elicitation process. Care is taken in choosing experts who have long experience in bridge design. Also, the authors were careful to select experts who are currently practicing bridge design to insure that their expertise will be relevant and useful; otherwise, there is a risk of their knowledge becoming out of date. The meeting involved an interview with the expert, in which the research was explained in full, ensuring the expert understood the intended capabilities of the proposed model, the degree of co-operation which would be necessary, and the format which the model would take. Providing an indication of the type of knowledge that would be required, allowed the problem-solving methodology employed by the experts to be quantified. heuristic information concerning bridge components was collected and gathered by interviewing two bridge design experts. The information was gathered through asking the experts some questions about the type and preliminary dimensions for all the bridge components, such as the choice of bridge deck, decisions concerning the supporting structure, the number of spans, and type of material for the bridge components. The collected information is stored in an Excel spreadsheet for later use in the conceptual cost estimating module. This can assist the designer or user to generate preliminary dimensions for the bridge components.

Figure 2. 1 Knowledge-Based System Process Flow
2.1.2 Bridge Type Selection

It is necessary to select the bridge type prior to starting the process of developing conceptual cost estimating of the bridge project. Due to the lack of information and data at the conceptual design phase the selection process is somehow difficult. The design experts interviewed recommended depending on existing bridges in selecting the bridge type. Historical data of all existing bridges in Ontario was collected from the Ministry of Transportation of Ontario (MTO). The data contains information about 2784 bridges in Ontario. The information include (1) bridge structural type; (2) bridge sub-structural type; (3) total bridge length; (4) total bridge width; (5) bridge span arrangement; and (6) material. The structural bridge types available in the database are (1) beam/girder; (2) arch; (3) frame; (4) slab; (5) temporary modular; and (6) truss. After collecting the data, a validation and consolidation process is applied to remove any repetitive or incomplete information. The data is presented in an Excel workbook. The data was divided into Excel workbooks based on the bridge span number. Each Excel workbook contains sheets that represent bridge types.

The criterion of selecting bridge type is based on comparing the user's input variables with the variables of an existing bridge, and selecting a bridge type that matches the user's input variables. As shown previously in Figure 2.1, the output variables of the knowledge base system are used as input variables for the bridge type selection process. These variables are (1) bridge length, (2) largest span length, (3) bridge width and (4) number of spans. In addition, the user is required to specify a value of Closeness Factor (K), which is a factor used in quantifying the similarity between the proposed bridge variables with existing bridge variables. Based on the number of spans, the existing bridge Excel spreadsheet is selected to be used in selecting the bridge type. The variables of bridge length, bridge width and largest span length are used to calculate the closeness weights. Closeness Weights, which are the ratios between the input variables and the existing bridge variables, are then to be calculated using the following equations:

\[ [1] \text{Closeness Weight of Bridge Width} = \frac{W_0}{W_{in}} \]

\[ [2] \text{Closeness Weight of Bridge Length} = \frac{L_0}{L_{in}} \]

\[ [3] \text{Closeness Weight of Bridge Span Length} = \frac{S_0}{S_{in}} \]

Where, \( W_0 \) = Width of the proposed bridge  
\( W_{in} \) = Width of the existing bridge \( i_n \)  
\( L_0 \) = Length of the proposed bridge  
\( L_{in} \) = Length of the existing bridge \( i_n \)  
\( S_0 \) = Largest Span length of the proposed bridge  
\( S_{in} \) = Largest Span length of the existing bridge \( i_n \)

The next step is to calculate the adjusted closeness weight, to see how close the proposed variables are to the existing bridge variable. The adjusted closeness weight has a range value between one and zero. Adjusted closeness weight value 1.0 means that the proposed bridge variables exactly match the existing bridge variables, while adjusted closeness weight of value zero represents that the proposed bridge variables do not match the existing bridge variables. The following equation is used to calculate the adjusted closeness weight:

\[ [4] \text{Adjusted closeness weight} = \begin{cases} 
\text{Closeness Weight} \geq 2, & 0 \\
\text{Closeness Weight} \geq 1, & 2 - \text{Closeness Weight} \\
\text{Closeness Weight} < 1, & 1 - \text{Closeness Weight}
\end{cases} \]
All of these steps are then repeated for all the bridge cases within the same Excel sheet. As mentioned above, each Excel sheet represents a bridge type. Once adjusted closeness weights are calculated for all the bridge cases within an Excel sheet, the maximum value of the adjusted closeness weights is found. If the maximum closeness weight is found to be bigger than the closeness factor $K$, then the bridge type is recommended to the user. If the maximum closeness weight is found to be smaller than the closeness factor $K$, then the existing bridge type is rejected. All these calculations are repeated with all the bridge types available in the Existing Bridge Excel workbook. Figure 2.2 shows the process flow of the bridge type selection process.

![Figure 2.2 Bridge Type Selection Process Flow](image)

2.2 Conceptual Cost Estimating Module

It is necessary to define the dimensions and to select the bridge design type before one can estimate the cost. Thus the output of both the knowledge-based system and the bridge type selection process are considered as input variables in the conceptual cost estimation module. Preparing a cost estimate greatly depends on the accuracy of the collected data. Thus, data collection has to be carried out before developing the cost estimating module. Since published cost data is not available for bridges, the only remaining alternative source of cost data is the collected cost data from previously constructed bridge projects. In-house cost data is considered to be the best choice in this case; however, cost data of
previously constructed bridge projects can be used for the research purposes. The cost data collection process was conducted before developing the module. The resources of the collected data were from different previously constructed bridge projects in North America. Using the ASTM (E2103) standards and the collected cost data, a bridge elements and components Excel spreadsheet for each type of bridge is created. These Excel spreadsheets are used to calculate the estimated conceptual cost for the project by entering the dimensions and parameters obtained from the KBS. It is important to adjust the cost of previous similar projects for time and location so that they are suitable for the proposed project. Thus, inflation and location adjustments were implemented on the gathered data. Once the cost adjustments are applied, conceptual cost estimating reports can be generated. Three different types of reports are to be generated, which are: (1) detailed cost estimating report, (2) sub-classification cost estimating report, and (3) summary cost estimating report. The purpose of generating three types of reports is to explain the cost allocation clearly by generating a cost estimate for each work group such as, superstructure, substructure, and site work, etc. Figure 2.3 illustrates the data flow of the conceptual cost estimating module.

![Image of data flow diagram]

Figure 2.3 Conceptual Cost Estimating Module and 3D Visualization Module Data Flow

2.3 Visualization Module

The purpose of the visualization module is to visualize the information of each bridge element and to present it in a 3D model. It is important that the generated 3D model contain visual properties that allow the user to identify the texture and color of the material in order to visualize the realistic aesthetics of the bridge. To do that, AutoCAD is utilized as a visualization tool, because its capabilities suit the purpose of the module. AutoCAD has the ability to exchange information with many applications with high efficiency in performing data recall. In addition, AutoCAD has the ability to assign properties such as material type and color to objects. This ability gives the 3D object a realistic visualization, which can assist the user in judging the aesthetics of the bridge elements. Moreover, AutoCAD has the ability to add the effect of lightning on the 3D object to visualize the light and shade effect, which is one of the bridge aesthetics principles. Besides all these abilities, utilizing AutoCAD as a visualization tool will allow the user to orient
the 3D bridge model and visualize it from different views. As shown in Figure 2.1, both the conceptual cost estimating and the visualization modules share the same input variables, which are the output variables of the KBS and the bridge type selection process. Thus, the visualization module can also use the Excel spreadsheets created from combining the cost data and the ASTM standards of bridge element classification. An exchange of information between the two modules is provided. In other words, if any changes or modifications with the generated 3D bridge model result in changes in the Excel spreadsheet, it will lead to changes in the conceptual cost estimation reports. To implement this data exchange, it is important to create a link between the visualization tool, AutoCAD, and the Excel spreadsheets of the model. Figure 2.5 illustrates the data flow of the conceptual cost estimating module.

3 DEVELOPMENT AND VALIDATION

The Knowledge-Based System (KBS) consist of two main components, the knowledge base and the interface. To develop the knowledge base, the following two steps are followed:

- Develop an interface using VB.NET according to the order of the knowledge bases process flow.
- Write programming code for VB.NET by:
  - Converting knowledge base tables and information representation to IF-ELSE rules in the VB.NET language.
  - Representing formulas and equations in the VB.NET language to perform the calculations.

The outputs of the knowledge-based system are used in the bridge type selection excel sheets in order to recommend to the used the suitable bridge types. The user then has to select the desired bridge type. The output variables of both the knowledge-based system and the bridge type selection process are used as input variables for the conceptual cost estimating module. The visualization module shares the same source of data as the conceptual cost estimating module. This source of data is the Excel spreadsheets that store combined information from KBS, bridge type selection, and cost data. Figure 3.1 summarizes the development of the proposed model.

The performance of the model was validated by estimating the cost and generating 3D CAD drawings of an actual project. This performance is measured by comparing the model's results with the actual project values. The actual project was a two-lane concrete slab bridge located on Lakeshore Drive, Ontario, Canada. The comparison between the preliminary dimensions of the actual bridge and those of the model showed exactly the same values. Also, the model's preliminary dimensions were compared with the
values obtained manually from TAC (1999) Highway Geometric Design Guidelines and showed matched values. Regarding the construction cost estimation, both the actual and model's construction cost showed close values with a small difference, which is acceptable because at the conceptual stage there is not enough information known about the project. The generated preliminary dimensions and the estimated cost by the model were in the same range, which proves the feasibility and reliability of the developed model. 3D CAD drawings of the case project were viewed in VB.NET and AutoCAD platforms to provide flexibility in visualization.

4 CONCLUSION AND FUTURE EXPANSION

Bridge Information Modeling (BrIM), as a concept, has been introduced to enhance the procedures of the whole phases of a bridge life-cycle. Integrating BrIM and design tools would help improve the methods used in designing and constructing bridge projects at early stages taking into considerations their cost and time constraints. The main objective of this research is to develop an integrated model that helps owners, designers and construction managers visualize bridge projects in a 3D mode and accordingly automate the process of generating preliminary cost estimates during the conceptual design stage. A proposed methodology is applied where all the aspects needed to develop an efficiently integrated model are realized. The proposed methodology that incorporates three modules, which will be the core of the integrated model, is described. These modules are: a knowledge based system module, which is used to generate conceptual dimensions and parameters depending on algorithmic and heuristic knowledge gathered from codes, guidelines and design experts; a conceptual cost estimation module, which is used to generate conceptual cost estimate based on the results of the first module; and a 3D visualization module, which is integrated with the previous modules where users will visualize the proposed bridge in 3D based on the results of the knowledge based module. The integrated model was validated through an actual case project to test its workability and output. The integrated model performance is measured by comparing the model's results with the actual project values. The comparison between the preliminary dimensions of the actual bridge and those of the model showed exactly the same values. Regarding the construction cost estimation, both the actual and model's construction cost showed close values with a small difference, which is acceptable because at the conceptual stage there is not enough information known about the project. The generated preliminary dimensions and the estimated cost by the model were in the same range.

ENERGY-BASED SAFETY RISK MANAGEMENT: USING HAZARD ENERGY TO PREDICT INJURY SEVERITY

Abstract: Worker injuries and fatalities have long been problematic in the construction industry. To address this ongoing concern, recent research has focused on risk-based approaches to proactive safety management. Although the quantity and quality of safety risk data has improved in recent years, available data do not link directly to natural principles and are, therefore, limited in their application and scientific extension. This study offers a new explanation of safety risk using the concept of energy where the underlying proposition is that all hazards are truly defined by the exposure to one or more of ten distinct forms of energy (e.g., gravity, motion, electrical). This concept of safety energy was introduced by William Haddon, was operationalized in a past Construction Industry Institute (CII) research team, and is currently being tested by an active CII research team. The present study aims to link energy transfer to safety risk for the first time. Inspired by natural disaster modeling, the concept of energy is translated to risk by defining the severity of a potential event as the ratio of the magnitude of the energy to the resiliency of the impacted human body part and the pressure exerted on impacted body part. Additionally, the likelihood component of risk is defined by the combination of human, social, technological, and other factors that contribute to the chance that there is an unwanted transfer of energy. To test this proposition, energy-based risk data were extracted from two sources: (1) a random sample of 40 injury reports taken from a larger database containing approximately 7,250 injury reports obtained from 281 private construction organizations and (2) a random sample of National Institute of Occupational Safety and Health Fatality Assessment and Control Evaluation (NIOSH FACE) reports. For each report, a combination of manual and automated content analyses was used to extract the following data: the chief energy source(s) contributing to the incident, the quantity of energy involved, the part of the body affected, and the severity of the outcome. Generalized linear models derived from initial results demonstrate that energy possesses legitimacy in predicting the severity of an injury that will result from a particular hazard, tentatively confirming the proposed theory. This research indicates that energy-based safety risk analysis is a promising line of scientific inquiry with predictive validity that has the potential to increase our understanding of the natural phenomena that contribute to injuries. This research corroborates previous hazard recognition research that introduced the energy principle of hazard classification but challenges the scientific merit of past safety risk data.

1 INTRODUCTION

With an average of more than two fatalities per day, the United States construction industry’s 796 workplace fatalities in 2013 accounted for the highest number of workplace fatalities of any United States industry (Bureau of Labor Statistics, 2014). The construction industry’s disproportionate fatality and serious injury rate has been an ever-present trend which, until the creation of the Occupational Safety
and Health Administration (OSHA) in 1970, was largely viewed as an inherently unavoidable characteristic of the work being performed (Bureau of Labor Statistics, 2014; Cameron et al. 2008; Roudsari and Ghodsi, 2005). Current theory, however, is that workplace safety is an indicator of effective design, planning, training, and work execution (Hallowell et al. 2014). Injuries in the construction industry are extremely costly. In fact, Everett and Frank (1996) estimated that the direct cost of accidents account for 15% of the total cost of a project (Agarwal and Everett, 1997). In addition to the direct costs, indirect costs such as work stoppage, training replacement workers, repairing damaged property, and maintaining insurance coverage have been estimated to be as high as twenty times the magnitude of direct costs (Business Roundtable, 1982). The end result is that the financial impact of workplace fatalities and serious injuries within the construction industry is nearly double that of the all-industry average (Waehrer et al., 2007). Due to the significant humanitarian and financial impacts, improving worker safety within the industry has become an increasingly important priority for construction firms and professionals (Gambatese et al. 2008).

Since the creation of OSHA in 1970, researchers and practitioners have introduced a plethora of safety programs such as project-specific training and safety meetings, frequent worksite inspections, and safety and health orientation. However, the effectiveness of these traditional injury prevention approaches is limited due to their reactive and regulatory-based nature (Hallowell and Gambatese, 2007). Additionally, Esmaeili and Hallowell (2012) found that most traditional strategies have reached saturation in terms of new adoption, suggesting that research and development for construction safety is critical for future improvement. In response to these limitations and trends, researchers have begun to explore risk-based practices as a means for safety innovation. Conventional safety risk management methods assume that work can be decomposed into its constituent parts (Lingard, 2013), ranging from broad safety risk analysis of different construction trades (Baradan and Usmen, 2006) to detailed safety risk analysis of specific construction activities such as concrete formwork placement (Hallowell & Gambatese, 2009). The problem with this approach, as explained by Cooke-Davis, et al. (2007), is that the decomposition of a complex system such as a construction site is of limited value when the work elements are in constant dynamic interaction with one another. As a result, while helpful, conventional safety risk management methods within the construction industry are limited in terms of both their current application and potential for future scientific development.

The purpose and intention of this study is to address the current limitations in safety risk analysis by offering a new energy-based approach to characterizing the potential severity of injuries. The specific goal is to examine the extent to which the quantity and the type of energy predicts the potential outcome of a hazardous work situation. If a link is established, this study could reveal a more fundamental approach to characterizing and measuring safety risk on construction projects.

2 LITERATURE

Applying the concept of energy to explain safety risk requires an understanding of the concepts of both safety risk analysis and safety energy. In order to better illustrate how this study seeks to advance the cause of safety within the construction industry, the relevant literature is reviewed in these two areas.

2.1 Risk Analysis in Safety Management

In a broad sense, risk can simply be defined as the combination of uncertainty, or probability, weighed against the damage that would be incurred. In the context of occupational health and safety, risk is a measure of the likelihood of injury and the associated consequences a hazard present in a given situation (Baradan & Usmen, 2006; Jannadi & Almishari, 2003). In 1984, system safety engineers in the United States military were able to quantify the risk associated with an event as the product of the probability and the severity of an outcome (Quality, 1984). This definition for safety risk, shown in Eq. (1), has remained consistent since its indoctrination and will be the premise for the concept of energy-based safety risk. It should be noted that the probability that a hazard will cause an injury is analogous to the frequency of events within a given period of time. Typically, frequency is expressed in terms of incident rates, whereas the severity is defined in terms of the impact to the work or firm (Hallowell & Gambatese, 2009).

\[
\text{Unit Risk} = (\text{Frequency}) \times (\text{Severity})
\]
Over the past 15 years, several safety risk quantification methods, varying in complexity and application, have been employed utilizing the underlying concept of unit risk analysis. For instance, Everett (1999) quantified the risk of overexertion injuries for various trades by studying the frequency of particular overexertion injuries incurred while performing work tasks. Similarly, Huang and Hinze (2003) were able to quantify the risk of fall accidents using OSHA and Bureau of Labor Statistics (BLS) statistical data. Several additional studies have since contributed to the advancement of safety risk analysis, quantifying risk for such categories as struck-by accidents (Hinze, Huang, & Terry, 2005), fatalities between construction trades (Baradan & Usmen, 2006), and tower crane activities (Shapira & Lyachin, 2009). The commonality among these studies is that the research focused predominantly on analyzing the frequency of event occurrences to quantify risk. The reasons that safety risk quantification research has primarily focused on incident frequency spans two-fold: 1) frequency data is more easily measured and accessible through databases such as the BLS; and 2) the widely used “Safety Triangle” (Heinrich, 1931) derives its basis on the frequency of events. Nonetheless, the severity component in quantifying risk, which, in its truest sense, is equally as important to likelihood when quantifying safety risk, has not received significant attention in construction safety research. The purported concept of energy-based safety risk would address this major deficiency and serve as a means to reliably quantify the severity based on the physical characteristics of the hazard.

In comparison to advances achieved in general risk analysis techniques, the development of safety risk analysis methods has lagged due to two fundamental limitations: 1) there is a limited amount of reliable data sources; 2) the employed methods are restricted in their external applications. Of the data sources available, the primary sources used to quantify safety risk include empirical data from private organizations or companies (Desvignes, 2014; Prades, 2014), government statistics (Baradan & Usmen, 2006; Hinze et al., 2005), and opinion-based data (Brauer, 2005; J. Everett, 1999; Hallowell et al., 2011; Jannadi and Almishari, 2003). All of these data sources have inherent limitations that reduce the validity and reliability of safety risk assessments. Of all methods, empirical data are preferred because they tend to involve less bias. Unfortunately, researcher access to empirical data gathered by private organizations is limited because they often involve proprietary or confidential information. Although statistics made available through governmental agencies like OSHA and the BLS have provided researchers a credible source from which to develop safety risk analysis strategies, the granularity of government statistics limits risk analysis to the trade, work task, or injury classification level. Widely used in safety risk practices, opinion-based data gathered by industry experts has primarily relied on qualitative risk ratings using numerical or linguistic scales (Baradan and Usmen, 2006; Brauer, 2005; Everett, 1999; Shapira and Lyachin, 2009). However, as one might expect, expert opinion data are limited by the personal biases of human raters. For example, Capen (1976) revealed that subjective probability is heavily influenced by individual biases and that people have erroneous judgment in statistical intuition under uncertainty. Since Capen’s (1976) discovery, many other studies have confirmed this debilitating characteristic of expert opinion data (Gustafson, 1998; Kahneman and Tversky, 1982; Sjöberg, 2000). Thus, more robust empirical data must be explored to improve safety risk assessment techniques.

In addition to data source limitations, conventional safety risk management methods are limited in their breadth of application (i.e., external validity). All safety risk researchers assume that the work can be decomposed into its constituent parts in order to address the construction industry’s dynamic and transient nature (Lingard, 2013). Researchers have used a multitude of techniques to decompose and analyze safety risk, ranging from very high level studies looking at methods to evaluate safety risk amongst different construction trades (Baradan and Usmen, 2006; Fung, et al. 2010) and injury classifications (Hinze et al., 2005) to detailed studies looking at specific construction activities and the risk associated with elemental tasks being performed within those activities (Everett, 1999; Hallowell and Gambatese, 2009; Jannadi and Almishari, 2003). However, these risk decomposition techniques are either so overly broad that they have limited application to individual projects or are so specific that any new construction methods or variation upon existing methods requires a laborious research process to collect new data. Very recently, Esmaeili (2012), Desvignes (2014) and Prades (2014) explored attribute level risk analysis, which allows one to evaluate risk independent of specific tasks and environments by focusing on fundamental characteristics (e.g., uneven surfaces, work at height, etc.). The present study introduces the energy-level risk analysis strategy for the first time, building upon the new attribute-level theory.
2.2 Energy-Based Safety

The impetus for an energy-based safety approach is the concept of energy-based hazard recognition (Albert et al., 2014). According to Carter and Smith (2006), construction workers are customarily poor at identifying hazards during construction because of the industry’s diverse, fragmented, and dynamic nature. The inability to identify hazards in turn results in construction workers being exposed to unanticipated dangers or engaging in unsafe work practices without understanding the severity of adverse consequences (Wilson, 1989). Taking inspiration from William Haddon’s work on safety energy, Fleming (2009) sought to improve worker hazard recognition by categorizing hazards based on the primary energy source that could cause the injury (e.g. motion, gravity, electricity, etc.). Fleming’s (2009) principal theory is that all construction accidents originate from a specific energy source that is identifiable prior to work. When an energy source is released outside of the work plan, the unanticipated loss of control over the energy source creates the potential for injury. Principles of energy-based safety were soon implemented with respect to hazard recognition by an expert team sponsored by the Construction Industry Institute (CII), which identified and predefined ten energy sources relevant to construction to serve as cognitive cues (Albert et al., 2014). Using a multiple baseline intervention research method with six construction crews, Albert et al. (2014) demonstrated a significant 31% improvement in hazard recognition skill amongst workers. Unfortunately, existing literature detailing the use of energy in construction safety is very sparse as the concept of energy-based safety within the construction industry remains in its infancy. However, the initial research results indicate that there is significant promise in using the concept of energy to identify and rank safety hazards encountered in the construction industry.

3 POINT OF DEPARTURE

Current safety risk analysis appears to suffer from two primary weaknesses: (1) a lack of scientifically driven empirical data; and (2) risk analysis strategies which are often narrow in scope, thus limiting their effectiveness when applied to the construction industry’s diverse project portfolio. Inspired by energy-based hazard recognition, this study aims to test the null hypothesis that energy has no significant relation to the severity of an injury by offering a new approach to safety risk analysis using the concept of energy to measure the severity of potential hazards, and, by doing so, seeks to introduce natural principals that will allow safety risk analysis to become more universal in its breadth.

4 KEY NEW THEORY

Energy-based safety risk analysis theory draws inspiration from natural disaster modeling which, in essence, predicts the potential impact of a natural disaster by considering the magnitude of the event and the resiliency of the affected area (Johnson, 2004). This same fundamental analytical approach is taken within the context of energy-based safety risk. Specifically, energy is translated into severity of a potential hazard as the ratio of the magnitude of energy to the resiliency of the impacted human body part and the concentration of energy transferred. The probability, in turn is defined by the various action and inaction that results in the unwanted release and/or exposure to the human body. By quantifying the energy found in these potential hazards, energy-based safety risk analysis may result in a standardized approach to evaluate and predict the severity of potential injuries in any environment, which can subsequently utilize current frequency data techniques with the established principals of Eq. (1) to create a more robust safety risk analysis method Energy within Hazards. When evaluating energy-based safety risk, the magnitude of energy present within a specific hazard must first be determined. To illustrate the concept of energy-based safety risk, consider gravitational potential energy (PE), which depends on the mass and vertical position of an object as shown in Eq. (1), where \( m \) = mass; \( g \) = gravitational constant; and \( h \) = vertical position or height above the ground.

\[
PE = mgh
\]

Take, for example, the conditions where both a tape measure and a sledgehammer are dropped on your hand from a height of five feet. Due to their weight differential, intuitively one would expect the sledgehammer to inflict more damage and have a greater potential for breaking bone. Considering
energy, this intuition can be scientifically proven. Specifically, a tape measure, which weighs approximately one pound, would only inflict five foot-pounds of energy while a sledgehammer, weighing approximately 15 lbs., would transfer 75 ft.-lbs. of energy. Clearly, under these parameters, the sledgehammer would pose a much higher risk for severe injury; however, a change to one of the parameters can result in the tape measure having the equivalent potential to inflict injury. For example, if the tape measure were dropped from a height of eight stories it would transfer energy in an amount equivalent to that generated by a sledgehammer dropped from five feet, thus transferring equivalent energy to the hand. Thus, according to this new theory, a sledgehammer at a height of five feet and a tape measure at eight stories possess the same potential to inflict injury. Although the prospect of a tape measure being dropped onto a hand from eight stories may seem remote, the concept is very real. Recently, a worker on a New Jersey construction site was fatally injured as a result of being struck by a tape measure which fell from a height of 50 stories (Santora, 2014). Although at first seeming comparatively harmless, the tape measure, which weighed approximately one pound, inflicted 500 ft.-lbs. of energy on the worker’s head and ultimately led to the worker’s death.

4.1 Energy Transfer through Contact Area

Although calculating the energy provides an objective basis from which to quantify and rank most hazards on a particular construction site, further detail is required within the context of how the energy transfers to the human body. Specifically, when considering the severity of injury associated with a moving object, the contact area, or sharpness, must be taken into account. For example, by minimizing the contact area of a knife blade through sharpening, the pressure exerted by the blade is maximized with the same quantity of applied energy. Once translated to force, the ratio of the quantity of energy and the contact area helps to define the true potential damaging factor: pressure. In order to model how energy is linked to pressure one must first consider the concepts of momentum and impulse. Momentum is defined as the product of an object’s mass and velocity and impulse, in turn, is defined as the change of momentum per unit of time. The equations for momentum \( p \) and impulse \( J \) are shown respectively in Eq. (3) and Eq. (4), where \( m = \text{mass} \); \( v = \text{velocity} \); and \( \Delta v = \text{change in velocity} \).

\[
\begin{align*}
\text{(3)} & \quad p = mv \\
\text{(4)} & \quad J = \Delta p = m(\Delta v)
\end{align*}
\]

It is important to note that the variables used to evaluate momentum and impulse are identical to kinetic energy \((KE)\) as shown in Eq. (4), where \( m = \text{mass} \) and \( v = \text{velocity} \), and which, as a result of conservation of energy, can easily be found using Eq. (1) for potential energy.

\[
\text{(5)} \quad KE = \frac{1}{2}mv^2
\]

The final step in determining the severity of a potential hazard is to ascertain the pressure, defined as force per unit area, exerted by the energy source. By using Newton’s second law of motion, where force is the product of mass and acceleration, and the principals of momentum and impulse, variables used to calculate an object’s energy can be substituted and used to find pressure \((P)\) as shown in Eq. (5), where \( F = \text{force} \); \( A = \text{area} \); \( m = \text{mass} \); \( v = \text{velocity} \); \( a = \text{acceleration} \); \( \Delta v = \text{change in velocity} \); and \( t = \text{time} \).

\[
\text{(6)} \quad P = \frac{F}{A} = \frac{ma}{A} = \frac{m\Delta v}{\Delta t A}
\]

In order to illustrate the relationship between pressure and the severity of a sustained injury, the one-pound tape measure provides a compelling example. It was determined that dropping this tape measure from a height of five feet was relatively harmless, exerting approximately 5 ft.-lbs. of energy. Replacing the tape measure with a concrete chisel of equal mass (1 lb) and dramatic differences in damage would be sustained because of the sharpness of the concrete chisel. Assuming the respective impulse durations and final velocities of the two objects have equivalent values of 0.05 seconds and 17.9 ft/s, the tape measure, landing on its end, would have an estimated contact area of \(2 \text{ in}^2\), thus exerting a pressure of about 5.6 psi. By comparison, the concrete chisel, with an estimated contact area of \(0.01 \text{ in}^2\), would exert a pressure of 1121 psi. Although the concrete chisel and tape measure possess an equivalent
amount of energy, the large disparity in contact area between the objects caused a drastic increase in the
injury suffered by your hand. For this reason, the contact area, or sharpness, of a hazard must be
accounted for in evaluating the potential severity of an outcome.

4.2 Resiliency

Using the analogy of natural disaster modeling, the magnitude of a natural disaster, such as a hurricane,
does not fully predict the magnitude of damage. For example, due to differences in infrastructure, a
hurricane striking the coast of Haiti would presumably inflict more damage than a hurricane striking the
coast of Florida. This concept, referred to as resiliency, also applies in the context of energy-based
safety risk where the extent of injury caused by a particular hazard varies depending upon the resiliency
of a particular body part to the energy transferred or pressure inflicted. For example, if the unfortunate
New Jersey construction worker had been struck by the tape measure in the shoulder rather than his
head, his injury would almost certainly have not been fatal. In summary, the resiliency of the particular
body part involved is a critical factor in predicting the outcome of a hazard event, and thus must also be
taken into account when evaluating safety risk using energy.

4.3 Conceptual Framework for Energy-Based Safety Risk

A conceptual framework has been formulated to evaluate the safety risk for gravity, motion, mechanical,
and electrical energy sources. The rationale for including these energy sources is that they are
associated with the four leading causes of worker fatalities in the construction industry (falls, struck-by,
caught in/between, and electrocution), known as the “fatal four” (Bureau of Labor Statistics, 2014). The
conceptual framework, which is illustrated below in Table 1, builds upon the principles of energy,
pressure, and contact area previously discussed. With the exception of the body part impacted, the
inputs into the conceptual framework are all objectively measurable hazard factors such as mass,
height/speed, sharpness, and voltage of observable physical objects. To simply illustrate relative
magnitudes and mechanisms by which a severity score can be established, one may consider the each
variable on a 1-3 scale, with 1 representing a low quantity and 3 representing a high quantity. The final
component included in an energy-based risk score is the affected body part. Rating the affected body
part is based on the resiliency levels of different body parts and is also scored on a scale of 1 to 3, with 1
representing a less critical body part such as a hand and 3 representing a more critical body part such as
the head. The Severity Score is calculated by Eq. (7), resulting in a range from 1 to 81. It should be
noted that the conceptual framework set forth below is preliminary in nature and, as such, the hazard
factors used the simplistic 1-3 rating scale in addition to being weighted evenly for purposes of illustration
only. As further analysis is performed, the conceptual framework can be readily adjusted in a variety of
ways to provide for a greater degree of precision; for instance, the use of actual, physical values for the
measurable factors in the place of rating scales.

\[ \text{Severity Score} = (\text{Mass}) \times (\text{Height}) \times (\text{Sharpness}) \times (\text{Body Part}) \]

5 METHODS

The objective of the analysis is to test the proposed theory by investigating the relationship between the
severity of worker injury and the energy present before the injury was sustained. To achieve this
objective, samples of injury reports spanning a three year period were taken from a database consisting of 7,250 injury reports obtained from 281 private construction sources. Reports with sufficient detail to quantify the elements in Table 1 were extracted. Using a system established by Hallowell and Gambatese (2009), the severity of various injury outcomes was classified and assigned a relative rating. The injury classifications, as well as their respective definitions and “relative impact scores”, employed in this system are listed in Table 2.

</table>

*Footnote ~ Average Relative Impact Scores were used for Medical Case and 1st Aid

Despite the relatively large database of text reports from past injuries, the sample size used in the analysis was comparatively limited because fatalities and disabling injuries were (fortunately) rare. To compensate for this limitation, fatality reports were chosen at random from the National Institute for Occupational Safety and Health’s (NIOSH) Fatality Assessment and Control Evaluation (FACE) program. Even so, a lack of injury reports involving the “Permanent Disability” outcome were sparse, and consequently removed from this preliminary analysis on the basis of having an insufficient sample size. Ultimately, the resulting sample size was 40 injury reports, involving 10 injury reports chosen at random for each respective severity level (excluding “Permanent Disability”) in order to maintain consistency for comparison purposes. Once the reports were extracted and compiled, the energy source associated with the hazard involved in each injury report was assigned using either kinetic, potential, or rotational energy techniques. Unfortunately, due to the lack of detail in the injury reports, estimations of object height, speed, and weight were often necessary. To minimize bias, at least two researchers conducted independent assessments.

6 RESULTS AND ANALYSIS

To assess the relationship between accident severity and the magnitude of energy involved in a particular incident, the resulting energy data were compared to the respective severity scores for each injury. By examining the raw distribution of energy contained in the various severity levels, one can see a correlation between the amount of energy involved and the severity level of each outcome (see Figure 1, Figure 2 and Table 3). Because the severity scale and the quantity of energy follow a power distribution, a power regression model was created and confirms a strong correlation, having an $R^2$ value of 0.69. However, although an increase in energy level appears to be positively correlated to the severity of an outcome, there is a wide variability between the various energy levels contained within any specific injury classification. The variability in energy at each severity level relates to the importance of pressure and resiliency as previously discussed. For example, the two injury reports that represented the maximum and minimum amount of energy under the fatality classification involved a 40 ft. crane boom section falling onto a worker and a worker hitting his head after falling 10 ft. off of a ladder, respectively. The crane boom was found to have approximately 40,000 ft.-lbs. of energy, while the worker on the ladder only had 1500 ft.-lbs; however, both incidents were fatal. In addition to the wide variability of energy found within each corresponding severity level, the ranges of energy between corresponding severity levels had significant overlap (see Figure 2). Much like the variability within severity levels, the overlap between severity levels is explained through resiliency and pressure. For instance, the injury report that possessed the highest amount of energy for the 1st Aid severity level and the two lowest energy situations for the
Medical Case and Lost Work Time severity levels possessed nearly an identical amount of energy. The respective outcomes for these 1st Aid, Medical Case, and Lost Work Time injury reports were a 2x4 hitting a worker in the back causing a minor contusion, a worker hit his head on a steel pipe, leaving him temporarily disoriented, and a steel pipe struck a worker's fingers, breaking two fingers. Although these injury reports only varied by 20 ft.-lbs from one another, the three situations possessed very different outcomes due to the factors of resiliency and pressure. Initial results indicate that areas where the energy of severity levels overlap are heavily influenced by resiliency of the human body part affected as well as the pressure exerted on that body part (as indicated on Figure 2, where medical case and lost work-time overlap). Note that there is no overlap between first aid and fatality. These results tentatively confirm the proposed theory, demonstrating that the energy of a hazard has predictive validity in determining the severity of an injury.

| Table 3: Mean, Median, and Standard Deviation |
|-----------------|-----------------|-----------------|-----------------|-----------------|
|                | $\bar{x}$ (ft.-lzs.) | $\bar{x}$ (ft.-lzs.) | $\bar{x}^2$ (ft.-lzs.) | Min. (ft.-lzs.) | Max. (ft.-lzs.) |
| 1st Aid        | 21               | 18               | 16              | 3.9             | 58.5             |

Figure 1: Severity Level vs. Energy (Raw Distribution)  
Figure 2: Severity Level vs. Energy (Raw Value Range)

7 CONCLUSION

To reiterate, the purpose of the research was to test the null hypothesis that energy has no significant relation to the severity of an injury. In order to test the null hypothesis, a theory using the concepts of energy, pressure, and resiliency was introduced and tested using a sample of 40 reports randomly extracted from a database containing 7,250 injury reports obtained from 281 private construction organizations spanning a three year period as well as NIOSH's FACE database. Despite considerable variability in energy data within injury classification levels, statistical and regression analysis indicate that energy may have significant predictive capability in relation to the severity of an injury outcome, thus tentatively confirming the proposed theory. Although the research provides the preliminary evidence of energy’s predictive validity, the study performed possessed limitations. Most notably there was a lack of detailed data for fatal and disabling injuries. The injury reports used for analysis were sufficiently detailed for this analysis. Future researchers, however, could find greater levels of detail by increasing the breadth of the reports analyzed. Furthermore, the study only included three of the ten identifiable energy forms on a construction site (gravity, motion, and mechanical). Supplementary exploration needs to be conducted.
regarding other hazardous energy sources in addition to more detailed research exploring the energy sources used in this study.

The inspiration for assessing whether energy can be useful in predicting the severity of an injury arose mostly from the CII-funded work of Albert et al. (2014), who were recently able to improve deficiencies in worker hazard recognition by using the concept of energy to better identify hazards. The safety risk practices currently employed within the construction industry share flaws similar to those of past hazard recognition techniques in that they lack scientifically driven empirical data and are narrow in scope, thus limiting the effectiveness of these practices when applied to the construction industry's diverse project portfolio. By introducing the concept of energy into safety risk analysis within the construction industry, the goal and intention would be to improve upon these two weaknesses.

According to Lingard (2013), safety risk analysis is based upon decomposing construction activities and hazards in order to quantify risk. The concept of energy builds on this view by breaking down hazards to their most elemental form, thus making energy, when combined with probability data, theoretically translatable to nearly every construction project or activity. The initial research results indicate that energy has significant potential for predicting the severity of an injury. The outcome was that energy-based safety risk analysis shows significant promise in becoming a much improved and more universally accessible technique for safety risk analysis within the construction industry. If developed to its full potential, indications are that use of energy-based safety risk analysis will allow practitioners to more accurately model and respond to hazards as they are introduced and removed from a work environment. The method may also have application to BIM where energy may be calculated during work sequencing and work packaging.

AN INVESTIGATION INTO CURRENT TENDERING PROCESS IN SAUDI CONSTRUCTION PROJECTS

S. Al-Hammadi¹,²
¹ Shaqra University, Saudi Arabia
² dr.alhammadi@su.edu.sa

Abstract: Underachievement in project performance, lengthy delays and financial loss in construction projects in Saudi Arabia has been realised due to the approach of current tendering process. This research aims to investigate the current process adopted for tendering construction projects in Saudi Arabia. The study employs a qualitative study of three organisations utilising semi-structured interviews with managers to gauge clients, contractors and consultants' perspectives on current tendering practice and associated challenges and impacts. Results revealed a number of challenges and impacts facing stakeholders to the adoption of a holistic approach to tender planning process. These include: stakeholders' dissatisfaction, lack of effective strategic plan for tendering system; rigid, inappropriate and bureaucratic tendering process; complicated legalisations used for entering large international construction firms in Saudi construction markets; unscheduled tendering of huge number of projects by both public and private sectors; failed and breakdown projects; low quality of building and expected high expenditure on maintenance and operation. Solutions focus on formulating a strategic planning involved the key factors. The study is one of the few studies that have investigated Saudi tender process from a practical views and dynamic perspective. It reveals not only the challenges and impacts of current situation, but also draws a road map for a better solution.

1 INTRODUCTION

The construction sector plays an important role in the Saudi economy and is closely related to other economic sectors. Additionally, construction is one of the major industrial sectors of the Saudi Arabian economy, worth more than $20 billion accounting for 11.7 per cent of Gross Domestic Product (GDP) in 2011. It is also regarded as an important and reliable indicator of trends and the success of the national economy. The Saudi construction industry has faced several changes since 2006 due to the national dependency on the nearly stable prices of oil revenues. A significant number of construction projects are currently being implemented in both public and private sectors. Despite the high government expenditures on the construction sector, there are concerns about the underachievement of project performance, breakdowns, delays, cost and time overruns, and client dissatisfaction.

The Saudi construction is facing serious challenges in terms of project tendering process. Lack of emphasis on strategic planning to improve the tendering process resulted in some negative impacts such as aborted projects or incomplete tender documents, and lengthy delays that have caused underachievement in project performance and financial loss. Indeed, official government statistics reveal tender inadequacies and shortcomings in over 3000 public projects. Al-Kharashi and Skitmore (2009) agreed with the Ministry of Economic and Planning (MOEP) (2011) report about the most influence on
underachievement performance in Saudi construction projects is the lack of innovative process related to tendering strategy.

Among the required development in construction industry is the need to apply the partnering with international firms. Nevertheless, the globalization of construction, the pressure on resources on one hand as against rising expectations of quality on the other, the need to adopt a long-term perspective to position the economy appropriately and so on, have created a situation where nations and their construction industries need to adopt tendering strategies. However, literature appears that little has been published relating to current tender process in the context of the Saudi construction industry. Specifically, a review of literature revealed that no publications have addressed the challenges, impacts and solutions related to the Saudi construction projects.

2 LITERATURE REVIEW

The construction industry is an important part of the economical backbone in many countries (Ngai et al., 2002), often accounting for between 7-10 percent of the Gross Domestic Product (Voordijk et al., 2000). In many countries the construction industry has, however, attracted criticism for inefficiencies in outcomes such as time and cost overruns, low productivity, poor quality and inadequate customer satisfaction (Chan et al., 2003). In order to achieve successful governance of construction projects a holistic and systemic approach to procurement procedures is crucial (Eriksson and Pesämaa, 2007).

In construction management literature several studies have indicated that procurement systems have significant effects on construction project performance. Noted in this direction are studies of Rasid, Taib, Ahmed, Nasid, Ali and Zainordin (2006) and Hashim (1999). Studies of Ogunsanmi, Iyagbaand Omirin (2003), and Dada (2012) all confirm the use of various types of procurement methods for project delivery in Nigerian construction industry which significantly affect the performance of most projects. The study of Hashim, M.B. (1999) also confirms the effects of procurement methods on performance of construction projects in Malaysia.

The common approach to procurement used in Saudi construction sector is the Design-Bid-Build (DBB). Ibbs et al. (2003) describe DBB as the method in which a project is separated into design and construction phases which means that construction can start when the design is completed. Idoro and Iyagba (2008) state that in the DBB, the project delivery process in both design and construction are separated. However, this method was criticised by a number of researchers especially in Saudi construction. Al-Ghamdi (1999) and Arain (2002) reported that conventional procurement practice in the Saudi construction industry does not involve the contractor in the design conceptual phase. Involvement of a contractor may assist in developing better design and reduce the interface problems with designers (Arain 2002; Adrian 1983; AL-Hazmi 1987). On the other hand, Design build (DB) was described by Chan (2001) as a recent arrangement that is conceived as a solution to the numerous shortcomings in DBB. Moreover, it has been defined as an arrangement whereby a developer contracts a single part or entity to perform both design and construction of a facility or project under a single DB contract (Bennett 1992). Nevertheless, although the general acceptance of the main feature of the method that focuses on the integration between design and construction stages, it observes that the method has variants (Akintoye, 1994 and Turner, 1997).

Practically, there has been a concern with the problems of bidding strategy since the time of Friedman (1956) to explore bidding decisions and establish methods within the modelled bidding decisions. Egan (1988) reported that a competitive tendering must be replaced with long-term relationships based on clear measurement of performance and sustained improvements in quality and efficiency.

In the Saudi construction, projects are usually awarded to the lowest bidder, neglecting other considerations such as technical measures and historical records, such considerations are facing a real challenge. In an early study conducted Aitah (1988), it was found that projects awarded only to the lowest bidder had, in general, a lower performance. Similarly, Alotaibi et al. (2013) identified the current procurement practice used in Saudi construction as one of the critical failure factors that contributes to the underachievement of projects’ performance.
Considering the lowest price or bid as a criterion for selecting a contractor has been criticised by many authors (e.g. Hatush and Skitmore 1998; Stein et al. 2003; Al-Reshaid and Kartam 2005). They collectively argued that the serious problems which arise within the construction phase as a result of accepting the lowest bid can lead to serious overruns of time and cost, serious quality problems and eventually to increased litigation. Many of the research studies criticized the lowest cost tendering process as the main procurement tool and suggested some other criteria to select contractors in order to achieve better performance (Egan 1998, Sebastian 2011, Eriksson and Nilsson 2008, Tikkanen and Kaleva 2011).

Padhi and Mohapatra (2010) claimed that past work performance of contractors is not taken into consideration during the selection procedures and thus, the project will be delivered with poor quality because of the contractor’s poor record of past work performance. Ogunsemi and Aje (2006) highlighted that past performance; contractors’ experience; workmanship quality; tender sum and plant and equipment were the most important criteria for contractors’ prequalification evaluation in Nigeria.

The research studies that aim to assess the holistic strategic plans for tendering construction projects are still limited. Most of the tendering research studies concerned are on evaluating the technical aspects for tendering, evaluating bids and tendering models.

This research aims to investigate the current process adopted for tendering construction projects in Saudi Arabia. But without a better understanding of this phenomenon, it would be hard to address precisely the issue in theory and practices. Hence, an appropriate research strategy and method was required.

3 RESEARCH METHODOLOGY

To achieve the study aim, the research methodology was developed as shown in Figure 1. Consequently, a case study strategy was adopted in this research as an in-depth investigation into the Saudi tendering process to provide an in-depth insight into the current tendering process; and identify challenges and impacts, and forward solutions to address the identified tendering hindrances.

Eight case studies were conducted that used two data collection methods: semi-structured interviews and eight case studies-related documents. For the eight cases, relatively big Saudi companies carrying multiple projects in the housing, industrial and office buildings were considered. From each company three projects were considered. The study of cases was focused on projects already performed or near the end of the completion from which it was possible to obtain required information regarding the procurement process. Three such projects were taken from each company/case totalling 24 projects for eight cases.

Semi-structured interviews were selected as a style of interviewing to give form to the interviews whilst allowing probing questions (Hussey and Hussey 1997; Fellows and Liu 2008). The semi-structured nature of the interview technique enabled researchers to allow the interviewees to elaborate on any topic, but required all predetermined topics to be covered (Love et al. 2002). Therefore, it enables the researcher to probe for further insights and clarification while maintaining some structure in the views collected.

The semi-structured interviews were held with 72 key stakeholders as shown in Table 1 who are involved in the planning and implementation of projects. In each case study project (three projects for each Case Study), 3 representatives were selected, one each from the client, consultant and contractor. Candidates were selected based on multi-criteria: their accumulative experiences in identifying challenges and impacts in such topic, their positions, and their qualifications, involved in tendering committees. Each interview lasted between 90 to 120 minutes to cover the identified issues and to ensure that the necessary information was obtained. The interview sessions were taped, at the interviewee’s discretion, transcribed and coded. The template developed for the interviews includes personal background, current tendering process, challenges, impacts, and suggested solutions which are related to tendering process. A framework analysis technique was used to analyse the interviews as reported by (Ritchie and Spencer...
1994). Furthermore, eight case studies-related documents such as governmental purchases system, invitation documents, tendering documents, project contract documents, prequalification request documents were used and analysed as case studies-related archives to gather the needed information relevant to the eight cases. Qualitative content analysis was used to analyse these documents. During the analysis of data, the factors involving challenges and impacts were not ranked but only identified.

4 FINDINGS

The findings obtained from the eight case studies for both the documents and semi-structured interviews were categorised into three groups: current tendering process challenges; impacts of the current tendering process; and suggested solutions.

4.1 Current Tendering Process Challenges

Table 2 below shows a list of challenges that were identified by the interviewees.

The respondents agreed that the current tendering process is unsatisfactory and could not lead to a successful outcome for projects. All respondents agreed that the main problem is the lack of an effective strategic plan that contributes towards organising the tendering process. Most of respondents considered the bids evaluation and contractors’ selection based on lowest price as a major challenge. Contractors stressed that the long and slow tendering procedures adopted, especially by governmental sectors as a major challenge. Contractors also considered the use of DBB method as one of the main challenges and called for using Design and Build (DB) method to avoid serious mistakes that could occur during the design process. This was rejected by the consultants and clients who argued that generally contractors lack insufficient skills and relevant experiences. On the other hand, clients disagreed with contractors in relation to slow procedures with regards to awarding the projects, which are considered sensible for identifying the targeted competitors. Consultants and contractors criticised the mechanism adopted for offering very large projects as a single package. Clients concurred with other stakeholders about the adopted mechanism, which in their view is due to end-users’ requirements, as well as economic considerations.

These stakeholders' conflicts would suggest that strategic planning for tendering is impeded by lack of clear collaborative framework. All respondents agreed that the inflexibility and bureaucratic process used in the governmental purchasing system is a significant challenge. In this respect and as a reference to a good practice, the respondents referred to the successful projects implemented by private sectors, which is due to the flexibility and organized process used in tendering projects. Clients and consultants pointed out that despite the shortage of experienced contractors in the Saudi market, there is a complicated legislation used by the government to grant large international firms part of construction contracts.
independently, without using the approach of joint ventures. All respondents considered the lack of a central database or league table used for assessing the contractors' performance is also a critical barrier in the tendering process. Additionally; they identified other challenges, namely lack of references of ruling and issuing the tendering plans, and who should be responsible for managing these processes.

4.2 Impacts of Current Tendering Process

The second classification identified from the findings is an impact of the challenges due to using current tendering process on the projects in the Saudi construction industry as shown in Table 3.

<td>client &amp; consultant</td>
</tr>
</tbody>
</table>

All respondents agreed on a number of direct impacts on the implementation of projects. They emphasised the lengthy completion delays or failed projects. This resulted in retendering a huge number of projects due to insufficient offered bids or withdrawn failed projects. The majority of respondents, particularly clients and consultants argued the financial loss due to failed and retendered projects which finally influences the cycle of the national economy. Contractors discussed the unclear process used for tendering in terms of criteria which affected the fairness of awarding the bids. Consultants and clients criticised the strategy of competition used by contractors in which the contractor could evaluate his capabilities. This resulted in a number of bankrupt contractors which has led to direct impacts on delivering successful projects. This has created several disputes and claims between contractors and clients which often have to be solved in litigation.

Contractors stated that the use of DBB method contributed to mistakes and discrepancies in design documents, delays in producing design documents, unclear and inadequate details in drawings, and the complexity of projects design, insufficient data collection and surveys in the early stages of design resulted from the current tendering process.

A shortage of resources was identified as one of the impacts resulting from the use of the current tendering process. This has placed considerable pressure on achieving the sustainability of natural resources. Respondents discussed the breakdown of many projects due to the shortage of resources as a result of huge demands coming from the construction sector. Moreover, they agreed that the use of the
current tendering process influences the quality of delivered projects due to awarding projects to incapable contractors. Nevertheless, this has occurred because of using the lowest price system. Most of respondents discussed the cost of operation and maintenance which will be affected negatively due to the low quality of project implementation. Public services (water, sanitation, electricity and transportation) have been affected by the tendering process. Furthermore, the process of importing materials from abroad has been affected by the current tendering process, thus resulting in long queues of containers waiting for customs clearance. In addition, labour market prices have been affected by the tendering process and this has resulted in a shortage of labours both skilled and unskilled. Respondents stated that shortage of specified lands owned by clients for tendered projects appeared as a major impact and was a hindrance at the start of projects. They fully agreed that the current situation increases the price of materials and labour and has a direct influence on the cost of the projects execution, for either ongoing or future projects. Additionally, the current situation contributed towards realising the large differences between estimated cost of projects and the final executed cost.

4.3 Suggested Solutions for the Tendering Process

Many solutions and suggestions were delivered by the respondents as shown in Table 4.

<td>Adopting innovative procurement techniques (partnering)</td>
<td>client</td>
</tr>
</tbody>
</table>

All respondents suggested that developing a comprehensive strategic plan based on the real needs is necessary. This plan involves developing an effective system for bid evaluation which is not dependant only on the lowest bid price. Additionally, this plan should focus on supporting and encouraging small and medium local contractors. This can be done by aligning local firms with the participation of international firms to improve the performance of construction projects, as well as allowing the transferring of their experiences to the Saudi construction sector. Indeed this will reflect positively on the performance of local contractors.

However, most of contractors disagreed with the participation of international firms and were concerned that it would reduce the opportunity of winning a large number of projects for Saudi builder. Adopting innovative procurement techniques are delivered by client as a best tool for delivering successful projects (partnering). Consultants and clients stated that attracting the international firms is considered as part of strategic plan. At the same time, they focused on the prequalification of those contractors as major criteria for their selection.
Clients suggested that a workable system should be developed to organise and manage the engineering offices and contractors. This could start with establishing a central database containing the required information about consultants and contractors such as: qualifications, classification, past and current performance, financial abilities, skilled staff and available construction equipment. Consultants and clients suggested that the way of tendering projects as a single large package should be avoided because it has been recognised that projects are affected by the failure of other projects implemented by the same contractor. Respondents suggested that rescheduling the tendered projects should be done based on determined criteria to mitigate the current fragmentation, and improve the overall performance of construction sector. The criteria should depend on crucial factors such as high priority projects, project documents’ readiness, site’ readiness and the clients’ capabilities for supervising the projects. Clients suggested that government could place additional monetary funds in other investments rather than the current blending of monetary funds. Respondents agreed that the aforementioned should be involved in an effective strategic plan that should be formulated, implemented and evaluated, to improve the current tendering process.

5 DISCUSSION

The findings reveal that all participating stakeholders were dissatisfied with the current tender process. Additionally, the agreement focused on the serious challenges due to the lack of an effective strategic plan that improves the current tendering process and contributes toward successful implementation. Similarly, Egan (1988) criticised the methodology of using competitive tendering when there was no practical strategic plan adopted by the construction industry. Results also show that the bids evaluation and contractors’ selection based on lowest price are a major challenge. Aitah (1988) pointed out that a lower project performance is considered as the expected outcome of the lowest bid price. It has been argued that the serious problems which arise within the construction phase as a result of accepting the lowest bid can lead to serious overruns of time and cost, serious quality problems and eventually to increased litigation (Hatush and Skitmore 1998; Stein et al. 2003; Al-Reshaid and Kartam 2005). In the context of the Saudi construction, it seems that the lack of a central database for contractors and consultants is regarded as a serious problem.

Impacts of the current tendering process directly affect the overall Saudi construction sector. Retendering huge numbers of projects is a serious challenge of continuing to support the current tendering system. Disputes and claims made by contractors have arisen as a result of delayed and failed projects which resulted in these claims having to go to litigation to be resolved. It was identified that the Saudi construction suffered from a lack of skilled and experienced staff involved in the undertaking of projects (Al-Kharashi and Skitmore 2009). Major mistakes, inadequate design and insufficient data collection and surveys were identified as having a negative impact on the current tendering process. This has resulted in producing low quality buildings and structures and thereby increasing the cost of operation and maintenance of facilities (Assaf and Al-Hejji 2006). Shortage of resources was another issue that affected the performance of Saudi construction projects. The resources of construction materials in Saudi were affected by the current tender system and therefore this affects the sustainability. The need for resources to be concentrated up-front on projects is necessary for any project to deliver greater efficiency and quality.

Solutions delivered by respondents focused on drawing up a strategic plan that contributes towards improving the performance of construction projects and results in leading to the stakeholders’ satisfaction. The inclusion of international construction firms were put forward as a suitable solution to avoid the current challenges which leads to the financial bleeding of the project budget. Rescheduling projects based on proper criteria in parallel with a sound methodology for tendering is a high priority. Establishment of a central database for having information about consultants and contractors is a crucial factor and is a clear priority.
6 CONCLUSIONS

The findings of this research show that there is a common stakeholders’ discontent with regard to the current tendering process, which is adopted in publicly funded projects. A practical strategic planning is necessary to mitigate the negative impacts resulting from the current tendering process, which is based on low bid competitive tendering. This topic will be covered in a further paper. The findings also indicate that the current tendering process is an inappropriate method for the extensive programmes that are implemented in the Saudi construction sector. Furthermore, results highlight the serious problems that may appear in the future when large expenditures are wasted on failed and incomplete projects. Valuable lessons learnt from what is occurring in the Saudi construction sector in terms of challenges and impacts as well as suggested solutions should be activated to achieve sustained improvement. It is recommended that further research should be conducted to validate the identified factors that were derived from this paper through specific case study projects. This further research can be extended to the quantification of the performances of the projects due to current practice of tendering process particularly with respect to the factors like time loss, delays, cost, quality, failure rate, retendering, litigation cases etc. Based on an in-depth investigation that takes into consideration the strengths, weaknesses, opportunity and threats (SWOT) to produce solid and robust a strategic plan for tendering to be implemented in the Saudi construction projects. This plan should involve the key factors mentioned by respondents such as (effective system for bid evaluation, rescheduling the tendered projects, extend the invitation to international firms and activate lessons learnt as an improvement tool). A central database centre of contractors and consultants is an essential need to overcome part of that problem facing the Saudi tendering processes.

\textsuperscript{2} PCL, Canada
\textsuperscript{3} MostafaAli@ualberta.ca

Abstract: Using BIM technology is well established in construction projects, especially in industrial projects where a maze of pipes and modules have to be installed in congested work areas under tight time schedule. BIM offers potential benefits (e.g. visualization, collaboration, alignment …etc.) that can be key for complex project success; however, these benefits have not been fully implemented in industrial projects. The authors worked last two years closely with a construction company -which specialized in oil and gas projects- trying to discover ways to maximize utilization of knowledge embedded in BIM models. Though the partner company has used BIM for long time, we noticed many obstacles that hinder reaping the full benefits of BIM for construction planning and control. These obstacles are related to the ability to extend a model by adding new attributes and to link the model to data from external sources (e.g. cost or schedule control information systems). This paper discusses these obstacles, illustrates implemented short-term solutions to work around and mitigate these obstacles, and finally concludes by proposing using semantic web as a long-term solution to overcome these obstacles and clear the path for gaining all potential benefits during industrial projects construction.

1 INTRODUCTION

Industrial projects are one of the first projects to use BIM technology; this is largely due to project complexity and size, as these two factors determine the degree of information technology usage in the project (Thomas, Macken, & Lee, 2001). However, the degree of usage varies based on company policy and employee expertise. (Jung & Joo, 2011) categorized BIM usage into passive and active utilization, passive usage encompass engineering analyses like safety and scheduling; while active usage works on extracting embedded knowledge in BIM.

BIM builds a virtual model that can be investigated and tested before constructing the real project. It offers many benefits for construction projects like saving cost and time (Cooperative Research Center for Construction Innovation, 2007), (Azhar, 2011), and (Gilligan & Kunz, 2007). However, not all benefits are fully gained as some benefits are more popular than others; for example, clash detection and space utilization are more common than automating shop drawings for fabrication (Gilligan & Kunz, 2007).

Although BIM has potential benefits, there are some unsolved issues. These issues can be grouped into contractual (e.g. model ownership) and technical level (e.g. interoperability) (Azhar, 2011). This paper represents a case study regarding BIM utilization in industrial projects. It tracks developing the model in engineering firms and shows the consequences of their decisions on the contractors.
The paper starts by a brief introduction about technologies used or proposed to enhance BIM utilization, then, it discusses current practice and issues found in the partner company’s current practice. Afterwards it presents short-term solutions that have been developed to mitigate these issues. Finally, we conclude by our vision for using semantic web technology as a long-term solution for these issues.

2 CURRENT PRACTICE AND ISSUES

Industrial project model usually consists of multiple sub-models (e.g. structural, mechanical, electrical model, etc.), each model is designed separately and then all models are compiled by engineering firm into one model to review and detect any clashes. After that, the engineering firm issues the model for the contractor as one model. Figure 1 shows IDEF0 diagram for this process.

Engineering firms that work with the partner company use two proprietary software applications (NavisWorks® and SmartPlant®). Based on their preferences, the engineering firm will determine which software they will use and the contractor has to comply with this choice; this adds overhead cost on the contractor including purchasing the two software and training its employees.

![Figure 1: IDEF0 for issuing BIM model for the contractor.](image)

During our work with the model, we observed the following issues:

1. **BIM ownership (contractual level)**: The contractor receives only the compiled model for reviewing and visualization. However, the contractor cannot add to the model and, therefore, any operational attributes have to be saved in a separate database,

2. **Lack of standards (contractual level)**: The same item might be labelled “I beam”, “I-Beam”, or “I Beam column” based on the engineering firm convention. In addition, some items do not have essential attributes (e.g. item type),

3. **Model limitation (technical level)**: The contractor cannot calculate quantity take-off accurately as only boundary volume of the item is available, and
4. **Interoperability (technical level):** It is a tedious task to transfer data between different systems or software. This task requires using intermediate format and it is very prone to error and missing data.

3 **SHORT-TERM SOLUTION**

In order to overcome the previously stated issues, a complete change in the process has to be done. However, this is not always feasible and it will take time to accomplish. Hence, we proposed some short-term solution to work around these issues temporarily while working on a longer-term solution. While developing this solution, we take into consideration two points: 1) **We will try not to change current practice.** In other words, changing the contractual relationship between contractor, owner, and engineering firm to facilitate more effective exchange of BIM details is outside the scope of this work; and 2) **our solution should clarify limitations of the current practice to proof the need for long-term solution.** This section will describe two of our quick solutions that have been implemented in the company.

3.1 **Filter by discipline**

As we stated earlier, the partner company receives multiple BIM models from different engineering designers compiled as one model (Figure 2). With the lack of standards and conventions between the designers, the company found it hard to filter model items based on trade (e.g. extract all concrete piles, or all pipes). A coordinator has to visually inspect model items and add them to different display set based on their type. This is a daunting work that takes days to complete, and it becomes more problematic in case of fast tracking projects where new models come sometimes every week.

![Figure 2: This BIM model lacks essential attributes to filter by trade. This model contains more than 700,000 model items.](image)

By investigating four models for four different projects that has been done in the last ten years, we found that although there is no explicit attribute that indicates the item trade, well-defined rules can be used to extract trade’s items. For example, in one of the projects we found that almost 30% of the pipes have an attribute called “Source file” that ends with “dgn”, different rules can be found for the rest of the pipes. Therefore, we decided to define a “Filter” structure that contains attributes for one rule. Figure 3 shows an example of a filter that captures the previously stated rule. It contains seven attributes as follows:
1. Criteria ID: to intersect multiple filters as shown later;
2. Condition ID: because filters are stored in SQL database, it was required as a part of the primary key;
3. Category: the trade name to apply the rule;
4. Category display name: this points to the tab name in Navisworks (Figure 3), although this attribute is not essential, we preferred to use it as it reduces the process time significantly;
5. Property display name: the property name as in Figure 3;
6. Condition: either equals, not equals, contains, not contains; and
7. Property value: the value we are looking for as in Figure 3.

![Figure 3: An example of a rule.](image)

Table 1 shows the set of rules used to extract all items for four trades (namely; concrete, pipe, steel, and piles). It took three trials to get all items by refining the rules to capture these items. These rules are stored in SQL server database and a .NET plug-in reads the rules and applies them on the 3D model.

As shown in Table 1, some trades require one rule while others require more than one. This clearly will depend on the project. However, we designed our tool to compile multiple rules using intersection and union to accommodate any complex filtering case. The general formula for intersection and union is:

\[
\text{Trade} = (\text{Filter 1 AND Filter 2 AND \ldots\ldots Filter N}) \text{ OR (Filter N+1 AND Filter N+2 AND \ldots\ldots Filter M}) \text{ OR \ldots}
\]

For example:

\[
\text{Concrete} = (\text{color is green and source file contains “dgn”}) \text{ OR (Color is blue and Material is “C50”)}
\]

If more than one filter have the same criteria ID then they will be combined using intersection (AND operator) to form a filter block, then filter blocks will be combined together using OR operator. For example, there are four rules for pipes in Table 1, the first two have a criteria Id of “2” while the other two rules have a criteria Id of “3”. This means the result of the first two filters will be intersected together to form the first block then the results of the other two filters will intersected together to form the second block then the two blocks will be merged using union operation as in Figure 4.

Using the plug-in to apply these rules finds all items in the four trades, the plug-in will label each item with its trade so it can be retrieved later; in addition, a display set is created for each trade as in Figure 5.

### 3.2 Work areas

With complex project that covers large area and consists of millions of components, it is always a good practice to partition it to small work areas. The partner company partitions their project according to two criteria: “Work packages” and “work areas”. Work package represents a set of items that have to be installed together and costs 500 to 1000 man-hours (i.e. one rotation), while work area represents a set of
items that reside inside an imaginary 3D box. These two breakdown criteria are independent of each other, so one pipe might span multiple work area (because of its length) while it belongs to one work package.

Because of model ownership issues and software limitation, work area boundary boxes cannot be directly applied on the model. Therefore, we developed a plug-in using .NET technology that reads boundary boxes coordinates from database (Figure 6) and create a display set that contains all items inside any boundary box. This enables the user to isolate one or more work areas easily as in Figure 7. Moreover, these display sets can be accessed by people on site using handheld devices to check a virtual prototype of their required task.

Table 1: Set of rules required to capture four trades in the project.

Figure 5: A display set will be created for each trade and each item will be labeled.

Figure 6: Work Area boundary box is defined in a separate database.

Figure 7: The plug-in will create display set for each work area, so it can be filtered easily.

4 LONG-TERM SOLUTION

4.1 Overview

The aforementioned solution overcomes the obstacles but it shows many limitations that can be overcome only by changing the current process. These limitations can be stated as following:

- Manual inspection of the model to find filtering rules;
• Rules can filter steel items, but it cannot identify their classes;
• Need for customized configuration for each project (impossible to automate); and
• Any non-graphical data (e.g. work area boundary box and scaffold log) have to be stored in a separate database, which requires management and sometimes causes discrepancies.

A more effective solution will require a complete change in the process to streamline the flow of data from engineering firms to construction and allow linking multiple data sources flawlessly. The first step, in our opinion, is using layered system approach. Layered system separates data layer from the application, which will eliminate interoperability issue and any software limitation while providing one source for all kind of data.

The structure of the data layer should be chosen carefully as it has a direct impact on all aspects of the system. Here, we suggest using semantic web technology; many scholars (e.g. Jung and Joo 2011) have mentioned its potentials in BIM future to facilitate data exchange and information integration.

Our long-term solution (Figure 8) consists of two main steps: creating the data layer and using it to automate some tasks (e.g. schedule generation). The first step will require developing ontology for the data layer, which stores all attributes related to BIM model items, and another component will use shape recognition techniques to recognize unlabelled items and 3D legacy CAD models.

After defining the data layer, many applications can be developed to automate different task. We selected three applications (partial models, schedule generation, and scaffold discovery) that we thought would be most useful for a contractor. The following two sections give a brief introduction to shape recognition and semantic web technology as they apply to the proposed long-term solution.

4.2 Shape recognition

Since the mid-1970s, Computer Aided Design (CAD) starts to replace traditional paper drawing as it provides more quality, facilitates editing, increases productivity. However, CAD systems lacks object oriented concept, which limits the ability to share data between different systems (Anumba, et al., 2008). However, the advent of BIM quickly supersedes CAD systems as BIM seams to address CAD limitations. Yet, there are huge legacy projects, which use CAD models.

On the other hand, the proliferation of 3D objects required new methods to search and query these objects (3D objects retrieval) as traditional text search is insufficient (Funkhouser, et al., 2003). There are many researches regarding 3D object retrievals (see (Cardone, et al., 2003), (Iyer, et al., 2005) and (Tangelder & Veltkamp, 2008)) that have been used to many application like cost estimation in engineering mechanics by comparing the current model with previously done models (Cardone, et al., 2003).

The basic idea behind 3D objects retrieval is finding the shape signature (also called descriptor and shape representation in some references) and compare it the previously stored signatures database. The similarity between two 3D objects is measured by the distance between the two signatures (zero means the two objects are identical).

4.3 Semantic web technology

During the project life cycle, different parties (e.g. architectures, engineers, contractors...etc.) generate a sheer volume of documents and drawings (Rujirayanyong & Shi, 2006). These documents used to be stored in binders; each binder –which represents a project or a cycle - was stored in lockers. Accessing data from these binders requires a huge amount of time and effort to the extent that companies have to hire people just to archive and organize these binders.

With the advent of PCs, binders have been replaced by folders that contains electronic version of all documents and drawings (scanned or CAD drawings). This means faster information retrieval in a cheaper way. However, as governed by old expertise, PCs have been used to store files without paying
much attention to describe their contents. That means user will have multiple files that should be explored manually to find the required information.

(Berners-Lee, et al., 2001) suggest extending the structure of World Wide Web to a computer-readable format that called semantic web. Semantic web will use schema (called ontology) to define the data stored in machines. This will enable machines to interpret the data instead of just storing them. Using this powerful structure, machines can link multiple data sources to generate information automatically.

Semantic web utilizes two profound technologies: eXtensible Markup Language (XML) and the Resources Description Framework (RDF) (Berners-Lee, et al., 2001). XML is very similar to HTML language (that is used for current World Wide Web); however, it gives the user the ability to define his own tags and structured them in any sophisticated way to capture complex data model that cannot be contained in traditional database. Though its flexibility, it is hard for anyone to build on or extract data from existing XML file other than the creator due to its arbitrary structure. On the other hand, RDF specification has been developed by World Wide Web Consortium (W3C); it uses triples (subject, predicate, and object) to express data. RDF provides a standard way to exchange data (Segaran, et al., 2009).

Incorporating these two technologies will offer data model flexibility and yet a standard way to represent data; however, it requires another component that can identify similar concepts from different data sources. For example, how the machine can know that the “mouse” in animal context is similar to “mouse” in mammal context while it is different from “mouse” in hardware context or from the programming language “mouse”, here where ontology comes to play as it uses Uniform Resource Identifier (URI) for different concepts. Therefore, ontologies are an essential tool for merging data from different sources (Deshpande & Kumbhar, 2011), and semantic web success depends on ontology proliferation (Maedche & Staab, 2001).

In construction domain, semantic web applications can be grouped into files’ management and knowledge extraction. As an example of files’ management, (Jiayi & Anumba, 2008) utilized semantic web technology to discover relations between construction project files. In addition, (Wang, et al., 2011) developed ontology to manage construction files contents.

Regarding knowledge extraction, researchers developed ontologies to extract information from 3D models: For estimation purposes, (Lee, et al., 2014) developed an ontology to evaluate multiple work items for tiles. Another ontology is developed by (Zhang & Issa, 2013) to extract partial models from IFC format. However, most of these applications have been verified by simplified case studies rather than real ones.

4.4 Long-term solution summary

The following list summarizes the main points of the proposed solution and states success criteria for each point:

1. **Create ontology to enable error-free exchange of data** that should be able to merge data from different sources (e.g. combine two 3D parametric models). **Success criteria**: Using Quality value (Fröbel, et al., 2011).

2. **Recognize 3D shapes** and convert it to the proposed ontology. There are many techniques to calculate shape signature to recognize 3D items; these techniques vary on their efficiencies and computational power based on the type of 3D object (e.g. 3D solid or 3D surface) and the degree of intricate details. We propose using shape distribution technique (Osada, et al. 2002) because of its robustness and insensitivity to small details (i.e. It will not be largely affected if the item missing some parts). This step will be applied on legacy CAD projects and unidentified items in BIM models. **Success criteria**: a ratio of correctly recognized objects over total number of objects.

3. **Generate partial 3D models based on the proposed ontology**, After constructing and populating our ontology, it can be queried using the semantic query language (SPARQL). It will be used to filter
the model items by trade, work package, work area ...etc. to generate partial models. These models will be very helpful for tradesmen who need a 3D model for only their trades within a specific work area. **Success criteria:** Expert opinion.

4. **Automate entities mapping to a schedule** by mapping every work package (“work package is a detailed plan that contains 500: 1000 hours to be executed during one rotation” (Ryan 2009)) to an activity and create relations based on spatial attributes and traditional sequences between trades. **Success criteria:** Expert opinion.

5. **Scaffold discovery** based on reported progress, the system will discover required scaffold ahead of time so the user can remove this constraint before actually starting the required task. The system should estimate erection man-hours based on historical data. This will be an example of automation in execution phase. **Success criteria:** Expert opinion and scaffold estimation models.

![Diagram](image)

Figure 8: Long-term solution framework: shape recognition algorithms will be used to classify items. These data will be stored on ontology data format that can be queried using SPARQL to generate partial models. It also can facilitate automating schedule generation and scaffold discovery.

5 **CONCLUSION**

This paper discussed a case study related to the use of BIM by a partner company on industrial projects. We identified a number of obstacles regarding implementing BIM technology. In order to overcome these obstacles, a solution that relies on multiple filtering rules is proposed as a short-term solution that can mitigate these obstacles, but has limitations and cannot be generalized. Therefore, we propose a different approach that relies on separation of the data layer from the model and the use semantic web technology to facilitate sharing data between different users and extraction/integration from different information sources. This approach can automate different tasks like generating partial models for trades, schedule generation, and scaffold discovery.

INTEGRATING BUILDING INFORMATION MODELING AND CONCEPTUAL DESIGN TOWARDS EFFECTIVE FACILITIES MANAGEMENT: A FRAMEWORK TITLE

Elaf Al-Kattan¹ and Ahmad Jrade¹
¹ Civil Engineering Department, University of Ottawa, Ottawa, ON, Canada

Abstract: The engagement of Facilities Management (FM) during the conceptual design stage of building projects has been recently explored. Incorporating FM during the design stage through the concept of BIM has the potential to minimize the possible waste of project resources (time, money, materials, and sustainability impacts) especially during the operational stage while offering the essential tools to keep buildings running to the required living standards. This paper proposes a framework to develop an integrated conceptual design model towards effective FM. Based on an intense literature review and series of interviews with FM and design professionals, this innovative framework is created to fulfil the following basics attributes: (1) tackling the key factors that affect FM; (2) Identifying the most effective stage of design (conceptual design) to involve facility managers; and (3) Detecting the major aspects that will directly contribute in enhancing the quality of managing, operating and maintaining facilities at the early design stage of a project. The expected results of the integrated BIM-FM model should show the importance of facilities managers’ contribution during the conceptual design stage that leads in reducing the operating and maintenance costs, while providing 3D Integrated Design within Building Information Modeling (BIM) environment by generating list of design alternatives through design simulations. An actual case project is used to test the models’ capability and workability.

1 INTRODUCTION

The use of advanced materials and building technologies in the construction industry has been evolving, particularly in the past three decades. Consequently, complex building systems and supporting services are implemented, which have increased the need to bring the Facility Manager (FM) on board at the early design stage, known as the conceptual design stage (Mohammed & Hassanain, 2010). The International Facility Management Association (IFMA) defined facility management as “a profession that encompasses multiple disciplines to ensure functionality of the built environment by integrating people, place, processes and technology” (Wang et al., 2013). The data required to operate and maintain any building is usually enormous and requires an advanced integrated platform to fill the existing gap that resides in missing, misleading and misplacing project information (Al-Hussein, 2000). BIM is an integrated process that is used to facilitate the exchange of design and construction information to project participants. It is the act of collecting and of using consistent, reliable and sufficient data to support any desired activity throughout the construction lifecycle (BIMCAN, 2011). All of the building information is translated into a digital format that is represented in the modeling process and it is used to support integrated data exchange in a secure reusable fashion. These models create a platform in which physical and functional features can be explored through visualization, simulation and analysis of the existence of the physical facility/building (BIMCAN, 2011). The use of BIM by facility managers will provide all the necessary information for the building components to keep buildings up to the required living standards, while minimizing possible
wastes of resources (time, money, materials, and sustainability impacts) associated with managing those resources. Furthermore, BIM enables facility managers to obtain access to all life-cycle information of the project, especially during the planning and implementation phases by allowing them to supplement their professional inputs towards a more efficient FM (Sabol, 2008). Moreover, BIM is ideal to categorize, modify, monitor and integrate data gathered from various building systems and components throughout the entire lifespan of the project and to secure facilities’ information and data (i.e., CAD drawings, operation instructions, maintenance manuals and schedule of equipment).

A study completed by BIM-Canada in 2011 indicated that most of the current commercial tools used in BIM focus on the needs of the planning and designing phases of a building project. Currently, other parts of the building lifecycle are being considered by various software developers to add the required tools to support the activities that take place during the construction and operation phases. These tools will offer access to new BIM tool functionality, either through add-on modules or through embedding the new BIM tools’ functionality in their own main applications or through using existing BIM applications and applying their required improvements as add-ons. Add-ons will usually come from third party developers who have access to large vendors’ databases. Although this approach has significant benefits to the user, such as effective workflow and seamless integration between modules, there are also disadvantages, such as the compatibility issues resulting from miscommunication and lack of integration (BIMCAN, 2011).

Mohammed & Hassanain (2010) stated that an increase in the cost of maintenance during the operation of systems and components can result as a consequence of deficiency in design. Currently, as buildings are designed to meet greater building standards, design can have a positive influence during the operating and maintenance stage of buildings. The effects of decisions made during the design stage can have far-reaching effects on future building maintainability (Mohammed & Hassanain, 2010).

In 2012, The British Institute of Facilities Management (BIFM) listed the following consequences of the British government’s role in specifying the use of BIM in all governmental projects effective in the year 2016. These benefits will be spread across the globe as the benefits of BIM concepts and its tools starts to arise. BIM can support the creation and maintenance of facilities in a more efficient way, lower carbon emissions, lower and enhance operation costs, and create more effective and safer places to live and work. However, this is not achieved without the involvement of an integrated project team that includes the FM at the early stages. Moreover, while addressing the barriers to FM engagement, the following is stated (Tranced, 2012): “Databases are absolutely key to the issue of interoperability for different tools, to enable software from different manufacturers to talk to one another.” They also added that, “In the UK the government is targeting level 2 BIM, which accepts a series of architectural, structural and MEP models requiring a tool to pull them together. The UK government cannot spend on any number of interfaces between current BIM applications (Planet FM, Maximo, Revit, Bentley, etc.), and it cannot support proprietary software so it has to have something that’s open. Because, of this, it is adopting the freely available, non-proprietary system called Construction-Operations Building Information Exchange (COBie) as an information exchange mechanism between information models and asset management systems” (Tranced, 2012). This should encourage the use of one of the widely-used BIM applications, which in this paper will be Autodesk Revit.

Becerik-Gerber and Jazizadeh (2011) designed an online survey based on the outcomes of in-depth interviews with FM. The survey distributed to FM professionals to determine the current practices and interests related to the application of BIM in FM. The results, as illustrated in Figure 1, show that the most significant operational functions that FMs are looking to include in BIM are energy management, maintenance, and repair and space management. These results are going to be the basis of the proposed model, since those are the most measurable components that can affect FM during the conceptual design stage of a project.
Furthermore, the participants of that survey were asked to share their comments and thoughts about the difficulties they are facing in implementing BIM in FM. The participants’ responses were categorized as: 1) Unclear and invalidated benefits of BIM in ongoing FM practices (for example, unclear productivity gains, or benefits gained from reduced equipment failure and better-automated building energy usage); 2) The amount of work that has to be done in order to define the FM-specific needs for which a model is necessary and how that model should be prepared to meet these needs; 3) Lack of interoperability between BIM solutions themselves and between BIM solutions and FM systems; 4) Lack of demand for BIM deliverables by owners due to the uncertainty about the potentials of using BIM; 5) Lack of clarity about who will be responsible for project insurance and contracting; 6) Lack of FM standards and working process; and 7) Lack of experience among facility managers in using BIM technology.

The model’s proposed framework will be created in an attempt to fill the gaps identified from the implemented literature review. It will explore the abilities of BIM concepts and the required role that FM should perform as early as possible during the conceptual design stage of building projects. At this stage all the design modifications will result in less impact on time and effort which means cost savings across the entire life cycle of the project. Creating a detailed database for the proposed model will also fill the gap of finding a comprehensive database that can integrate the various disciplines that deal with common projects. The proposed database will contain three main subcategories. The first stores information from the FM historical reports that reflect the experience and case studies that occurred in previous FM projects. The second incorporates the standards and guidelines used to implement FM in a BIM environment along with the systems and vendors’ information available in the market. This innovative framework will consider the following basic attributes: (1) tackling the key factors that affect FM; (2) Identifying the design stage in which the involvement of facility managers will be more effective with respect to time, cost and quality; and (3) Detecting the major aspects that will directly contribute to enhancing the quality of managing, operating and maintaining facilities at the early design stage of a building project.

2 METHODOLOGY

The proposed methodology used to develop the framework starts with identifying the limitations of the existing FM software, followed by clarifying all the aspects of the anticipated model’s components and architecture. An actual case project will then be implemented in a BIM tool to test the capabilities and workability of the developed framework.

2.1 Existing FM Software Limitations

Based on many reports and reviews, ten of the top existing FM software packages were explored and evaluated to find their limitations and capabilities as illustrated in Figure 2. Those ten software providers where chosen according to their customer base popularity, reviews and features provided (Business-Software, 2015).
Many vendors offer various services towards a goal of a more reliable FM practice; the key features selected in Figure 2 were based on the common services required by the FM and the available features of those tools that can be accordingly analyzed. The figure shows that the capabilities of most of the software are common when it comes to delivering a Software as a Service (SaaS) solution or on-premise solution: preventive maintenance, work order management, planning and scheduling, and reporting and analytics features. However, the limitations start to appear in fully applying Computerized Maintenance Management Software, in which the dependence on paperwork will be fully replaced by e-files. Moreover, applying BIM, Space Management was minimal comparing to the other provided features, while the integration of the Conceptual Design Stage was totally missing in all of the software. This increases the need to introduce a comprehensive platform that allow the supplement of professional inputs from facility managers during the conceptual design stage through the BIM concept towards a more efficient FM that will contribute in minimizing the possible waste of project resources (time, money, and materials), enables facility managers to obtain access to all of the life-cycle information of the project and offers the essential tools (i.e. monitoring, scheduling and integrating) to keep buildings running up to the required living standards.

2.2 Model Components

As illustrated in Figure 3 the proposed model consists of four interrelated modules that are developed within the BIM environment based on the most important factors FM required to include with BIM (Figure 1) and the limitations of the existing FM tools (Figure 2). The first module, the Operation & Maintenance Module, consists of different elements such as scheduling, building systems, parts/replacement, operational instructions and cost. This module combines all the FM technical information that can be affected or enhanced during the conceptual design of a project. The second module, Space Management Module, includes three elements which are: usable spaces, move management and non-usable spaces.
The focus of these three elements reflects time and cost savings. The usable spaces cover the utilization, circulation, accessibility, zones, future expansions, and technical requirements, whereas the move management comprises the utilization, circulation, accessibility, zones, future expansions, and special equipment allocation. The non-usable spaces, on the other hand, involve equipment, systems, circulation, accessibility, zones, future expansions, and special equipment allocation. Moreover, the “Life Cycle Costing (LCC) Module” covers the capital costs, expenses, revenue, risk analysis, and forecasting.

Figure 3: Proposed Model Components

The result of these modules is a list of recommendations that will be based on probability studies that will generate various design simulations in the “Knowledge Based Integration Module” to help the owner, architect, and FM team to decide on the best design approach that will result in an effective FM practice. This module includes a Design Decision Support System that will collect all the results of the four modules and throughout the knowledge acquisition database. The Knowledge acquisition databank contains three main databases. The first stores information from the FM historical reports that reflect the experience and case studies that occurred in previous FM projects. The second incorporates the standards and guidelines used to implement FM in the BIM environment along with the systems and vendors’ information available in the market. The FM team will reflect all the owners’ requirements from the FM point of view, and their professional opinion to what specific requirements are needed for this specific project will generate the third database.
2.3 Model Architecture

The proposed model consists of several components and its architecture includes: data input, data analysis, criteria, and output, as illustrated in Figure 4. The data input is divided into three different parts. The first part is related to the project information. It will cover the project type (residential, commercial, hospitality, etc.), project program (users’ information, required spaces for each zone, and their relation), conceptual plans, which should be in a BIM-supporting format. Additionally, site constraints (location, orientation, accessibility, geometry, weather, etc.) will be covered in the project information part, as well as the key issues and guidelines, construction and FM of the project, along with the specified budget to reflect on the sections of building techniques, materials, equipment and the entire LCC of the project. All the data in the first part will be gathered from the owner(s) and the project architect. The second part is the information related to technical standards and also input by the architect of the project. This input will cover all the required equipment specifications, the replacement circulation and special equipment whenever it is needed according to the project type, location, and stage. The third part is related specifically to the maintenance information that will be provided by the FM team. This part will cover the FM item requirements for this specific project, the essential systems data and equipment information. Moreover, the operational instructions, maintenance manuals and schedules will be gathered in this part of the input by the FM team.

![Figure 4: Proposed Model Architecture](image)

The data analysis, in its turn, is divided into four sections. Three of those are: 1) Operation and Maintenance (O&M), 2) Space Management and 3) Life Cycle Cost Analysis (LCCA) has been classified as the data that will have a direct input to the FM practices which can be enhanced in the conceptual design of a project. However, the fourth section will focus on the reliability of the data to generate the required data analysis for such a complicated and multi-input model. The O&M section will involve data for scheduling, building systems, parts and replacement, operational instructions and cost data. However, the space management section will generate data regards the space utilization, zoning classifications,
circulation for both usable and non-usable space, standards required for specific space, building codes and standards, equipment specifications, and accessibility. Moreover, the space management section will include the date for possible future expansions, specific technical requirements, special equipment allocation and time- and cost-saving practices from previous projects. The LCCA will contain data that is related to capital, expenses, revenue, risk analysis, and forecasting. The Reliability section of data analysis will gather the following information: FM in BIM guidelines, functionality, maintenance system, operational systems, specific project requirement, and the data of vendors and system information (availability, cost, location, durability, technical specifications, delivery dates, etc.).

The data analysis will be based on the following criteria: productivity, LCC, and FM in BIM guidelines. In the productivity section the equipment performance rates, systems integration compatibility, zoning flexibility, and safety (of allocating commonly-used zones to hazardous ones) will be examined. It is very important to verify the data input source, which in this model will be either from the project owner, architect, or FM. Knowing the input source will allow categorization of the requirements according to their importance. Moreover, the FM historical report will be filtering the data to provide solutions and insights based on comparing the current data input to comparable historical measurable. However, in the LCC section, the data analysis criteria will be energy consumption, overhead cost, O&M cost, salvage, inflation rates, taxation and other expenses that might be added to the LCC of the project. In the third section of the criteria, the data will be tested to check its validity with regards to FM in BIM Guidelines that consist of Construction-Operations Building Information Exchange (COBie), National BIM Standards, U.S. General Services Administration (GSA) BIM Guideline for FM, and the National BIM Library. Collecting all of those guidelines in one model will generate a comprehensive database that will contribute in savings of costs and time during the FM stage of the project.

The output of the proposed model will be a series of recommended design alternatives and solutions through design simulations. Moreover, FM effectiveness reports, will provide the facility manager with all the information related to the operation, maintenance, and evaluation of the facility in an effective way. Additionally, all the main building systems—LCCA, market availability, recommendations and comparison reports—will be generated along with the 3D integrated design that will allow all the professional inputs from various project parties throughout the entire project life-cycle. The platform of this model is developed using the BIM concept, in which systems integration is achieved by using an existing BIM model at the conceptual design stage and assuring data-updating from all the parties throughout the project life cycle, as described in the validation below.

3 VALIDATION

To validate the developed model, only the space management module will be tested in this study as part of the ongoing overall model validation, by using a sample project (AL Dammam Four Seasons Hotel), which is located in the eastern province of the Kingdom of Saudi Arabia. This project is currently at the conceptual design stage (30% of the design is completed). The authors created a 3D model of that project in the BIM tool, which is Autodesk Revit in this case, where the space management module is added into Revit’s toolbar as a plug-in, as shown in Figure 4.

Once the conceptual design of that case project is done, the user will activate the space management module by clicking on the plug-in, which will generate an alert after analysing the data in the knowledge acquisition database to produce the following information: 1) Suspended scaffold equipment; 2) Data Input; 3) Impact; 4) Alert description; 5) Recommended actions; 6) Read More, which will provide an in-depth LCC, Vendors Information.

Figure 4 shows a list of recommended actions that will contribute in saving costs and energy during the operating stage and the FM practice. In this case the architect did not consider the location of the window-cleaning machine for the project because apparently the focus is on using every possible space in the project to reflect the owner's requirements. This required data is recorded in the model through the FM team. The model will then describe the problem after a process of filtering that will go through the database and according to the set of criteria (productivity, LCC, and FM in BIM guidelines) that are provided in the model architecture.
Figure 4: Model Validation – Move Management Alert

Figure 5: Model Validation – Future Expansion Alert
Figure 5 indicates that one of the owner’s requirements is to expand this space. The model allows the architect to calculate the energy consumption aspect along with ensuring its workability and compatibility with other building systems.

This is ongoing research that is still underway with the attempt to achieve a fully automated process that integrates BIM tools with other applications for scheduling and estimating, as well as data acquisition. The results of the proposed framework prove the importance of facilities managers’ contributions during the conceptual design stage that potentially result in reducing the cost of operation and maintenance.

4 CONCLUSION

This paper described the framework used in developing a model that will be used by the project architect/design team to integrate existing Building Information Modeling tools (Autodesk Revit) with the data that can be gathered and generated by the owner, architect, and FM at the conceptual design stage of a project towards effective facilities management, as has been discussed. As this paper conceptually illustrated testing the capabilities of one of the four proposed modules, the space management module that was chosen for the purpose of this conference paper only, future work will focus on programming this model towards testing its workability and validating it as a plug-in through Autodesk Revit using an actual case project.

Abstract: The idea of culture has become a hot topic in construction engineering research. However, this term is used with many meanings. As such, the objective of this paper is to present a content analysis of the online record of ASCE Journal of Construction Engineering and Management (JCEM). A 2014 keyword search for “culture” in JCEM returned 557 articles. The authors reviewed the abstracts of each paper to categorize them according to the purpose statement: international markets (70 articles), safety (63 articles), and collaborative working arrangements (40 articles) emerged as the most frequent themes of the articles. The identified papers were then downloaded in full text form and imported into QSR NVivo, a qualitative coding software package. These articles were then searched for use of the word culture in conventional content analysis. Definitions of culture were extracted from the articles presenting a wide array of interpretations with respect to culture. Finally, this paper reviews the various theoretical bases for culture used in each category, and makes recommendations for future research in culture and construction based on the findings.

1 INTRODUCTION

Culture can be defined in a variety of ways. It can be used as a verb (to culture as in microbial cells), noun (culture as a group of beliefs or ideas), or adjective (cultural as in cultural traditions). The goal of this paper is to discuss the various meanings of culture in the construction research community. The construction practice is made of people from varying firms, countries, and perspectives trying to work towards common goals. The accomplishment of such goals typically involves a strict schedule and tight budget; this makes team performance vitally important for successful projects. Culture has therefore been a factor in many research analyses. The paper aims to determine how culture is used in construction research through a content analysis of Journal of Construction Engineering and Management (JCEM) research.

2 POINTS OF DEPARTURE

Changing technologies, geographies, and demographics have real impacts on construction projects and organizations (Levitt 2007). Within the past 15 years, culture has come into focus in research; unfortunately culture is not always well mobilized despite being the subject of ongoing research (Fellows 2010). In order to explore how culture has been used in the construction research community, this research identifies definitions of culture in construction and explores how construction research has approached culture research. Future investigations will focus on how culture is being operationalized.
When researchers conduct cultural studies, they assume a philosophical position, which will impact their choice of research methods and therefore results (Gajendran et al. 2012). In this paper, we identify culture as a traveling concept (Bal 2002). Bal's argument is that the transfer of concepts across disciplinary, national, and historic boundaries alters the intended meaning. These changes are what create discussions in interdisciplinary subjects. Culture, with its roots in the social sciences, has crossed over the disciplinary boundary (Murdock 1932). Concept mapping bridges the gap in varying academic disciplines (Neumann and Nünning 2012) and adds clarity to our theory. In support of this goal, this paper maps concept of culture throughout JCEM in order to determine how the idea of culture is being viewed from varying nations, sectors, and firms.

3 RESEARCH METHOD

In order to determine the various uses of the word culture within Construction engineering, a keyword search was performed for the word “culture” in the American Society of Civil Engineer's Journal of Construction Engineering and Management from March 1, 1983 until the present (December 29 2014). This search resulted in 557 articles from 1988 until 2014. 523 of those articles were primary articles. All editor's notes and discussions were excluded from this research. A conventional content analysis in which codes emerged from the data was performed twice: first on the purpose statements within the abstracts of these articles and second on the full text of 172 articles identified in the first analysis.

Content analysis is a proven research technique to study the characteristic meaning of messages (Krippendorff 2012). In this case, technical construction articles from JCEM were analyzed as the messages in order to determine the meaning behind the use of the word culture. Content analysis has several methodological advantages validating its use in this research. First, it is unobtrusive, as in the instrument by which the data was collected does not affect the results. Second, the results are directly taken from the data. Third content analysis does not require a specific format for the data; it takes context into account (which is of particular importance in this study); and fourth it allows for the study of large amounts of data (Krippendorff 2012). This study implemented both conventional content analysis, which is particularly useful in areas where research literature on a phenomenon is limited and a summative content analysis which focuses on interpreting the content (Hsieh and Shannon 2005). In conventional content analysis, categories are derived inductively. Subcategories are combined into larger categories, and definitions of the larger (parent) categories are developed. This approach was used to classify each articles purpose statement. In summative content analysis, searches for a particular word are performed in order to determine how that word is being used. This approach was implemented to find definitions of culture.

In the conventional content analysis, the articles were categorized into categories through an iterative process. International management, safety, and collaborative working arrangements emerged as the top three categories with 40 or more articles each. Descriptions of these categories can be seen in the results section. For this paper, only articles in these three categories were analyzed further. All 172 articles from these categorizes were further subjected to a summative content analysis for the word culture using QSR Nvivo. Within the 172 articles, several were categorized in two of the three categories. For example, the purpose statement in Ozorhon et al. (2008) [Statement: “In this study, the effect of cultural similarity/difference relative to the national and organizational characteristics of partner companies on IJV performance is examined through a questionnaire survey” pg. 361] was coded in collaborative working arrangements and international markets. Eight articles were repeated in both international markets and safety, and two articles were repeated in international market and safety.

4 RESULTS

4.1 Keyword Search

The 523 articles were analyzed and categorized according to the purpose statement given in the abstract. The purpose statement was defined as the statement in which the goals, intent, or purpose of the article was included. If no purpose statement was provided in the abstract, the article was categorized based on
the summarization of findings, also found in the abstract. The abstracts were read three times in order to iteratively categorize the articles. For brevity, table 1 only shows the top three categories and the description of the types of articles the category contains.

Table 1: Article Categories

<table>
<thead>
<tr>
<th>Category</th>
<th>Description</th>
<th>Article Count</th>
</tr>
</thead>
<tbody>
<tr>
<td>International Markets</td>
<td>Export of construction services to a nation outside of the firm’s home nation or comparisons between construction practices of two nations</td>
<td>70</td>
</tr>
<tr>
<td>Safety</td>
<td>Qualities of or related to risk or causes of injury;</td>
<td>62</td>
</tr>
<tr>
<td>Collaborative Working Arrangement</td>
<td>Relationships described between two or more companies in the construction industry which offer the potential for greater market competitiveness including alliances, joint ventures, and partnering</td>
<td>40</td>
</tr>
</tbody>
</table>

As mentioned in the research methods, several articles were listed in two categories as they were equally related to both topics. (Ozorhon et al. 2008) was the only article that was double coded and contained explicit definitions of culture. These definitions are contained within the collaborative working arrangements section although they could also have been presented in international markets.

4.2 International Markets (IM)

Articles related to international markets were distinguished by their mention of work outside of a home country or a comparison of international firms or nations. Seventy of the original 523 related to the international market category. Table 2 below shows the definitions given in the full text.

</table>
| Culture    | "Loosemore (1999) states that "it is now accepted that a culture of a society is its shared values, understandings, assumptions and goals learned from earlier generations. It results in common attitudes, codes of conduct and expectations that guide behavior."
                                                                                                                                                                                                 | (Chan and Tse, 2003, pg 376) |
| Culture    | "Culture describes the social system created by a group of people; it starts from the moment that a few people get together regularly and begin to establish norms and rules through which they will interact and communicate with each other and maintain order; it is about patterns of meaning; it is about shared beliefs, values, perspectives, and worldviews; it is about shared behavior, practices, rules, and rituals; … (Tso 1999)."                                                                 | (Chan and Tse, 2003, pg 376) |
| Culture    | "Culture as the word is understood by every man in the street without elaboration."                                                                                                                                                       | (Chan and Tse, 2003, pg 376) |
| Culture    | "Culture represents a general pattern of values, attitudes and behavior in one nation that distinguishes it from other culture groups."                                                                                                         | (Chua et al, 2003, pg 135) |
| Culture    | "Culture serves as a socially shared knowledge schema giving meaning to incoming stimuli and channeling outgoing reactions (Triandis 1972)."                                                                                                                                                  | (Tsai and Chi, 2009, pg. 957) |
Culture

"Every national culture describes distinct beliefs (what is true), values (what is important), and norms (what is appropriate) that are deeply embedded in people's mind and demonstrated in their behaviors accordingly (Trompenaar 2004)."

(Tsai and Chi, 2009, pg. 957)

Culture

"Kotter and Heskett [1992] think of culture as having two levels, which differ in terms of their visibility and their resistance to change. At the deeper and less visible level, culture refers to values that are shared by the people in a group and that tend to persist over time even when group membership changes. At the more visible level, culture represents the behavior patterns or practices of an organization that new employees are encouraged to follow."

(Ozorovakaja, et al, 2007, pg 901)

Cultural

"Widely shared, socially constructed symbolic representations"

(Javernick-Will and Scott, 2010, pg 547)

Four articles defined the word culture just once. Chan and Tse (2003) present three definitions as they explain how culture lacks true definition in the literature. They conclude by defining culture for their paper as a concept generally "understood by every man" (pg 376). Tsai and Chi (2009) present several definitions of culture shown in Table 2 while explaining the uses of Hofestede's cultural dimensions that the study used to measure cultural characteristics of Taiwanese-Chinese construction professionals. Finally, as previously mentioned Ozohorn et al (2008) also defined culture in international market, but the definitions are in the collaborative working arrangement category.

4.3 Safety

Sixty-two articles described safety in their purpose statements and were therefore analyzed for their use of culture. In this set of articles culture was used in a compound noun (i.e. blame culture, corporate culture etc.) to describe which type of culture to which the author was referring. Seven articles provided the seventeen definitions of culture as seen in Table 4 below. There are six definitions of corporate culture, two for organizational culture, and eight for safety culture.

</tr>
<tr>
<td>Safety Culture</td>
<td>&quot;Safety culture is a subfacet of organizational culture, which affects workers' attitudes and behavior in relation to an organization's on-going safety performance.&quot;</td>
<td>Mohammed 2003, PG 81</td>
</tr>
<tr>
<td>Safety Culture</td>
<td>&quot;Mohamed (2003) suggested that safety culture is concerned with the determinants for the ability to manage safety (top-down organizational attribute approach); whereas, safety climate is concerned with the workers' perceptions of the role safety plays in the workplace (bottom-up perceptual approach).&quot;</td>
<td>Choudhry et al. 2009, PG 891</td>
</tr>
</tbody>
</table>

As seen in the table, blame culture, corporate culture, organizational culture, and safety culture make up the four terms used in the safety articles. Although all subsets of culture, each of these terms implies a slight narrowing from the broad term of culture. Four articles provided more than one definition of these culture related terms. Molenaar et al. (2009) provided all the definitions of corporate culture in an attempt to explain how it relates to safety and references Molenaar et al. (2002), published outside of JECM and therefore out of the scope of this paper, for further definitions of corporate culture. Martin and Lewis (2003) defined both safety culture and blame culture. They differentiated between safety climate and culture, as they wanted to understand the key drivers of risk taking behaviours on construction sites before attempting to measure safety climate. Similarly, Chen and Jin (2013) offered two definitions of safety culture in an attempt to describe the difference between safety climate and culture before they conducted a study measuring safety culture. Finally, Mohammed (2003) referenced by Chen and Jin (2013) provided one definition of organizational culture and three definitions of safety culture. Mohammed (2003) sees safety culture as a subset of organizational culture; therefore he defined organizational culture and then safety culture in the article's literature review before recommending the use of a scorecard approach to measuring what he calls organizational safety culture.
4.4 Collaborative Working Arrangements (CWA)

For purposes of this article, collaborative working arrangements are defined as relationships established between two or more firms in the construction industry, which together attempt to create a more competitive team to complete a project. Examples are relational contracting, alliances, joint ventures, and partnering. From the original 523 articles, 40 related directly to collaborative working groups. Of these 40 articles, only four defined a term containing the word culture as shown in Table 6.

<tr>
<td>Organizational Culture</td>
<td>Organizational culture refers to the set of values, beliefs, understandings, and ways of thinking that are common to the members of an organization or corporation (Daft 2001)</td>
<td>Ho et al., 2009, pg 521</td>
</tr>
</tbody>
</table>

Of particular note in Table 6 is the number of definitions that come from Ozorhorn et al. (2008). The purpose of this study was to measure the cultural effect on international joint venture performance. Both national and organizational realms of culture were operationalized through Hofstede and Hofstede’s (2005) framework.

5 DISCUSSION

Thirty-seven definitions were found in 17 of the 172 articles studied, meaning only 10% of the articles contained in this detailed search contained a definition of culture. All 37 definitions were unique; there is no single understanding of culture in construction research. Unique here does not imply that every one of the 37 definitions is radically different from the other; however, it means that no two definitions have the
same combination of ideas. For example, Molenaar et al. (2009) combines the concept of a set of values in a group and persistence over time as the defining components of corporate culture; where as the working definition of culture for this same article adds such ideas must also be spread out throughout the entire organization in order to be considered culture. No other definition combined these two components. The definitions contained two general themes. In 38% of the articles, culture was thought to be a set of values, beliefs or ideas held by a particular group of people; however, 54% went beyond that idea and thought that these values were translated into behaviours and actions taken by certain groups. Just 8% saw culture as just the actions take by a group of people.

As was mentioned after each table of definitions, articles frequently include several definitions in order to properly convey a point (Mohamed 2003; Molenaar, et al 2009; E. Chan and Tse 2003). This range of definitions offered the audience a range of perspectives about how people have sought to define aspects of culture. The unique nature of these definitions can cause variation in the measurement of culture as a variable which should be considered in future research. Behaviour and actions are inherently easier to measure because they are observable; conversely, values and beliefs have to be measured or quantified indirectly. In our data set, this is most commonly been done through questionnaires. Both observations and questionnaires have their advantages and disadvantages as well as their own biases. When interpreting results from studies related to culture it is important to notice this distinction in order to realize the generalizability of the previous data as the field moves forward. For example, Molenaar (2009) defined corporate culture as including beliefs and behaviours consistent through time and throughout the organization. The resulting study then measured both belief and behaviour in a longitudinal study at every level of the company. Molenaar (2009) conducted a survey that resulted in a structural equation model which provides guidance for future researchers who intend to define culture in a similar fashion.

Another foundational difference seen in the definitions was the inclusion of time. Four definitions included time culture included maintenance over time (Molenaar et al. 2009; E. Chan and Tse 2003). While those two articles only represent 1% of all the articles, time was considered in several other studies within this paper’s scope. For some, safety culture developed very slowly (Huang and Hinze 2008; Kleiner et al. 2008; Patel and Jha 2015), while for others project culture in partnering could be developed rapidly (A. Chan et al. 2004). Definitions of culture without time imply cross-sectional studies of an environment are suitable to make evaluations of culture; however, these few definitions with time might require a longitudinal study in order to get a full view of culture. As for all research, specific research questions will define the appropriate theoretical grounding.

Another distinction made in the definitions of culture was the organizers of culture. 74% of the definitions made a reference to who governed a certain culture. Thirty-five percent of those articles argued that culture was controlled by an organization while 65 percent argued that the members or employees guided the culture. This was particularly apparent in the definitions of safety culture. Chen and Jin (2013), Choudhry (2013), Fang et al (2006), Mohammed (2003) reference safety culture as a product of the organization; where as the remaining two safety definitions (Martin and Lewis (2014) and Mohammed’s definition from Cullen (1990) see safety culture as the product of the employees. This distinction is important to note because of the impact it has on the types of beliefs and behaviours a group takes on. A culture imposed by a single source (like upper management of an organization) can heavily influence the resulting culture, which in the case of safety could save lives; however, this influence could allow for certain values to be ignored such as communication. A culture founded in beliefs from the employees can be much more comprehensive by allowing employees to contribute their views to company; however, priorities of each belief could vary among employees causing conflicts when different priorities oppose. From a construction research perspective, where the culture is founded substantially influences who to survey and what questions to ask, as was noted by Gilkey et al. (2012) and Chen and Jin (2013).

Sixty-one percent of the definitions originated from a source outside the field of engineering and construction, meaning there were only seven definitions, which referenced a source in construction. In fact 39% of the definitions came from engineering and construction, 33% came from business and management and finally 28% came from the social sciences. The field was determined by the journal in which the reference was published or author’s background. For multiple authors the definition was counted once for each author. The ideas of Bal (2002) and Neumann and Nünning (2012) offer a viable
explanation for the large variability that was seen in the definitions of culture. The concept of culture is changing as it is converted into a usable concept for construction engineering. As conceptual misinterpretations can lead to inaccurate interpretation of results, our results emphasize the need for careful and explicitly given definitions as construction researchers mobilize the idea of culture.

6 CONCLUSIONS AND FUTURE RESEARCH

This paper presented a conventional content analysis of 523 articles in the JCEM produced by ASCE and a more detailed summative content analysis for 172 articles relating to the same category. Thirty-seven unique definitions were found, suggesting that culture is not uniformly defined in construction research. Fifty-four percent of the definitions contained beliefs and behaviours as part of the definitions, and 11% of the definitions included time (i.e. the amount of time the beliefs and behaviours have persisted). Finally, culture was seen as the product of the organization by 35% of the definitions and as a product of the people by 65%. All three of these variances in the definitions effect the way in which culture in construction is researched, particularly the measurement of culture (surveys or observations) and research design (longitudinal or cross-sectional, and target population). Finally, the definitions of culture referenced literature in engineering/construction, business/management, and social sciences approximately equally which may explain some of the variation in the definitions. In conclusion, these results show definitions of culture travelling across disciplinary boundaries to create a set of definitions which researchers should carefully consider. More research is needed to determine if larger trends exist in defining of culture. Further analysis into the effect of a definition of culture on the methods and results of a study would provide valuable insight into how the definitions should be chosen and standardized across construction research. Expansion of the current content analysis to search for definitions of culture in all 523 articles as well as adding more academic construction journals would also add valuable knowledge.

Abstract: Generally, a tremendous amount of waste and debris are generated by the demolition of existing buildings. Construction managers and site engineers are encountering difficulties in accurately calculating the volume of these materials, which have big influence on the duration and cost of projects. This paper describes the methodology used in developing a model that integrates Building Information Modeling (BIM) and Geographic Information System (GIS) to facilitate demolition waste management and control for megaprojects. The suggested model aims at facilitating the processes of estimating the quantities of waste by calculating the travel distance between the site, storages, and landfills and related time, as well as computing the number of trucks required for loading and hauling the waste from and to multiple sites. The main goal of this study is to demonstrate how this integrated model will provide construction managers with a comprehensive tool that could substantially benefit them in comparison to solely utilizing BIM. This paper will demonstrate how the model works and explain how it has the edge over using BIM only. The suggested BIM-GIS model will contribute to more green and efficient construction management. A hypothetical case project is given to test the workability of the model.

1 INTRODUCTION

BIM and GIS are powerful platforms widely used in the construction industry due to their various individual features and capabilities; however, each platform lacks important features the other platform offers. For instance, GIS provides topological (georeferenced) data, which allows for 3D analysis, spatial analysis, and queries such as calculating the distance between two different points, calculating routes, and defining the optimal location (Irizarry and Karan, 2012). BIM, on the other hand, is incapable of such analysis, but it provides a detailed database of object-oriented parametric information for the building and represents it in a 3D model, a feature that GIS is lacking (El-Mekawy, 2010). Research efforts conducted on leveraging the integration between BIM and GIS in the construction management process are rather scarce in comparison with ones that are carried on utilizing BIM only. Thus, this paper attempts to highlight various areas in which such integration is useful for construction managers and practitioners. Furthermore, the paper will underline some of the advantages of using the BIM-GIS model in managing the waste generated from the demolition of an urban development (a megaproject), plus controlling and monitoring some of the processes involved.

2 LITERATURE REVIEW

Poon et al (2001) pointed out that demolition (D) waste is estimated to be 10% to 20% higher in weight than waste generated from new construction (C). Llatas (2011) emphasized that as requirements for C&D
waste quantification become more and more accurate, concise and detailed, it is believed that computer-aided estimation has good development prospects. Wu et al. (2014) argued that one advantage of giving a detailed classification of construction waste is that the chances of recovery of waste may be increased. As a result of the urgent need for such tools, efforts to use BIM technology in construction management have increased. Cheng and Ma (2013) developed a model to improve C&D waste sorting and quantification and estimation processes by leveraging BIM tools. Jalali (2007) considered that the estimation results could provide fundamental data for practitioners to evaluate the true size of the waste and hence, make the adequate decision for their minimization and sustainable management. Wu et al. (2014) believed that the waste generation rates derived from different projects can assist in providing information for benchmarking the effectiveness of different management practices. The optimal technologies and work procedure can be selected by comparing the waste generation rates. Furthermore, studies on the integration of BIM and GIS in the construction management field are few in general. Irizarry, et al. (2013) developed a BIM-GIS integrated model to improve the visual monitoring of construction supply chain management. Liu and Issa (2012) emphasized on the importance of 3D visualization for pipeline maintenance and how it overcomes the shorting in 2D illustration. El Meouche, et al. (2013) investigated multiple approaches to integrating BIM and GIS but did not propose a model or a solution to a particular construction management problem. Isikdag, et al. (2008) suggested a BIM-GIS model for the support of the site selection and fire response management processes. Irizarry and Karan (2012) utilized BIM-GIS integration to optimize the location of tower cranes on construction sites. Other research work, such as (El-Mekawy, 2010); (Berlo and laat, 2011) and others, worked on the interoperability issues between BIM and GIS; and how to unify both domains at the semantic level to make communication and the data transfer between the two platforms easier and more efficient. Borrmann (2010) developed a spatial query language for 3D building models using tools and concepts from GIS on BIM. The query language is meant to enable inquiring about walls located in certain story, if a certain room is equipped with heating system tools, determining the columns that intersect with a certain slab, defining the fire extinguishers positioned within a given distance from a certain building component such as a window or a column, etc.

It is evident, based on the above literature review, that the research work done on BIM-GIS integration in recent years has not suggested a solution for demolition waste management for megaprojects (urban development), even though it is an important area with much room for optimization of the current practices and numerous issues to solve. It also can be concluded that there is an urgent need to use computers and technology in construction management and to explore how this will benefit professionals. This study will establish how integrating a spatial analysis capability, in GIS, is rather beneficial and will add greatly to the typical construction management practice of just using BIM tools. Hence, the suggested model aims to facilitate the processes of waste estimation, sorting, and removal, on an urban scale, by leveraging the capabilities of both BIM and GIS and it provides this to the users in a single unified place. The model includes two main modules, a management module and a monitoring and control module, as shown in Figure 2. Each module has subdivisions, two of which are under the monitoring and control module, which are work progress and sustainable demolition practice implementation. The management module includes three subdivisions, which are waste estimation, waste sorting, and resources management. Later in this document, each subdivision will be explained in detail to show how the module works and what privileges it provides over using BIM only.

3 METHODOLOGY AND DEVELOPMENT

Data transition, query and analysis between BIM and GIS are further problematic due to interoperability issues between both platforms at a semantic level, among other issues (El-Mekawy, 2010). Thus, this paper is going to demonstrate a methodology, based on a literature review of Isikdag, et al. (2008) and El Meouche, et al. (2013), for integration between the two platforms, leveraging the GIS analytical and query tools to perform some tasks on the imported BIM file. The two programs used in this paper are ArcGIS 10.2.2 by ESRI (as a GIS tool) and Autodesk Revit 2015 (as a BIM tool). The methodology used to develop the integrated BIM-GIS model process flow is shown in Figure 1. Section 3.2 illustrates the main modules encompassed by the model and explains how it works, presenting the capabilities and
advantages of the model comparing to solely using BIM. A hypothetical case project, in Section 4, will be used to test the workability and capability of the proposed model.

3.1 Model Development

First, the Revit file of the urban development is exported as an IFC2x3 file. The BIM file's coordinates should match the real world coordinates of the city or the region where the urban development is located, to allow for the drafted buildings to be set in the right place after the importing process. Once the file is imported into the GIS, all the families (objects) included in the design will be categorized and put in groups (feature classes), based on the type of that class. For instance, all doors will be put together in one feature class named IFCDoors, and the same goes for windows, walls, floors, ceilings, etc. Some IFC components such as doors and windows contain a mix of materials: aluminum, steel, glass, wood, plastic, etc. As this paper is part of an ongoing research project, the current model does not automatically separate those materials or distinguish between their condition (reusable, recyclable, and total loss). After that, the imported BIM (IFC) file is georeferenced by allocating the proper projection system. If the urban development BIM (IFC) file is going to be imported on an already existing transportation network and topography layers (triangulated irregular network, known as TIN), it has to have the same projection system as them in order for all layers to work properly. It should be noted that using a multiuser Geodatabase (.gdb) file is preferable when dealing with cases such as urban development or megaprojects, as it allows what is called "versioning" which enables data to be shared and used by different users simultaneously and allows nullable fields in the attribute table associated with the geometric features imported into GIS (ESRI, 2009). Afterwards, the user defines the work zones. Depending on the nature and requirements of their work, these zones could be digitized (drafted) manually using a GIS sketch tool or also imported if they are already drafted in the BIM file. Each zone should be given a unique name to avoid the issues of conflict and to ease the analysis processes. The zone allocation could be based on a variety of characteristics defined by the main contractor. Next, two major fields should be created, within the GIS, in the attribute table of each component or feature class (door, window, etc.) in order to facilitate the waste estimation, sorting, categorizing, and quantification processes. These fields are: "condition", with the following attributes, reusable (onsite and non-onsite), recyclable and total loss and, if applicable, “classification” (Inert or Non-inert). Accordingly, each building component should be categorized and allocated one unique attribute from the aforementioned attributes. The proposed BIM-GIS model should be successful in estimating the demolition waste generated, sorting the waste according to material condition (reusable, recyclable, and total loss), material type or element (steel, wood, concrete, glass, plastic etc.) and estimating the number of trucks needed for loading and removing the waste. The material condition attributes (reusable, recyclable, and total loss) are to be put manually in the model based on experience from previous projects and/or data collected on materials and building components. Those attributes could be updated later based on a field survey of the actual buildings. The attributes could be entered manually into the BIM (IFC) model and then exported to the GIS or entered into the GIS directly. It must be emphasized that the output data acquired is only as good and as reliable as the input data is.
3.2 Model Components (Modules)

Figure 2 provides a detailed explanation of the model's components and its associated modules. In each module, there are subdivisions that represent the main operations involved in the demolition-waste management and control that the BIM-GIS model is capable of processing efficiently and in a timely manner.

![Diagram of BIM-GIS Module Components]

Figure 2: Explanation for the modules (components) of the BIM-GIS model

4 CASE STUDY

The case study provided in this document is hypothetical and meant to confirm the workability of the presented BIM-GIS model and aims at validating it, considering its efficiency for the purpose of C&D waste management and control. It encompasses twelve simple and similar buildings that are equally distributed over three different work sites. Each building includes 4 windows, 4 doors, ceilings, walls, stairs and railings with an approximate area of 2,000 ft². Land use (residential, commercial, and industrial) is assigned to the work zones (work sites) instead of lots on which the buildings are. This is because it will be hard for the reviewers to tell the difference at such a scale (urban scale) when reading this document. Also, the low number and simple structure of the buildings is meant to be as this case study is meant to test the workability of the model, which can be done sufficiently with the provided data. A true waste treatment facility, close to the project area as shown by Google maps, was selected and drafted in GIS as the destination point to which the demolition waste is going to be transported. The model is used to estimate the demolition waste, sort the materials and calculate the number of trucks required to remove the waste generated.

5 THE BIM-GIS MODEL VALIDATION

5.1 Management

5.1.1 Waste Estimation

The waste estimation process in this model could be conducted in various ways. First, the fields required for the demolition-waste estimation process (material condition, total waste per material and land use), are created. All the required parameters and measurements for all the materials available in the building already exist in the imported BIM (IFC) file. Accordingly, the volume for all the materials is calculated by utilizing Equation 1. Then all the condition attributes, reusable (onsite or on other site), recyclable or total loss, are assigned to every single material. These different condition data could be determined first, based on standards or experience and then calibrated during the process of the demolition for more precision. After the previous steps, the utilizer could easily retrieve the information about the estimated waste volume in any required way. For instance, the user could use the model to estimate the total waste of a certain building, work zone (as in this case study), or for the entire project. This could be done by the “select by location” function in ArcMap’s (GIS) main menu. Also, the waste could be calculated for a certain type or condition of the materials one wants to inquire about, such as concrete, wood, steel, glass, etc., or reusable (onsite or other site), recyclable, or total loss. This also could be done by first “select the location”, as previously mentioned, of the wanted materials and then by the “select by attribute” function available in the ArcMap’s main menu. Equation 3 is used in the model for estimating the total loss that will be calculated after estimating the total waste, reusable and recyclable waste volume generated as illustrated in Figure 4. Even though BIM is capable of inquiring about materials according to their conditions, the proposed BIM-GIS model is evidently advantageous in terms of estimating the waste for targeted location exploiting the spatial relationships between objects. The model could also estimate the waste generated from a certain building located within a certain radius or within a certain distance from a street or another building. Furthermore, the model can include the waste index values discussed in (Cheng and Ma, 2013), such as the Global Index method introduced by (Jalali, 2007) and the waste index presented in (Poon et al., 2001). Cheng and Ma (2013) explained the waste index as the amount (in unit of volume or weight) of construction waste generated per m$^2$ of Gross Floor Area (GFA) and the global index as a more detailed method that allocates certain changes or increased percentages to every kind of building material. For example, concrete, steel, wood, glass, cement, and masonry have a value of 1.1, 1.02, 1.05, 1.05, 1.1, and 1.1 respectively. This could be easily done by creating a field named “increase factor” and assigning the values to the building materials, then, calculating the material adjusted volumes by using Equation 2. The previous step could be applied to any adjusting factors needed to be calculated even if it is related to the land use or project type, such as private residential, public residential, or commercial buildings. GIS also enables associating the attributes of one layer such as “land use” with all the building components by using a feature called “Spatial join.” This is one of the multiple features that GIS boasts, which the BIM tool lacks and thus could not run such process with the same efficiency if at all. Finally, maps, using BIM-GIS model, could be produced for determining the locations of the components need to be demolished with associated attributes and estimation to provide the workers or practitioners with a target volume to consider while demolition of the building or part of it. Also, a detailed description for the component could be printed out using the layout tool in GIS. Figure 5 shows how the model can estimate the waste volume for single building component.

Figure 4: Waste volume calculations generated by the BIM-GIS model.

Figure 5: Calculation of the waste volume for a single component (doors) in three different zones.
5.1.2 Waste Sorting

The BIM-GIS model helps in performing a variety of data manipulation, enquiry and analysis. The model allows users to run customizable sorting for the demolition-waste generated by placing it under three main categories; these are: by condition, material type and component. Each category is then subdivided into different attributes depending on the category as shown in Figure 6.

Each component in the building should get one unique attribute from the attributes given in this subcategory; these are: reusable (onsite or other site) and recyclable. Total loss could be subdivided into inert and non-inert material if needed. As stated by (Zhang et al., 2012) common inert materials include but are not limited to: "reinforced concrete, asphalt, cement plaster, mortar, aggregate sand, bricks, rocks, rubbles, and soil." Common non-inert materials include but are not limited to: "wood, metal, plastic, and other organic materials." Each sorting attribute, recyclable for instance, could then be exported using the GIS export option into a new separate layer (feature class) that could be used separately for further analysis and statistics. The model offers users with an abundance of analysis and statistics capabilities that are only possible by integrating BIM with GIS. Thanks to its feature of relating space (location) to geometry, the user can run analyses or ask questions such as "how much is the volume of recyclable materials generated in this zone?" and compare them to the other zones. This could help in identifying or studying the type of buildings that generate more recyclable, reusable or total loss materials and sorting them according to different attributes such as the age of the building, the structural system, etc. (This type of query is not part of this paper; therefore, its results were not included).

The BIM-GIS model also helps users to perform statistics on the types of materials in the demolition-waste estimate. For instance, the user can inquire about the amount of steel that would be generated in a particular building or zone. This sort of analysis and estimation is beneficial for the workers to help them plan and prepare their demolition operation. Also, by using the export feature class option within ArcMap, the users could isolate any material of interest in a separate layer to further analyze and perform more statistics and analysis as needed. By adding the cost of the different waste materials generated, the user could estimate how much money, as return on investment in some cases, could be gained in this case. This, again, can be estimated on the different project's scales previously discussed.

The model will provide subcontractors with necessary information such as the number of doors or windows in the building or area that needs to be demolished. Also it enables the operator to run such statistics in different levels or scales. The user can inquire for information about multiple buildings, a certain work zone, for the whole project area or even according to land use. This feature is unavailable for BIM users, as spatial data analysis, which BIM lacks, is required in order to get this type of information.
Furthermore, detailed specifications and drawings can be printed out for the workers to recognize the specified components along with maps showing exactly where they are in the building.

Resource Management:

Cheng and Ma (2013) calculated the number of trucks, as many studies did, by dividing the volume of waste estimated by the truck capacity. The suggested model can instantly calculate the distance and travel time between the waste location and the target destination as well as the number of trucks required for the process of removing the waste as demonstrated in Figures 7 and 8. However, this is not accurate enough, as the distance between the waste location and its final destination ought to be taken into consideration in order to get the appropriate number of trucks based on trip frequency as shown in Equation 4. Some other pieces of information, along with the round trip time, should be included before using that equation, which are the truck loading time, unloading time, time needed to check the load, and wash-up time. These parameters, with the round-trip time, are part of the “Total round-trip time (min).” Using this approach, no trucks will be waiting for the other trucks to finish loading nor will there be any idle time waiting for trucks to come back and start the loading process. To test the workability of this method, we can take the volume of the recyclable materials shown in Figure 8 that have a volume of 785.68 m³ as an example. The number of trucks is estimated to be 112 considering a 7 m³ truck capacity. This is a huge number, of course, considering the estimated volume. To calculate the number of trucks for the same volume of waste first, values of the different parameters included in the equation are assumed as: unloading time = 10min, loading time = 10min, checking time = 5min and washing time = 5min. The total in this case will be 30min and the travel time between the site and the recycling facility, as shown in Figure 7, is around 22min, which will make the approximate overall time to be 74min. Using Equation 4 the estimated number of truck will be 74/7=10.57 trucks, which is rounded up to 11 trucks. It is obvious that the difference between both numbers is substantially big, therefore the smaller number (11 trucks) is selected and this number can be adjusted based on the work productivity on site. The estimated number of trucks will increase as the trip time increases, which means that locating closer facilities is essential for this process, a spatial problem that the integrated model could solve instantly. This method (total round trip time) is used when the number of trucks does not exceed the number of loads estimated; therefore, both numbers have to be acquired and compared.

[4]: Total round-trip time (min) ÷ unloading time (min) = Number of trucks needed.
5.2 Control and Monitoring

5.2.1 Work Progress and Application of Sustainable Demolition Practice Onsite:

The subcontractors’ progress and efficiency in applying the best practices in demolition and sustainable waste management could easily be monitored with the developed model. Once the total waste is estimated, a certain percentage (5-8%) could be considered to cover potential error, then whoever is responsible for record-keeping can easily identify if a percentage of waste (recyclable or reusable) generated is far less than estimated, and can track down the reasons that led to this shortage. This could, again, be performed on the different scales (building, block or zone, and the entire project) as discussed previously in this document. On the other hand, the workers should be notified of the amounts expected from them to maintain the minimum level of applying the sustainable practices in the task performed, as mentioned previously in the literature review. The developed model is a useful tool to perform the tasks required from them adequately. Also, the model provides a useful tool in terms of establishing and calibrating benchmarking for the different types of waste generated as it can record the rate of the waste generated based on material condition, type, and component and compare among the results.

6 CONCLUSION

A BIM-GIS model is demonstrated in this paper, providing outstanding capabilities for facilitating some of the most demanding and experience-dependent processes in planning, management and control during the demolition phase of megaprojects. These procedures involve waste-sorting, estimation, and estimating the number of trucks required for loading, hauling, and removing the demolition waste. The model was validated and proven to be beneficial when it was tested using a hypothetical, but realistic, case study and capable of performing all the aforementioned tasks successfully and sufficiently. The model has even been proven to be able to go far beyond the scope and tasks discussed in this paper, which will lead to more research and testing in order to improve the model in the future. The analytical comparison between the capabilities of the proposed BIM-GIS model, versus using BIM tools solely,
emphasizes the benefits of the combination of spatial data and the object-oriented data of buildings in the construction management field. This paper is part of an ongoing research that seeks to improve the current model in terms of applications in construction management in general and the demolition phase and urban planning, management and control in specific. In addition, future work will focus on increasing the automation and integration procedures between GIS and BIM to further facilitate the use of the model and to maximize its benefits. Finally, there is no doubt that integrating BIM and GIS will enrich the current construction management and control tools used in the industry by adding a vast variety of new functions, all performed in one single place.

INTEGRATING BUILDING INFORMATION MODELING (BIM) WITH SUSTAINABLE UNIVERSAL DESIGN STRATEGIES TO EVALUATE THE COSTS AND BENEFITS OF BUILDING PROJECTS

Bader Alsayyar(1) and Ahmad Jrade(2)
(1) PhD Student, Department of Civil Engineering, University of Ottawa
(2) Assistant Professor, Department of Civil Engineering, University of Ottawa

Abstract: Building Information Modeling (BIM) is a well-known innovative approach in project design and construction. The use of BIM enables designers to control project cost from the early stage of its life cycle. The cost impact resulted from the construction of sustainable building is one of the main resources that designers should consider when designing such type of facilities. As the North American population is aging Universal Design requirements (design that accommodate the needs of human regardless of their ages and abilities) should be considered in conjunction with the sustainable design criteria to achieve sustainable universal design (SUD). The aim of this research is to investigate the benefits and costs associated with adopting the concept of sustainable universal design applied for building projects. Therefore, this paper proposes a methodology to develop a model that integrates BIM tools with SUD requirements and strategies (i.e. Energy, material, and indoor air quality and barrier free environment) and to evaluate the associated benefits and costs of proposed buildings at their conceptual design stage. The proposed model consists of three main modules. First, a database module, which is mainly devoted to illustrate items necessary toward SUD approach including: hand rails, entrance slope with its associated material and lighting shapes and specification. All of the mentioned items will be in accordance with the standards (i.e. Canadian National Building Code (CNBC), LEED, international standards). Second, a 3D design module will describe the design components and system used in the different areas in the 3D conceptual design (i.e. living room, toilet, and kitchen). Finally, a cost benefit analysis module that will evaluate the initial cost of each designated area that complies with the needs of aging people who have chronic health conditions, where the total cost and benefits is calculated accordingly. The effective development of the integrated model will help owners, designers, and developers to evaluate the cost and benefits of adopting sustainable universal buildings. An actual case project is used to test the workability, capability and performance of the proposed model.

1 INTRODUCTION

The sustainable approach is widely adopted in today’s construction industry. This notable adaptation of the sustainable approach emphasise its importance based on the economic, environmental and social improvement constraints. Kim and Emily (2007) consider that the visible and measured outcomes from some sustainably designed projects include increased occupant satisfaction, reduced construction and operation-related waste costs, reduced water use, and improved energy performance. While the adaptation of sustainable design (SD) approach in the construction industry is growing, the nation’s population is aging as well; therefore, more design strategies should be considered to overcome this issue. Recent studies devoted to guide designers in providing safe and functional facilities for inhabitants
who like to age in their living place (Demirbilek and Demirkan, 2004). Universal design (UD) is one of the innovative approaches that have been considered in the construction industry. It has been implemented to help disabled individuals to maintain their daily activities (Hunter et al., 2011). Although, implementing sustainable strategies in buildings (new/existing) showed better economical trend over the long run, its initial associated cost is doubtable. The results of a survey conducted in 2007 by the World Business Council for Sustainable Development found that the costs of sustainable buildings are “overestimated” for an additional cost of 17 percent added to the cost of conventional building which is considered more than triple the actual cost of 5 percent (Hoffman and Henn, 2008). Certainly, it is beneficial for owners, developers, and designers to accurately calculate the cost associated with the construction of Sustainable Universal (SU) buildings at the early stage of the project’s life. In order to evaluate such a cost, designers tend to examine and analyse multiple design criteria at the conceptual stage of projects (e.g. materials, technologies, spaces). Those criteria directly affect the principles, measures and costs of sustainable universal design (SUD). Building Information Modeling (BIM) is an innovative approach that allows designers to control project cost starting from the early stage of its life cycle. It helps designers to visualize their design and their associated materials and technologies before the building physically exists (Bryde, Broquetas, and Volm, 2013). This paper proposes a methodology to integrate BIM with the SUD principles and requirements in order to evaluate the benefits and costs of adopting such type of design over buildings anticipated life.

2 LITERATURE REVIEW

The primary objective at the early stage of building projects is to design and evaluate their budget and performance. Critical decisions concerning the profitability and performance can be made at that stage (König, 1995). Bogenstätter and Bogensta (2010) indicate that the conceptual phase of project’s life play an essential role toward sustainable buildings. They suggest that in order to integrate life cycle cost (LCC) and ecological requirements into the conceptual design, building specifications and knowledge about the characteristic values of LCC should be known at that stage. On the other hand, considering the concept of universal design affects the building cost, performance, and occupant’s wellbeing as well. Therefore, designers are expected to involve the universal design strategies at the early stage of designing buildings; this in return will reduce costs, improve designs, and solve usability problems during the design process (Afacan and Erbug, 2009).

Green building certification systems provide a guidance to design and operate buildings; it allows to document progress, compare buildings, and record design and operations outcomes and/or strategies (Wang and Fowler, 2012). One of the well-known designs, construction and operation rating system is the Leadership in Energy and Environmental Design (LEED), which was developed in 1994 under the U.S. Green Building Council. LEED is designed to rate new and existing commercial and institutional buildings based on the energy and environmental principles. Sets of criteria are included in the LEED system, where each criterion has its own required points; based on the accumulated points, a building would be awarded either certified, silver, gold, or platinum certification (Dhawade and Harle, 2014). Unlike the sustainable design, universal design has no specific guidance to design and operate buildings. However, many international standards were developed to support the usability of products. When reflecting the concept of universal design to the aging and people with disabilities, there is a wide number of established written documents, which are standards, references and/or norms to guide the design process such as ANSI 1986; BSI 1979; Fair Housing Act Design Manual 1996 (Demirkan and Olguntürk, 2014). Canadian National Building Code is one of the barrier free guidelines; it is a legal document that sets the minimum requirements for design and construction. It first introduced the accessibility requirements in 1965 and continued until 2010. During that period accessibility was mentioned in a several sets of requirements based on the national demand (Jrade and Valdez, 2012).

Researchers highlighted the need of knowledge when doing the integration between different computational tools applied at the conceptual design stage of building projects (König,1995). Building Information Modeling (BIM) is used to convert the 2D based drawing information systems (i.e. universal material specification, universal components, sustainable universal guides) into 3D object based information systems (Arayici et al., 2009). Multiple efforts were done in the construction industry to find the effective way to integrate BIM with sustainable design and analysis tools (Zhang and Xiao, 2013).
Achieving this goal have the ability to remove the construction industry’s obstacles, increase its productivity, efficiency, and quality and reach the sustainable development principles (Arayici et al., 2009). This paper proposes a methodology to integrate BIM with the SUD principles and requirements in order to evaluate the benefits and costs of adopting such type of design for buildings over their anticipated life.

3 METHODOLOGY

The proposed methodology is routed on an intense literature review related to the benefits of both sustainable and universal approaches. The literature illustrated factors that affect SUD such as: universal design features, sustainable building parameters, type of green materials, and proper technologies used toward SUD principles and strategies. All the information related to these factors is collected and accordingly the proposed model’s conceptual design process can be started. The process consists of three stages as shown in Figure 1. Starting by data analysis and comparison, passing through selecting the best types of materials and technologies that will be applied in the 3D model, then applying the life cycle cost analysis method and ending by the validation part. Afterwards, the model’s components and architecture are identified.

3.1 Model’s Components and Architecture

The proposed model consists of different components that are interrelated with each other in a way that data and information is shared in an automatic and efficient way. The proposed model incorporates the following three modules: a database module; a sustainable and 3D design module; and a life cycle cost analysis module. Figure 2 illustrates the components of the proposed model.

In order to simplify the development process of the proposed model its architecture is created as shown in Figure 3. The analysis section used to examine the input data and its criteria (i.e. SUD strategies, sustainable materials, and energy performance, Masterformat). The analysis is based on the set objectives of the research; therefore, the analysis takes into consideration occupants’ requirements, building codes and standards (CNBC), and LEED (Leadership in Energy and Environmental Design) system. The output is a list of selected sustainable universal materials, accumulated LEED credit points and certification level, total cost of the selected materials, total cost of the selected technology, net cost of the project, and life cycle cost analysis.
Figure 2: Model’s components

Figure 3: Model’s Architecture
3.2 Module 1: Database Module

The module’s objective is to establish a database necessary to apply the SUD approach. Set of data were collected form the literature, publishers, and suppliers, which include information related to materials and components used in doing sustainable universal design such as 3D design families for windows, walls, and roofs. This data is analysed and evaluated based on SU strategies and their technical specifications, LEED and CNBC. After that the collected data is stored and organized in the database based on the Masterformat Work Breakdown Structure (WBS), besides is the associated costs as shown Figure 4.

![Figure 4: Data collection process of the sustainable universal materials and components.](image)

3.3 Module 2: 3D Design Module

This module incorporates 3D design families that are created in accordance with the sustainable and universal design requirements. These families are made of different green elements and their associated information such as cost, keynotes, specification, description and comments. These elements are created to have them handy whenever designers are doing sustainable universal design for proposed buildings. Once the 3D design is done, the information related to the 3D project components can be exported to an external database using a Database Management System (DBMS) to calculate the project’s life cycle cost as illustrated in Figure 5. LEED accreditation system and UD design standard for each component (i.e. door width, height of handrails, height and width of the kitchen sink) will also be incorporated within the module.

![Figure 5: The process to integrate DBMS with BIM tool](image)
3.4 Module 3: Life Cycle Cost Analysis

This module is developed to evaluate the costs and benefits of adopting SUD; accordingly, a cash flow will be generated for analysis and comparison purposes. The module works based on two systems. The first system is to calculate the cost of the elements used in a 3D design of the proposed project by using BIM tool (i.e., Autodesk Revit). The second system is to extract the total cost obtained from "system 1" to calculate the cost benefits and to generate the cash flow accordingly. Figures 6 and 7 illustrate the module’s process and components.
4 VALIDATION

The developed model should be validated to test its capability and workability; therefore, a one floor case building project is used for that purpose. The project has an area of 8,089 ft². First, 3D sustainable universal design of the case building is created (using BIM tool, which is Autodesk Revit in this case, as shown in Figure 8). Second, the selected materials and components associated with the created 3D design chosen from the database created in module 1. The cost of a similar conventional building was obtained from RSMeans© Cost Data in order to compare it with the cost of the created 3D SU design.

![Figure 8: 3D sustainable universal model](image)

4.1 3D Model Design

The families created in accordance with sustainable and universal design requirements are implemented into the 3D designed model of the case building. They are imported with their associated information (cost, keynotes, assembly code, specification and description), which are stored in the database of module 1. The process of customizing BIM families is done by duplicating the existing family and adding the necessary parameters as illustrated in Figure 9.
4.2 Cost Benefits

This section presents the final result of the LCCA module that recognises the selected design elements by their keynotes. Therefore, after exporting the information of the 3D SU design model of the case building, the costs of these elements are automatically extracted from the external database based on their associated keynotes. Accordingly, the cash flow is generated for analysis and comparison as shown in Figures 10 and 11.

![Figure 9: Snapshot of customizing BIM families](image)

![Figure 10: Conventional building’s cash flow](image)
5 CONCLUSION

The paper emphasised the importance of considering sustainable universal design strategies at the early stage of designing buildings. The paper was developed in order to integrate BIM with SUD principles in order to evaluate the costs and benefits of adopting this type of building projects. Outputs of the developed model consist of a list of the selected SU materials and components, their associated LEED accreditation level; list of the associated universal design standards and suggestion; and a LCCA report presented in the form of cash flow that is automatically generated. Having such a model helps designers, owners, and developers evaluate and compare the benefits of adopting the construction of sustainable universal design buildings.

A NOVEL FRAMEWORK FOR BIM ENABLED FACILITY ENERGY MANAGEMENT – A CONCEPT PAPER

Firas A. Al-Shalabi¹, and Yelda Turkan¹, 2
¹ Department of Civil, Construction and Environmental Engineering, Iowa State University, USA
² yturkan@iastate.edu

Abstract: Building Information Modeling (BIM) enabled facility management has gained increased interest both in academia and industry. Previous research has shown the importance of having dynamic BIMs that can react and interact with real-time data obtained from building sensors. The other sought benefits of BIM such as improving workforce efficiency, proactive maintenance planning and improving maintenance records, which would lead to reduced energy and water consumption, are also acknowledged both by the academic community and the industry practitioners. However, BIM implementation for facility energy management activities, specifically for energy use monitoring, has not yet been explored, and one of the main reasons pertain to not having standards for BIM to be effectively used for facility energy management tasks. This paper provides a comprehensive literature review on BIM implementation and BIM requirements for facility management and facility energy management related tasks. Also, it proposes a conceptual framework that enables to achieve dynamic BIM for building energy use monitoring activities. The proposed framework connects BIM database with building energy management systems, while enabling BIM to act as a central data repository and a visualization tool to achieve energy use monitoring related tasks. Finally, it summarises the challenges to achieve dynamic BIM, and concludes with the expected benefits of implementing dynamic BIM for building energy management as well as recommendations for future research.

1 INTRODUCTION

Energy Management is one of the most important tasks among Facility Management (FM) responsibilities. Building Energy Management Systems (BEMS) are used to operate, control and monitor energy use in buildings. BEMS are also used to manage buildings’ environment and to control their heating, cooling and lighting systems. However, many of BEMS capabilities, such as automated data sharing, are not yet fully achieved.

There is a growing interest in the Construction Industry in using Building Information modeling (BIM) throughout buildings’ life cycle including Facilities Management (FM) practices. BIM implementation for FM applications, including energy management tasks, is considered an emerging field. Many benefits of implementing BIM in FM are sought during later phases of buildings’ life cycle. Those benefits include the ability to extract and analyze data for various needs that could support and improve decision making process, thus improve the energy performance during Operation and Maintenance (O&M) phase.

In this paper, a novel framework is introduced, where BIM is used as central data repository for operating buildings and managing their energy performance. This framework aims to achieve a dynamic BIM that
can act and react with BEMS and provide feedback to operators and building energy managers. This framework is part of a larger study that will be implemented for educational buildings in order to test its performance.

The paper is organized as follows; the next section gives background on current building operation and energy management practices including BEMSs. Section 3 then reviews current BIM uses and presents a novel framework for using BIM during building operations and maintenance phase. Section 4 focuses on the challenges that this framework would face and proposes solutions for each identified challenge. Section 5 draws conclusions and discusses future research needs.

2 CURRENT BUILDING ENERGY MANAGEMENT PRACTICES

Energy management is considered the top priority among the functional responsibilities in FM, followed by maintenance and repair (Sadeghifam et al. 2013; Underwood and Isikdag 2011; Yao 2013; Yiu 2007). Currently, tools such as Building Automation Systems (BAS) and BEMS are used to manage buildings' environment and control their heating, cooling and lighting systems, i.e. to perform building energy management tasks. Those systems are defined as a collection of microcomputer systems consist of Direct Digital Control (DDC) controllers and their control devices, which operate under supervisory control equipment or software collectively. Their abilities include sharing data with individual controllers for coordination and optimization, linking control processes, and performing operation tasks and reports (Doty and Turner 2009). BEMS are considered an essential source of information for building energy performance assessment that is used to optimize building energy performance as well as to fix any problems in building systems. However, many of BEMS capabilities, such as automated data sharing, are not yet achieved, and the current BEMS practices lack continuous data flow throughout facility life cycle (O’Sullivan et al. 2004) (Figure 1). Furthermore, data to the O&M phase is input manually, which results sometimes in inaccurate and incomplete information (Kelly 2013) that would require facility managers to re-enter the missing data they need to operate BEMS and guarantee optimal energy performance.

2.1 Design
- 2D drawings documents
- 3D models, lack sufficient specification
- Energy performance simulation

2.2 Construction
- As-built 2D drawings, 3D models
- Equipment testing and commissioning
- Minimum to no update on the energy performance simulation

2.3 Maintenance
- Re-entry of BEMS information
- Energy performance recording
- Minimum role of as-built drawings for O&M

Figure 1: Energy management related data flow throughout building life cycle

Continuous feedback from BEMS during O&M is considered essential to maintain the planned operational and energy performances of buildings. In addition to imprecise commissioning and BEMS malfunctioning, not providing real-time data to BEMS are considered as the main reasons for buildings’ performance deterioration. BEMS enable building energy performance monitoring, and help achieve energy savings of
up to 40% (Claridge et al. 1994; Herzog and LaVine 1992; Salsbury and Diamond 2000). However, they are becoming more complex and difficult to operate for an average operator (Hyvärinen and Kärki 1996).

BEMS records and stores building energy use data collected from sensors (e.g., temperature, CO2, zone airflow, daylight levels, occupancy levels, etc.) as well as data from fault detection and diagnosis sensors (e.g. air handler units controls, HVAC systems, valves controls and fans controls). Those sensors are numbered and organized based on their location in the building, and presented in list format. Sensor outputs, energy performance metrics (i.e. energy consumption), and other building performance metrics are presented in 2D histograms, tables and lists of tasks or in similar formats (Figure 2). Furthermore, maintenance records and other facility documents are kept in separate systems, not in BEMS, plus all these software have their own data structure that are not compatible with each other (Wang et al. 2013). As a result, when BEMS shows a problem for one of the building elements, facility energy managers and maintenance personnel need to obtain further information associated with that particular element. This requires them to check other systems such as building maintenance and warranty records. Finally, after gathering all necessary data, the problematic element needs to be located within the building, which maybe a tedious task, especially if the element is located in an area congested with other building elements such as pipes, ducts etc.

Figure 2: BEMS user interface

Overall, this makes it cumbersome to evaluate energy performance of an entire facility by gathering data from separate systems (Pietruschka et al. 2010; Yao 2013). Furthermore, it limits the possibility to react to any changes or possible problems in the system on time. It also prevents from developing a proactive maintenance strategy, which may increase energy losses due to system defects. For example, it is estimated that about 30% of the energy in commercial buildings is wasted because of degraded and poorly maintained equipment (Granderson et al. 2011).

3 A NOVEL DYNAMIC BIM FRAMEWORK FOR BUILDING ENERGY MANAGEMENT

There is a growing interest in the Construction Industry in using (BIM) throughout buildings’ life cycle including FM practices. BIM supports a collaborative approach throughout the project's life cycle phases and engages multiple stakeholders in the project including architects, engineers, contractors and the facility managers. Furthermore, BIM eliminates tedious and error prone data entry process, which leads to decrease/eliminate loss of project/facility information during project lifecycle (Figure 3) (Eastman et al. 2011).
BIM implementation for FM applications, including building energy management, is considered an emerging field that lacks real case studies (Kelly 2013). However, most benefits of implementing BIM in FM are sought during later phases of buildings’ life cycle, such as the ability to extract and analyze data for various needs that could support and improve decision making process (Azhar 2011). Furthermore, BIM in FM applications can help increase the efficiency of work order executions by providing faster access to data and by improving the process of locating various facility elements with its user friendly 3D interface (Kelly 2013). In addition, BIM implementation in FM and BEMS would help eliminate redundancy in data re-entry since BIM would act as a central data repository (Figure 4) that supports all activities throughout the buildings’ life cycle from design to maintenance and operations (Fallon and Palmer 2007).

Figure 3: Documentation loss of value during project lifecycle (Eastman et al. 2011)

Figure 4: BIM as Data repository in buildings’ life cycle
3.1 Dynamic BIM framework

BIM implementation for energy management activities has been limited to green retrofit modeling and design simulations. This maybe a result of unforeseen productivity gains that can be realized from reduced equipment failure as well as the productivity increases that maybe realized through an integrated platform (Becerik-Gerber et al. 2011). A suggested step forward would be to integrate energy use data with BIM database for building energy use monitoring (Muthumanickam et al. 2014) in order to achieve a dynamic BIM (Figure 5). Having dynamic BIM models that reflect actual as-built conditions and contain real time building information gained increased interest lately (Akanmu et al. 2013). A dynamic BIM model has the potential to provide improved documentation, minimize the cost of facility operations and maintenance, serve as a useful reference for future projects, and improve proactive maintenance planning (Chen et al. 2014; Teicholz 2013). This, overall, would lead to reduced energy consumption as a result of having well maintained, efficient mechanical equipment.

This paper proposes a novel framework that utilises dynamic BIM models containing real time building information obtained from sensors and BEMS to improve facility energy management activities (Figure 6). This framework aims to integrate BIM with BEMS systems using a programming application to enable industry foundation classes (IFC)-based BIM files read and update their database based on the BEMS live feed. Visualization of BEMS data in user friendly 3D BIM interface would enable facility energy managers to take timely actions about the problematic building elements, i.e. proactive maintenance, which would translate into energy savings.

In order to achieve the proposed framework, two programming applications will be developed; the first one is to link the BIM database with energy sensor output data, through BEMS, thus to visualize real-time energy use as color coded 3D models and to link it to each model element, where building maintenance and records of warranties and other information are stored. This would allow comparing the collected data with historical energy consumption data, the design or manufacturer claimed data and maintenance records simultaneously, which would help discovering any over consumption or flaws in the system in an efficient and timely manner. The second programming application will be developed to link BIM database with energy analysis programs, where energy consumption can be analyzed and over consumption can be detected.
Consequently, this should enable energy managers to detect any over consumption immediately, which would help them determine the reasons behind it faster. This would improve proactive maintenance plans and actions as it enables detecting defective or faulty equipment in a faster manner, so that they can be replaced immediately without causing more energy losses.

4 DYNAMIC BIM CHALLENGES

In order for BIM to be used in facility and energy management practices it needs to be dynamic; and that is, reflecting actual conditions of a facility and presenting real time building information. However, achieving “dynamic” BIM is faced by a number of challenges, which can be grouped into three main categories: (1) lack of guidelines for the necessary information required for BIMs to be used in building energy management related tasks; (2) inaccuracy and/or incompleteness of as-built BIMs; (3) interoperability issues between BEMS and BIM authoring tools (Laine et al. 2007). In this paper, a framework that connects BIM with BEMS is being introduced to help overcome one of these challenges, the interoperability issue.

The first obstacle, the necessary information required for BIMs to be used for building energy management tasks, has been addressed and stated in the literature. Becerik-Gerber et al. (2011) suggested that three types of energy management related FM data should be incorporated into BIM: (a) equipment and systems, (b) attributes and data, (c) portfolios and documents. However, specifications and details of this FM data, such as type of equipment that should be included in the model and attributes and the level of detail of the building model, were not described. Furthermore, the Pennsylvania State University computer integrated construction research program report (2013) suggested that the following items should be identified, documented and included in order to achieve dynamic BIMs: (a) type of building elements to be tracked (b) information display format (c) Level of Detail (LoD) required for each model element (d) properties and attributes of each element.

The second challenge pertains to inaccuracy and/or incompleteness of as-built BIMs. Several researchers suggested that early involvement of FM personnel in design and construction phases would be very beneficial for developing accurate and complete as-built BIMs (Teicholz 2013; Wang et al. 2013). However, such involvement remains limited due to lack of knowledge about BIM implementation for FM tasks (Kelly 2013), lack of specific data requirements (Becerik-Gerber et al. 2011; Kelly 2013), and interoperability issues (BIFM 2012). The issue related to inaccuracy of as-built BIMs (at object level), has been addressed both by researchers and industry practitioners. Several researchers emphasized the importance of having accurate and up-to-date as-built BIMs for FM tasks (Ahmed et al. 2014; Akinci 2015; Bosché et al. 2013; Son et al. 2014). Therefore, developing guidelines and requirements for BIMs to be used for building energy management practices is essential for achieving dynamic BIM and needs broader attention.
The third obstacle, interoperability issue, has been widely expressed both by researchers and industry practitioners. Interoperability enables to manage and communicate electronic data among collaborating firms, between different disciplines in individual companies and between different phases of a project, i.e. design, construction, maintenance and business process systems (Gallaher et al. 2004). Interoperability issues between FM and BEMS programs and protocols are common and well known. Furthermore, there are interoperability issues between BEMS and BIM as well as between various programs that are used for building maintenance, building condition monitoring and document management. Typically, these programs have their own data structure and are not compatible with each other (Wang et al. 2013). The role of BIM for FM and BEMS within current practice is still unclear. However, as shown in Figures 5 and 6, there are possibilities for connecting BIM with various BEMS and other FM software. BIM would act as a central data repository that collects and stores data from various systems, and provide access to this data through a 3D, easy to use, user friendly interface.

5 CONCLUSIONS AND FUTURE RESEARCH

BIM implementation for facility energy management practices has gained increased interest both in academia and in industry in recent years. The current energy management practices have several drawbacks such as lacking automated data sharing, requiring manual data entry during O&M phase, and not facilitating continuous data flow throughout facility life cycle. BIM enabled energy management facilitates extracting and analyzing data for various needs to improve decision making process, which would translate into increased efficiency in work order executions and elimination of redundancy in data entry. Dynamic BIM models could improve documentation, minimize the cost of facility operations and maintenance, serve as a useful reference for future projects, and improve proactive maintenance planning which would lead to reduced energy consumption. Lack of guidelines to prepare BIM for BEMS, inaccuracy or incompleteness of as-built BIMs and interoperability issues between BEMS and BIM authoring tools are the main challenges that prevents from achieving dynamic BIM. In this paper, a conceptual framework that proposes to connect BIM with BEMS was introduced to help overcome the interoperability issue. The proposed conceptual framework will be implemented by developing a programming application to link BIM and BEMS and tested in future research. It is expected that it would help improve current facility energy management practice, and help save energy.

BRIM IMPLEMENTATION FOR DOCUMENTATION OF BRIDGE CONDITION FOR INSPECTION

Firas A. Al-Shalabi¹, Yelda Turkan¹, ² and Simon Laflamme¹
¹ Department of Civil, Construction and Environmental Engineering, Iowa State University, USA
² yturkan@iastate.edu

Abstract: Bridge condition inspection data provide critical and rich information for assessing structural condition. Currently, the majority of bridge inspection methods use printed checklists, and their interpretation is labor intensive, subject to personal judgment, and prone to error. To realize the full benefits of bridge inspections, there is a need to automate the data management process. This study implements Bridge Information Modeling (BrIM) technology for bridge inspections and compare it to the conventional approach of paper checklists. The environment combines a 3D representation of the infrastructure, and allows the integration of inspection data, such as the presence, type, severity, and localization of damage and previous maintenance decisions. In this paper, we use the acronym BrIM to refer to the database that integrates a 3D bridge model and bridge element condition data. In order to validate our approach, we obtained 2D drawings and previous inspection and maintenance data from two bridges located in Ames, Iowa, and modeled them using Revit. We then synced both models using cloud-based solutions so that we could access them from tablet computers on-site. Then, we tested the BrIM based inspection methodology with Iowa DOT engineers and bridge inspectors, who confirmed that BrIM can be used to automatically query, sort, evaluate and send information to decision makers. Furthermore, we conducted a short survey with several DOT engineers and bridge inspectors regarding with possible expected benefits of using 3D BrIM based solutions for inspections. It is concluded that this methodology will substantially improve bridge assessment and maintenance operations, resulting in reduction of costs associated with bridge assessment, and improvement structural resiliency by enabling more effective maintenance and repair operations.

1 INTRODUCTION

The Federal Highway Administration (FHWA), according to Federal-Aid Highway Act of 1968, requires all states to perform a biennial inspection for each bridge to document its condition. Current bridge inspection and assessment methods rely heavily on a reiterative process of manual data entry and extraction, which are subjective, error prone and time consuming. Data collected during site inspections provides the foundation for maintenance and rehabilitation actions. Bridge Information Modelling (BrIM) is a fairly new technology that is still in its infancy in terms of its adoption in the industry. BrIM technology enables storing all bridge data, including its drawings and models, material specifications, inspection notes and others, in a central database that can be accessed both from the office and the field. This gives an opportunity to adopt BrIM to develop an automated bridge inspection method. BrIM has many proven benefits such as reduced construction duration and cost savings when implemented during design and construction. However, the benefits of adopting it for inspection purposes are still uncertain. In this paper, a novel framework that employs BrIM and cloud computing technologies for bridge inspection and
assessment is introduced. The framework was tested to determine its applicability and impact on bridge inspection. The test/mock inspection was conducted on a bridge located in Ames, Iowa with the collaboration of Iowa DOT personnel to evaluate and compare the current and proposed inspection practices. Furthermore, a survey was conducted among eight other DOTs in order to better understand current and possible future BrIM applications at their institutions. The survey included questions regarding 3D modelling, BrIM applications in general, as well as BrIM adoption for bridge inspections.

This paper is organized as follows: Section 2 provides a literature review on information technology and modelling applications in heavy-civil sectors. Section 3 presents the research methodology by detailing the BrIM based bridge inspection framework and by providing the details of the survey. Section 4 presents the results of the mock inspection and the survey. Section 5 draws conclusions and discusses future research needs.

2 LITERATURE REVIEW

The U.S. economy depends heavily on its road network and bridges. Any failure in maintaining this network can cause substantial economic losses (Elbehairy 2007). In order to keep this network maintained, all states must perform a biennial inspection for each bridge to document its condition. This requirement puts a cumbersome responsibility on state DOTs to manage their assets. As a result, standalone Bridge Management Systems (BMS) (e.g., AASHTOWare PONTIS and VIRTIS) were adopted to satisfy DOTs needs such as: the operational requirements, planning and program management, e.g. load rating, permitting and routing. However, those systems do not satisfy the need to coordinate management tasks of all phases of a bridge life cycle i.e. design, construction, operations and program management (Shirolé 2010). Furthermore, they require re-entry and transformation of data, which is a cumbersome, redundant and error prone process. On the other hand, comprehensive asset management solutions such as BrIM could improve the deployment of services and maintenance resources, reduce maintenance costs and increase the quality of services (Zhang et al. 2009). BrIM benefits are being recognised by DOTs and asset owners (Howard and Björk 2008). While the current BMS do not satisfy the need for a more comprehensive solution covering the entire life cycle of a bridge (Shirolé 2010), BrIM can offer an integrated comprehensive solution for life-cycle bridge management (Chen and Shirolé 2006; Chen and Shirolé 2007; Shirole et al. 2009; Shirolé 2010).

Building Information Modeling (BIM) is an emerging technology that has gained increasing popularity among designers and contractors in the civil, architectural, and construction industries. BIM is the development and use of a 3D digital model to simulate and represent the design, construction and operation of a facility. This model is a data-rich, object-oriented, intelligent and parametric digital representation of the facility, where data appropriate for various users’ needs can be extracted and analysed in order to generate useful information for decision makers in a facility and improve the process of delivering a facility (Eastman et al. 2008; AGC 2006). Despite a variety of definitions, the agreement is reached that BIM is a digital representation of a facility. Also, it is widely accepted that BIM is not only a modeling software, but an integrated design and construction process providing a collaboration and communication platform for various parties throughout the project lifecycle (Carmona and Irwin 2007).

Bridge Information Modeling (BrIM) is the specialization of BIM to bridge projects. Other similar terms in the field include Heavy BIM, Horizontal BIM, Virtual Design and Construction (VDC) and 3D Engineered Models for Construction. Heavy civil construction projects such as bridges have unique characteristics compared to a typical building construction project. Various land contour, changing site conditions over the long span of a project, existing infrastructure segments and traffic coordination during construction are some of those unique characteristics that impact the design and construction of a new project (Cylwik and Dwyer 2012). Previous research has highlighted many benefits that can be obtained from implementing BrIM for bridge maintenance and operations. (Shirolé 2010) summarised the benefits that can be obtained from adopting BrIM in bridge management as follows: 1) satisfied data needs at project level; 2) elimination of repetitive manual transcription of data; 3) improved data quality, reliability and speed of bridge inspection; 4) easy access to bridge safety related data so that it can be extracted and updated in an efficient manner; 5) improved communication between inspectors and bridge engineers by providing
virtual models which would eliminate the need for re-inspections and improve well inform the decision makers; and 6) cost effective bridge life cycle management (Shirole et al. 2009). Possible benefits of BrIM for bridge management are acknowledged both in academia and industry. However, its implementation and possible benefits for managing existing bridges is still unclear (Marzouk and Hisham 2011). This paper aims to create a better understanding of bridge inspection needs and how to meet them using BrIM. A novel framework is created and tested with cooperation of Iowa DOT, and then their feedback in addition to other DOTs was recorded.

3 METHODOLOGY

BrIM can be considered a comprehensive bridge management system as it enables managing bridge information from design through maintenance and operation phases. In this paper, a BrIM based bridge inspection workflow is presented. This workflow involves using a mobile device such as a tablet computer that enables inspectors to access an accurate, up to date 3D information model of the bridge via cloud data storage services. This 3D model contains all bridge elements including their maintenance history at object level. This environment allows entering and storing inspection data such as sketch drawings and measurements. The proposed workflow allows direct access to inspection data from home office. This BrIM based inspection workflow is tested with Iowa DOT inspectors and bridge engineers. In addition, a survey with several DOTs was conducted to evaluate the applicability of the proposed framework.

3.1 BrIM enabled inspection framework

This study has taken an existing bridge located on highway US 30 spanning the Skunk River in Ames, Iowa as a case study. Two dimensional (2D) plans and historical inspection data of the bridge were provided by Iowa DOT to the research team in electronic document format. The research team then combined all this data in an intelligent 3D model, i.e. 3D BrIM.

In the traditional way of inspection, a bridge is divided into three groups i.e. deck, super structure and sub-structure. Usually the inspection team divides the main three groups between the team members and each group is inspected using a separate inspection sheet. The other method is doing a loop by starting with one group to the next until they finish. The condition of each element at the time of inspection is documented to the best judgment of the inspector and according to the measurements that are taken from the damaged area, - e.g. in concrete structures, the inspectors look at the integrity of the bridge, specifically corrosion, spalling, concrete cracks and paint cracks. A crack comparator scale is used to measure the width of the crack. Any crack that is at least 1/16 inch wide should be watched. The depth of the crack is not measured, however if rust was found this is taken as an indication that the crack is deep and further inspection is required. Then, the inspection team draws manual sketches to document the size, severity, depth and location using true dimensions of the problem. Finally, the report and the sketches are taken to the office and re-entered again into the BMS to update the current status of the bridge condition. Then bridge engineers do a comparison with the previous inspection, and actions are taken to fix problems, if any existed.

The 3D BrIM model was built by mimicking the traditional way of bridge inspection. Model elements were divided into similar groups such as deck, super structure, sub-structure, channel and piers in order to mimic the traditional bridge inspection method. Each of those categories is downloaded as a separate model to the tablet application, and they can be merged again easily using the 3D modeling software application in the office. Then, each group is given a specific color, and each element is provided with details that are pinned to that element. Those details include previous inspection information with technical details. The BrIM-enabled inspection framework concept, as shown in Figure 1, consists of three major elements; data cloud, mobile devices and home office computer interface. The data cloud can be accessed both from home office and from the site, which enables data sharing with all stakeholders simultaneously. This procedure would help increase the speed of communication and eliminate any re-entry of the inspection data. It would also prevent any possible data loss during data transfer. Having a better representation of the field conditions and instantaneous access to inspection data would enable decision makers to make better informed decisions since they would have a better idea of the problem and direct feedback from other stakeholders such as bridge engineers and inspectors.
3D BrIM models can be downloaded to data cloud from home office where they can be accessed by inspectors in the field. Inspectors then choose an element that has a deficiency and by freezing the model they create an image where they can document the problem and enter all data that is required and upload all the inspection data back to the data cloud (Figure 2). This enables bridge engineers to access the inspection data from home office where they can conduct further analysis.

3.2 DOT Survey

A web-based survey, using the Qualtrics survey tool, was conducted in order to evaluate applicability of BrIM for inspection purposes in other states outside Iowa. The survey was sent out to eight DOTs in the Midwest in addition to New York and Pennsylvania DOTs to obtain their feedback on implementing BrIM.
technology for bridge inspection and maintenance. DOT personnel ranging from bridge engineer to a
director of bureau of structures from eight different DOTs participated in the survey.

The questions varied between open format questions where DOTs personnel provided their feedback,
and closed format questions that varied between Dichotomous questions and Likert questions. The
questions were directed to understand three key aspects; the first one was whether the DOT has any
experience in using BrIM technology and how they are using it. The second one was to find out whether
they are facing any problems with the current bridge inspection practices. Finally, the third one was to
determine the potential of the proposed BrIM based framework for inspections.

The surveyed DOTs acknowledged the benefits of BrIM and showed interest in using it. However, they
expressed several difficulties and challenges they are facing when implementing it during design and
construction phases. Furthermore, most DOTs acknowledged that BrIM would be beneficial for bridge
inspection. The detailed findings of this survey are summarized in Table 1.

4 RESULTS AND DISCUSSION

According to the survey, the number of qualified bridge inspectors range from 10 to 50 among the states
surveyed in this study. This number can reach up to 650 when consultants and freelance inspectors are
included. Typically 2-4 inspectors are required for inspection of a regular bridge. The number of
inspectors can reach up to 7 for inspection of special types of bridges such as over water bridges. The
yearly cost of inspections varies among states as the number of bridges and the size of the states vary.
When asked what means are being used for bridge inspections in the current practice, 71% of
respondents said that they use the paper based method. And the other 29% of the respondents stated
that they are using mobile computing technologies such as Personal Digital Assistant (PDA), tablets and
laptops. About 50% of the surveyed states responded that their DOTs use 3D information models and
information technologies during design and construction of civil projects, and 33% of the respondents
stated that they are using it specifically for bridge design and construction. This result is compatible with
the opinion that states that large asset owners are moving towards more comprehensive tools to manage
their assets (Howard and Björk 2008; Zhang et al. 2009).

The DOTs who participated in this survey recognized BrIM as a beneficial tool for bridge inspections.
However, they are not planning to adopt it in their bridge inspection practices in the near future. The
reason for this maybe the invalidated benefits of BrIM for the inspection process (i.e. BrIM must prove its
ability to improve inspection process over current practices). In this study, while conducting the mock-up
inspection, the time needed for inspecting each element as well as signing and dating the inspection
documents were reduced significantly. This is mainly due to the user friendly sketch drawing and input
recording functionalities of the software.

The surveyed DOTs predict several challenges that maybe faced when implementing BrIM technology for
bridge inspections. One major challenge mentioned by most survey respondents was the concern of
damaging portable electronic devices during the inspection process. They stated that electronic portable
devices used for inspection tasks must be durable in rain, sunshine and extremely cold weather
conditions. And they need to be sturdy enough so that they do not break down if dropped; should be
small enough to fit in inspector’s harness, and large enough for sketching and visualization. This problem
was also stated in the literature (Chen and Kamara 2008; Tsai et al. 2014), and can be overcome as
mobile devices are being improved continuously; e.g. their mobility, durability, hardware compatibility and
battery life being improved constantly to satisfy the needs of construction job environments. Moreover, a
variety of accessories are available to protect tablet computers in harsh outdoor environments.

</table>
Another critical challenge mentioned was cell phone signals. There are many bridges located in rural areas where no cell phone service is available. The authors and other researchers (Tsai et al. 2014) suggest an offline BrIM approach to overcome this challenge. An offline BrIM tool for inspection enables downloading all models before arriving to the site. The inspector can record and save all inspection data on the device while offline and upload them to the data cloud when he/she has a wireless connection. This procedure was tested during the mock-up inspection with Iowa DOT inspectors where no cell phone signal was available under the bridge. Another challenge mentioned was related to the initial costs of implementing a new technology, along with the software costs, cost for keeping them up-to-date. In addition, initial investment in time and money to build 3D information models of existing bridges needs to be taken into consideration. The authors suggest that this barrier could be overcome by adapting new technologies into current practices gradually. In addition, case studies from institutions that received benefits from implementing new technologies in their projects would help and encourage other asset owners adopting new tools and technologies into their practices. For example, (Cox et al. 2002) documented that using mobile devices such as PDAs reduce costs and labor time during data collection.

While many DOTs listed lack of resources and initial investment cost as an institutional barrier to implementing BrIM for inspections, others listed human factor as a barrier, such as inspector’s education and training. And some DOTs were concerned about legal issues such as digital signatures of inspectors, integrity of data during transmission and the critical details that must be kept confidential for security purposes.

When asked about the current inspection practices, around 60% of the responses admitted that DOTs are facing many challenges with the current inspection practices. The main challenge is to conduct inspections on time in order to comply with the federal law. Furthermore, challenges in training inspectors, inadequate staff, aging staff and new inspection problems with newer bridge designs were also mentioned. Overall, the current inspection practices challenges DOTs in their bridge management practice as there are problems with effectively processing and integrating inspection data with bridge management databases (Agrawal et al. 2009; Lee et al. 2008; Shirolé 2010).

The surveyed DOTs stated lack of knowledge in using 3D information modelling. On a five level Likert scale ranging from poor to excellent, 62% of surveyed DOTs considered themselves having fair or poor knowledge; while 13% considered themselves as good and 25% ranged between very good and excellent. Finally, 71% of the surveyed DOTs did not think that uploading inspection data to the data cloud directly would increase the speed and precision of the inspection. This might explain the small percentage (28%) of the surveyed DOTs that indicated having future plans for implementing BrIM in their bridge inspection process.

5 CONCLUSIONS

Bridge inspection is considered a time consuming and redundant task in the traditional way. Errors are likely to occur depending on the way the inspection is conducted and based on the inspector’s experience and personal judgment. This study shows the possibility of extending the benefits of BrIM technology for bridge inspections. DOTs are recognizing the benefits of BrIM as a comprehensive solution for managing their bridge assets. BrIM based inspection would help eliminate redundant data collection, data re-entry, and minimize possible errors that may result from inspector’s personal judgment or limited experience. It would also help reduce errors and improve overall inspection quality and safety by reducing the time needed for inspection. Furthermore, it can also help reduce the time needed for each inspection by improving the way sketches are drawn on site, as well as reducing the time needed for signing and dating each inspection paper. Bringing mobile devices and BrIM to the bridge management practice is applicable. However, its sought benefits need to be validated for its adoption. For future research, the research team would recommend validating the benefits of BrIM for bridge management through several case studies.

GUIDELINE TO APPLY HEDGING TO MITIGATE THE RISK OF CONSTRUCTION MATERIALS PRICE ESCALATION

Mohammad Ammar Al-Zarrad¹,², Gary P. Moynihan¹ and Stephanie C. Vereen¹
¹ Department of Civil, Construction and Environmental Engineering, University of Alabama, USA
² mazarrad@gmail.com

Abstract: Accurately forecasting cost is vital to the success of any construction project. Cost estimation encompasses uncertainty, since construction projects are exposed to many forms and degrees of risk. Materials price volatility and shocks constitute one aspect. Most current approaches for material risk assessment are deterministic and do not take into consideration material price fluctuation. The application of hedging, to mitigate the risk of construction material price fluctuations, is proposed in this research. Although it is known that using hedging as a risk management tool adds value to a financial firm, limited knowledge has been established about using hedging for construction material price risk mitigation. Hedging has also been a practice applied in the airline industry for a long time, and substantive research has been completed in the field of airline fuel hedging. The objective of this research is to identify best practices in the area of airline fuel hedging to provide an outline for implementation in the construction industry, and to develop a step-by-step guideline to applying materials hedging in the construction industry. This is considered to be the first attempt to match construction material hedging with the airline fuel hedging application. The guideline presented herein helps construction companies to apply hedging to mitigate the risk of construction material price fluctuations. This guideline improves construction companies’ ability to submit a very competitive bid on a specific project.

1 INTRODUCTION

Cost estimation is considered to be one of the most important tasks in the development of a construction project budget. However, due to the possibility of material price fluctuation, cost estimation is usually uncertain. Construction materials may encompass 50-60% of the total cost of a project if combined with other services such as equipment (Spillane 2011). When left unmanaged, materials may have a greater significant impact on total project cost fluctuation. Materials price uncertainties are extensive throughout the project lifecycle, occurring at project initiation and continuing until termination. Fluctuations of materials’ prices, which are volatile, are a driver of project costs. The engineering and construction (E&C) industry has tried to address materials risk through numerous approaches. Most current approaches for material risk assessment are deterministic, which means that they treat variables such as price as if they were fixed. However, in reality, material prices fluctuate up and down (EUFRA M 2014). Indemnification and insurance provisions are the primary risk mitigation devices in any construction contract. These provisions obligate the party with less bargaining power to insure the other against certain risks. These provisions could help the two parties allocate materials risk and other risks contractually (Thomas 2014). However, they cannot address unforeseen circumstances that can affect materials pricing (i.e., the 1973 oil embargo). Current approaches for material risk assessment do not reflect price volatility issues. The construction industry has been slow to realize the potential benefits of new methods in risk management.
Although it is known that using hedging as a risk management tool adds value to a financial firm (Marsden and Prevost 2005), limited knowledge has been established about using hedging for construction material price risk mitigation. Macdonald (2013) first suggested using hedging as a tool to mitigate material price risk. In her research, Macdonald provided an overview of the construction industry need, and introduced the problem of materials price risk mitigation in construction projects. Hedging has been the practice in the airline industry for a long time, and substantive research has been found in the field of airline fuel hedging. Identifying best practices in the area of airline fuel hedging, then applying it in the construction industry, could save time and eliminate trial and error process improvements. The objective of this research is to develop a step-by-step guideline to apply hedging to mitigate the risk of materials price in construction projects.

2 METHODOLOGY

The first step of this research was conducting a literature review to reveal what is already known in the body of knowledge about hedging practice in the airline industry and the construction industry. The literature search revealed that there is a gap in the body of knowledge about using materials hedging in the construction industry. This research is an attempt to fill this gap. The second step of this research was collecting and identifying the best hedging techniques in the airlines industry. A best practice refers to a way that has constantly shown results superior to those achieved with other means, and that is used as a benchmark (Stevenson 1996). This research considered qualitative and quantitative criteria to identify best practices in the area of airline fuel hedging. The quantitative criteria looked for the hedging practice that consistently showed the pursued results. This means that the practice has been used for a long time, and each time the practice has been used, it gave the same result. The qualitative criteria looked for the practices that had a direct or immediate effect on the results. This means that the practice had a direct relationship with the result. For example, if a company uses only swaps as a hedging technique, and the hedging was successful, then the swaps technique has a direct relationship with the result. The hedging practice should meet both criteria to consider it as a best practice. Figure 1 shows the process to identify best practices using the quantitative and qualitative criteria.

Eight primary research articles has been identified to meet the quantitative aspect, and one research article has been identified to meet the qualitative aspect. The third step was investigating the possibility of applying the knowledge collected from step two to create a guidance to help construction companies apply material hedging successfully. The researcher utilized the traditional risk analysis process to develop the guideline presented in this research. The final step was drawing conclusion and providing recommendation for future research direction.

3 NATURE OF FINANCIAL HEDGING

A hedge is an investment position projected to offset potential losses that may be incurred by a companion investment (Mattus 2005). Derivatives are financial instruments used in the hedging process.
They are contracts whose value is derived from one or more variables called underlying assets (i.e., fuel). Forward, future, option and swap are examples of derivatives contracts. Both forward and future contracts are an arrangement to buy or sell something at a future date at a fix price. Contrasting with forward contracts, futures contracts trade on central exchanges, called future markets (Morrell and Swan 2006). Another type of derivative is called an option. Options are of two types: calls and puts. Options give the buyer the right, but not the obligation, to buy or sell a certain quantity of the underlying asset, at an agreed price on or before a certain future date (Morrell and Swan 2006). The last type of derivative is called a swap. Swaps are private arrangements to exchange cash flows in the future according to an agreed formula (Morrell and Swan 2006). Hedging derivatives and their integration make up the major part of an oil company's operations in the worldwide oil market (Mattus 2005).

4 FUEL HEDGING IN THE AIRLINE INDUSTRY

Based on a survey of the relevant literature, eight primary research articles provided the level of detail to indicate best practices in airlines industry. Mercatus Energy Advisors (an independent energy trading, marketing and risk management advisory firm) conducted a survey of executives at 24 global airlines. Participants in the Mercatus (2014) survey stated that they are currently and/or have previously utilized various hedging instruments and structures. However, the majority of these airlines are utilizing fixed price swaps, call options, and collar options, which tend to be the favored hedging instruments of the industry. According to Mercatus (2014), only 3% of the companies use futures while 39% use swaps. Also, 29% of the companies use call option and 26% use collar option while 3% use forwards. Carter, Rogers, and Simkins (2006) conducted a similar study on the airline industry and they arrived at the same result as Mercatus (2014). Carter, Rogers, and Simkins (2006) stated that the call option is used primarily by airlines, since it protects them from any fuel price increase.

Options are more flexible than futures, giving the holders the ability to protect themselves against undesired price movements, while at the same time giving them the chance to participate in favorable movements. However, in order to hedge their exposure to fuel prices, airlines have more recently moved to use blends of a call and a put option called a collar (Carter et al. 2006). The call option protects the holder from price rising higher than its strike price (the price at which the contract can be exercised). The holder of this call option also writes a put option to limit any possible gain if the price decreases below its strike price (Carter et al. 2006). The total cost of taking the two options is the difference between the call option premium paid and the put option premium received. This is popular with airlines because it fixes the price for fuel between two identified values.

Carter, Rogers, and Simkins (2006) stated that a swap is often considered the "most favorite" hedging strategy for airlines. The airline would buy a swap for a period of one year at a fixed strike price for a stated amount of jet fuel per month. The average price for that month is then compared with the strike price. If the average price is larger than the strike price, the counter-party (which is a bank) would pay the airline an amount equal to the difference between the average price and the strike price times the amount of fuel (Carter et al. 2006). However, if the average price were lower than the strike price, then the airline would pay the difference. A third study is done by Gerner and Ronn (2013). They backed up the results of both Mercatus (2014) and Carter, Rogers, and Simkins (2006). Gerner and Ronn (2013) stated that most airline companies use call options to provide insurance against sudden upward price shocks. Also, buying a jet fuel swap allows airlines to hedge their exposure to jet fuel prices fluctuation. If the price of fuel goes up, the gain on the fuel swap offsets the increase in fuel cost (Gerner and Ronn 2013). On the other hand, if the price of fuel declines, the loss on the fuel swap offsets the decrease in fuel cost. Either way, once the swap is executed, the airline has locked in their fuel cost (Gerner and Ronn 2013).

According to Scott Topping, Director of Corporate Finance for Southwest Airlines, “the majority of airlines depend on plain vanilla instruments to hedge their fuel costs, including swaps, call options and collars” (Carter et al. 2004). This is consistent with the argument of the first three articles above. Cobbs and Wolf (2014) state that “the most frequently used hedging contracts by airlines are: swap contracts (including plain vanilla, differential, and basis swaps), call options (including caps), collars (including zero-cost and premium collars)”. Further, Lim and Hong (2014) state that futures are used by some airlines, but most airlines today use primarily swaps and call options to hedge their jet fuel price risk. Westbrooks (2005)
supports this argument and he state that most airlines use hedges to some extent to limit their fuel risk. This has been done mostly by utilizing swaps, call options, and collar options.

Carter, Rogers, and Simkins conducted an earlier study in (2002) investigating the fuel hedging performance of 27 firms in the U.S. airline industry during 1994-2001. They found a positive relation between using call options and swaps as hedging tools and value increases in capital investment (Carter et al. 2002). These eight articles identified call options, collar options, and swaps as the best practice for fuel hedging application in the airlines industry. One of these articles found a positive relation between using these hedging tools and capital value increases. As a result, call options, collar options, and swaps meet this research’s quantitative and qualitative criteria for best practice since they are the primary derivatives that are used by airlines and they have a positive relation with airlines companies value increase. The fuel hedging process includes nine steps as shown in Figure 2. First, the airline industry identifies all energy-related risks including market, credit and regulatory risks. These risks can be investigated using quantitative or qualitative analysis. Next, an energy risk management policy can then be established to formalize the goals, objectives and risk tolerance, and to determine who executes the hedging policy. A hedging committee is the preferred choice for the airline industry to make hedging decision (Mercatus 2014). The responsible party should determine three main values:

- The strike value, or the value of the jet-fuel at which the contract starts to pay out.
- The tick value, or the payout amount for $ increment change in a gallon of jet fuel price beyond the strike value.
- The maximum financial payout of the contract that need to be purchase.

Once the previous steps are in place, then the execution of hedging and trading strategies can begin. Airline companies ask financial institutions and fuel suppliers to provide them with hedging advice, data, and information. Then, the airline company purchases hedging contracts that fit their need. The
preferred types of contract are options and swaps. These contracts are traded Over-The-Counter (OTC). OTC derivatives are traded directly between the airlines and banks, and as such have counter-party risk that must be taking into consideration (Gerner and Ronn 2013). Hedges should be constantly examined to determine if they fit within the company’s goals and management policy. The positions should be enhanced when possible. As the company’s risk exposure changes, there should be an efficient process for reporting and determining if the hedging policies need to be modified or if the existing policy and strategies are correct. A call option protects the airline company from fuel price increase. As suggested by Gerner and Ronn (2013), an example of a call option for an airline is shown in Table 1.

Table 1: Call option for an airline company

<table>

In this example, the option seller would pay the airline company $1,000,000 per 10 cent in excess of $5 per gallon of jet fuel, up to a maximum payment of $5,000,000. Figure 1 shows the airline hedging process steps.

5 CONSTRUCTION MATERIALS HEDGING PROCESS

Based upon investigation of airlines fuel hedging practices, this research provides construction companies with a step-by-step guidance to apply material price hedging successfully. These steps are based on the knowledge collected from the fuel hedging application in the airline industry. As shown in Figure 3, these steps are: identify and analyze risks; determine tolerance for risk; develop hedging management policy; develop hedging execution strategies; implementation, monitoring, analyzing and reporting risk; and, finally repeat the process.

![Figure 3: The seven step guideline for construction material hedging application](image-url)
5.1 Identify and Analyze Risks

The fuel hedging process start with identifying all risks related to hedging. The construction company can apply this step during the bid process. Before bidding, the construction company estimates the cost of material needed using a cost index. That leads to an understanding of the impact of the material price fluctuation on the company profit by projecting cash flow requirements in the event that material prices significantly exceed norms. During this step, the exact type of materials that affects the company should be identified and looked at in monetary terms (i.e., price fluctuation of one ton of steel).

5.2 Determine Tolerance for Risk

The fuel hedging process mentioned determining tolerance as an important step in hedging process. Once relevant material variables have been identified, analysis of the price volatility of this material should be done to decide at what point price volatility become unacceptable for the company. Consideration of any schedule penalties (i.e., late delivery of the project), as identified in the project contract, will be incorporated into this step.

5.3 Develop Hedging Management Policy

Hedging management policy should be developed to clearly describe the decision-making process and define who (individuals and/or committees) executes the hedging and related activities. The fuel hedging process mentioned clearly the importance of determine who is responsible for hedging decisions. Based on the knowledge collected from airline fuel hedging, creating a dedicated hedging committee is the best choice for making the hedging decisions for the construction industry.

5.4 Develop Hedging Execution Strategies

Execution strategies are the process for implementing the hedging strategies, and complying with hedging management policy. For example, the execution strategies determine which hedging and trading instruments should be used to meet the targeted hedge objectives. Based on the fuel hedging application in the airline industry, the best trading instruments are swaps and options (i.e., call, put, or collar options).

5.5 Implementation

The airline fuel hedging application shows that the primary market trade for derivatives is Over-The-Counter. OTC securities are unlisted so there is no central exchange for the market. The first step a construction company must make before they can trade in OTC securities is to open a hedging account with a broker. After the company places the market order with the broker, the broker must now contact the material supplier. The material supplier then will quote the broker the ask price that the material supplier is willing to sell the security at. If the construction company accept the price quoted, the broker will transfer the necessary funds to the material supplier’s account and is then credited with the respective securities. It is important to address the following four points during the implementation process:

- At what point do material price volatility become intolerable (the strike value or the value of the construction materials at which the contract starts to pay out);
- What is the incremental cost to your company for each $ increase per ton/lb of the material (this is the tick value);
- What is the worst possible case (the maximum financial payout of the contract);
- What is the duration of the hedging instrument that fits the company need (short-term, mid-term or long-term)?

A hypothetical example of a call option for a construction company is shown in Table 2.
Table 2: Call option for a construction company

</tbody>
</table>

When the steel price hits $800 per ton, the hedging contract begins to pay off $100 per ton, up to a maximum value of $500,000. The strike value, tick value, and maximum payment can all be changed to meet the company's preferred risk coverage. Companies should take into consideration that the price of a material risk hedging contract to protect against financial loss depends on the likelihood of a contract payout. If the probability of certain material price volatility is low, so will the cost of the contract.

5.1 5.6 Monitoring, Analyzing and Reporting Risk

Reporting and deciding if the hedging policies or strategies need to change is one of the process steps to apply fuel hedging. Similarly, materials risks should be continuously monitored, measured and reported. As the company's risk exposure changes, there should be a methodical process for reporting and determining if the existing policy and strategies are correct. Also, hedges should be modified when market conditions change, as noted in the next section.

5.2 5.7 Feedback Loop

Continuous revision to the entire process of material hedging is necessary, because the material price could be affected easily by a variety of factors (i.e., regulatory change, world political and economical stability). Changes in material price may then have a subsequent effect on the initial steps of the process. Further, these derivatives may be initiated for varying short-term, mid-term and long-term durations throughout the project.

6 RESULT

This research identified best practices in the area of airline fuel hedging, and discussed how these best practices can be applied to the construction industry. The identification of fuel hedging best practices provided a general outline for material hedging application. This research used the analysis of the fuel hedging process in the airline industry to develop a seven step guideline for the construction material hedging application. These steps are: identify and analyze risks; determine tolerance for risk; develop hedging management policy; develop hedging execution strategies; implementation, monitoring, analyzing and reporting risk; and, finally repeat the process.

The research concludes that applying material hedging in the construction industry could be very useful and should not be overlooked by construction companies. The guideline presented by this research helps construction companies to apply hedging to mitigate the risk of construction materials price fluctuations. This guideline could improve the ability of construction companies to submit a low price bid on a specific project.

Future work in this area could include the investigation of material hedging cost to determine if the hedging application is feasible. This is very important and could be added to the tolerance phase of this guideline to help the company decide if material hedging is economical for them. Further research could be done to investigate the best way to settle the hedging contract. This could be done by simulating different scenarios of hedging situation. Different scenarios could generate different settlement options such as moving out from the hedge early or keep the hedge contract until its due date.

DISCOVERING THE VALUES OF RESIDENTIAL BUILDING OCCUPANTS FOR VALUE-SENSITIVE IMPROVEMENT OF BUILDING ENERGY EFFICIENCY

Kadir Amasyali$^1$, Nora El-Gohary$^{1,2}$

$^1$ Department of Civil and Environmental Engineering, University of Illinois at Urbana Champaign, United States
$^2$ gohary@illinois.edu

Abstract: Improving building energy efficiency is one of the best strategies to reduce building energy consumption. Recent studies emphasized the importance of occupant behavior as key means of enhancing building energy efficiency. It is critical that while we strive to improve the energy efficiency of buildings through the understanding of energy use behavior that we also understand the values (such as thermal comfort, indoor air quality, productivity) of building occupants, how these values may impact energy use behavior, and how we can improve energy efficiency without negatively impacting these values (i.e., while maintaining the satisfaction levels with these values). This paper focuses on presenting the authors work in (1) identifying potential occupant values that may impact energy use behavior and energy consumption in residential buildings, (2) discovering actual building occupant values and the importance levels of these values to residential building occupants, and (3) discovering the current satisfaction levels of residential building occupants with these values. The discovery of actual occupant values and current satisfaction levels was conducted using an online survey. A randomly selected set of 310 residential building occupants in Arizona (AZ), Illinois (IL), and Pennsylvania (PA) were surveyed using an online questionnaire. The paper discusses the value discovery, questionnaire design, survey results, results analysis, and conclusions. The results showed similarities and differences across occupants in AZ, IL, and PA in terms of what they value in buildings as well as their current satisfaction levels with these values.

1 INTRODUCTION

Residential and commercial buildings consume 40% of the primary energy and contribute 30% of the annual greenhouse gas emissions. The production and consumption of non-renewable energy, including oil and natural gas, pose adverse environmental impacts on the ecosystem in terms of air pollution and global warming. Enhancing building energy efficiency is one of the most effective ways of reducing both energy consumption and CO$_2$ emissions (Becerik-Gerber et al. 2013).

Recent studies emphasized the importance of occupant behavior as key means of enhancing building energy efficiency. For instance, a two week study revealed that dormitory occupants reduced their consumption by 31% when they received weekly energy consumption data and by 55% when they received real time energy consumption data (Petersen et al. 2007). Similarly, a short-term study compared the energy consumption of four groups: (1) control group, (2) a group of occupants that had access to their past and present individual energy consumption data, (3) a group of occupants that had
access to their past and present individual energy consumption data, in addition to average energy consumption data of all occupants in the building, and (4) a group of occupants that had access to their past and present individual energy consumption data, average energy consumption data of all occupants, and individual energy consumption data of other occupants. The results showed that the fourth group made the most significant saving (Peschiera et al. 2010).

It is critical that while we strive to improve the energy efficiency of buildings through the understanding of energy use behavior that we also understand the values (such as thermal comfort, indoor air quality, productivity) of building occupants, how these values may impact energy use behavior, and how we can improve energy efficiency without negatively impacting these values (i.e., while maintaining the satisfaction levels with these values). On one hand, values impact energy use behavior. “Values influence behavior because people emulate the conduct they hold valuable” (Boundless 2014). On the other hand, people spend the majority of their time in buildings, and therefore it is essential that while we aim to reduce building energy consumption that we also satisfy their values (Frontczak and Wargocki 2011). A number of important research efforts (e.g., Klein et al. 2012; Yang and Becerik-Gerber 2014; Gao and Whitehouse 2009; Dong et al. 2011; Agarwal et al. 2010; Mohammadi et al. 2007) primarily focused on reducing energy consumption of buildings by utilizing occupancy information. More focus is needed on understanding the interdependency between occupant values and energy consumption.

In this paper, the authors focus on (1) identifying potential occupant values that may impact energy use behavior and energy consumption in residential buildings, (2) discovering actual building occupant values and the importance levels of these values to residential building occupants, and (3) discovering the current satisfaction levels of residential building occupant with these values. The paper also compares importance ratings of values and satisfaction levels with the values across occupants in AZ, IL, and PA.

2 OCCUPANT VALUE DISCOVERY

In the context of building energy efficiency, a comprehensive literature review was conducted to identify all potential values that could be related to energy use behavior and energy consumption. As a result, three main categories of values were identified: (1) values that may impact energy use behavior and energy consumption level (thermal comfort, lighting/visual comfort, and indoor air quality), (2) values that may be impacted by the set of values in the first category (health and personal productivity), and (3) values that may motivate enhanced energy use behavior towards reduced energy consumption (environmental protection and energy cost saving).

Thermal comfort is “that condition of mind that expresses satisfaction with the thermal environment” (ASHRAE 2010). There are six primary factors that determine thermal comfort conditions: metabolic rate, clothing insulation, air temperature, radiant temperature, air speed, and humidity (ASHRAE 2010). Among these factors, metabolic rate depends on a number of subfactors such as activity level, gender, and health conditions (Maiti 2014). Clothing insulation varies by occupant clothing type. Air temperature, radiant temperature, air speed, and humidity, on the other hand, are highly dependent on the settings and parameters of the HVAC system of buildings, which in turn may impact energy consumption.

Visual comfort is defined as “a subjective condition of visual well-being induced by the visual environment” (EN 2002). Visual comfort or discomfort is impacted by luminance distribution, illuminance and its uniformity, glare, color of light, color rendering, flicker rate, and amount of daylight (EN 2002). Illuminance is the factor which associates visual comfort with energy consumption.

Indoor air quality (IAQ) is “a term referring to the air quality within and around buildings and structures” (EPA 2014). The amounts of indoor pollutants and of ventilation are the major factors that impact IAQ. Building materials, combustion sources (wood, coal, oil etc.), cleaning products, tobacco, and air pollutants entering from outdoor space are main causes of indoor pollutants (EPA 2014). On the other hand, the amount of ventilation is determined by the amount of air that enters the building. Poor IAQ is seen as the primary environmental health risk by EPA (2014). In order to maintain good IAQ to building occupants, the amount of pollutants should be controlled and a proper amount of ventilation should be provided (EPA 2014). While controlling the amount of pollutants can be achieved by improving occupant
behavior and eliminating the causes of pollutants, the amount of ventilation is highly dependent on the building ventilation system which may consume energy. Health and personal productivity are the values that may be impacted by the set of values in the first category. With the majority of people spending about 90% of their time indoors, the impact of thermal comfort, visual comfort, and IAQ on occupant health and productivity has been emphasized in recent years (EPA 2014). Good thermal comfort, visual comfort, and IAQ are linked to decreased number of illnesses and sick building syndrome symptoms and enhanced productivity.

Environmental protection and energy cost saving are values that may motivate enhanced energy use behavior towards reduced energy consumption. Energy consumption is associated with both environmental impacts and cost. Residential buildings account for 20.8% of the US total CO₂ emissions (EPA 2009) and residential building occupants spent 2.7% of their household income for home energy bills in 2012 (EIA 2013). The role of energy consumption behavior in reducing energy consumption, and in turn environmental protection and energy cost saving, is vital. EIA estimates a 50% increase in energy demand caused primarily by buildings by 2050, and highlights that this increase can be capped to 10% without any sacrifice in the comfort of building occupants, if necessary improvements in energy use behavior and energy efficiency can be achieved (2013).

3 RESEARCH METHODOLOGY

A questionnaire survey was conducted to solicit the input of a randomly selected set of residential building occupants in Arizona (AZ), Illinois (IL), and Pennsylvania (PA) on (1) the importance levels of occupant values and (2) the current satisfaction levels with these values. The scope of the energy studies are focused on IL and PA. AZ was additionally selected to capture potential variability in responses as a result of a different climate, which provides an opportunity of investigating the impact of climate on occupant values and satisfaction levels with the values. According to the Köppen-Geiger climate classification, IL and PA have a humid continental (warm summer) climate (Dfa), whereas AZ has a desert climate (Bwh). The research methodology was composed of four main research tasks: (1) questionnaire design, (2) questionnaire validation, (3) survey implementation, and (4) survey results analysis. Further details on the research methodology is provided in the following section.

4 SURVEY OF ENERGY-RELATED VALUES AND SATISFACTION LEVELS

4.1 Questionnaire Design, Validation, and Implementation

The questionnaire was composed of four sections. Section 1 included two filtering questions that were asked to verify eligibility of participation in terms of occupancy type and residency state (i.e., occupancy of a residential building and residency in AZ, IL, or PA). Responses which failed to pass Section 1 were disregarded. In Section 2, respondents were asked to rate the importance levels of occupant values to them on a 6-point Likert scale (very unimportant, unimportant, moderately unimportant, moderately important, important, very important). Section 3 was composed of three questions, all which aimed at soliciting the satisfaction levels with the values. Question 1 directly asked respondents to rate their satisfaction levels with the values on a scale of 1 to 6 (very dissatisfied, dissatisfied, moderately dissatisfied, satisfied, very satisfied): thermal comfort in winter, thermal comfort in summer, visual comfort, IAQ, energy cost saving, and environmental protection. Because both productivity and health are values which may be impacted by the values in the first category (i.e., thermal comfort, visual comfort, IAQ), Question 2 and 3 aimed at assessing satisfaction levels with productivity and health through quantifying the changes in productivity and health caused by the values in the first category. Using a 9-point scale (40% or more, 30%, 20%, 10% decrease, no effect, 10%, 20%, 30%, 40% or more increase), Question 2 asked respondents to rate how they think their personal productivity or level of activity at home is decreased or increased by the current indoor environmental conditions (temperature, lighting, IAQ) at home. Using the same 9-point scale, Question 3 asked respondents to rate how they think their perceived health is decreased or increased by the current IAQ at home. Section 4, included a set of background questions about the characteristics of the occupants, the frequency of
experiencing some health symptoms such as headaches, the characteristics of the building including energy efficiency features and level of occupant control of the building system, the level of energy cost and consumption data given to occupants, and the behavior of occupants to control the indoor environmental conditions such as opening windows.

Prior to launching the survey, a pilot study on fifteen building occupants was conducted to test the effectiveness and clarity of the questionnaire. Participants were requested to complete the survey and, then, to provide feedback on the format and content of the questionnaire. Feedback was solicited on different aspects of the questionnaire, such as question wording, response options and evaluation scale, instructions to respondents, visual appearance, and clarity of value concepts. The questionnaire was revised based on the feedback. For instance, the scale of some questions were modified in order to improve clarity.

The survey was conducted from October to November 2014. Potential respondents were recruited by Qualtrics, a provider of online panels (potential respondents). Panels were generated using samples from various database and were verified to prevent any fraudulent or duplicate respondents (ESOMAR 2014). Qualtrics hosted the survey and sent emails to potential respondents inviting them to complete the survey, for research purposes, in return for incentives. Two response quality filters were used: (1) an attention filter question and (2) a minimum survey completion time of two minutes. Responses that failed to pass these two filters were disregarded.

4.2 Survey Results and Analysis

The analysis of the survey results aimed at answering the following research questions:

- What are the ratings of the values by residential building occupants in AZ, IL, and PA?
- What are the rankings of the values by residential building occupants in AZ, IL, and PA?
- What are the satisfaction levels of residential building occupants with the values in AZ, IL, and PA?

Three statistical analysis methods were utilized to address the above research questions: (1) mean indexing, (2) Kendall’s coefficient of concordance, and (3) Kruskal-Wallis H Test. Mean indexing was used to determine the mean ratings of values. Kendall’s coefficient of concordance was computed to examine whether there was a significant agreement in the ranking among occupants across the three states. Kruskal-Wallis H test was conducted to identify whether specific values were rated differently across occupants in the three states. The Statistical Package for Social Sciences (SPSS) version 20.0 was used to conduct these statistical analyses.

4.2.1 Classification of Respondents

A total of 310 valid responses were collected. Qualtrics identified approximately 4,800 potential respondents and invited them via email. A total of 381 responses (including invalid responses) were received, representing a response rate of 8%. This is consistent with the reported response rates for online panels (Neslin et al. 2009). This sample size is statistically significant with 95% confidence level and 10 confidence interval. Responses were classified into three subgroups by state: AZ, IL, and PA. The descriptive statistics of the three subgroups are shown in Table 1.

<td>104</td>
<td>310</td>
</tr>
<tr>
<td>Response Rate</td>
<td>8%</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
4.2.2 Reliability of Survey Questions

In order to validate the internal consistency of the data, prior to data analysis, a Cronbach’s alpha reliability analysis was conducted. Internal consistency indicates the extent to which all the items in a test measure the same concept. Alpha values greater than 0.7 indicate adequacy of internal consistency (Tavakol and Dennick 2011). The overall Cronbach’s alpha values for the survey is 0.883, which indicates a high level of reliability.

4.2.3 Occupant Ratings and Rankings of Values

The rating frequencies of the values by occupants is shown in Figure 1. Overall and across the three states the majority of occupants rated the seven values as “moderately important” or higher. Health is the most important value; 93.9% of the occupants rated health moderately important or higher. Indoor air quality, energy cost saving, personal productivity, thermal comfort, visual comfort, and environmental protection, respectively, are at least moderately important to 92%, 91.6%, 91.6, 90%, 89.7%, and 85.8% of the occupants.

![Figure 1: Importance of values to residential building occupants in AZ, IL, and PA](image-url)
Table 2 and Figure 2 show the mean ratings and rankings of the values by occupants overall, in AZ, in IL, and in PA, and a comparison of the mean ratings of the values across these three states, respectively. As shown in the Table 2, all mean scores are higher than 4.00, which indicates that on average, occupants give importance to all seven values. On average, health was ranked highest among the values – overall, and across the three states, which indicates that occupants of residential buildings, across AZ, IL, and PA, valued health the most among the seven values. Previous studies are partially supportive of the survey results. For example, Zalejska-Jonsson and Wilhelmsson (2013) conducted an empirical study on residential building (single houses and apartment buildings) occupants in Sweden and investigated the importance of three values – IAQ, thermal comfort, and sound quality – through quantifying their impact on the overall satisfaction of occupants. The results showed that IAQ is the most important value, whereas sound quality is the least important value. On the contrary, however, Lai et al. (2009) conducted a study on residential apartment occupants in Hong Kong and found thermal and acoustic comfort as the most important and IAQ as the least important.

Kendall’s coefficient of concordance (Kendall’s W) was computed to examine whether there is a significant agreement on the ranking among occupants across the three states. The results of the test were interpreted based on the W value and the significance level of the test. If Kendall’s W is 1 there is a complete agreement and if it is 0 there is no agreement at all, with the result being significant if the significant level is less than 0.05 (Kendall and Gibbons 1990). Kendall’s W value is 0.96 (p<0.05), which indicates that there is a significant high agreement on the ranking of values among occupants across the three states.
4.2.4 Occupant Satisfaction with Values

Figure 3 and Figure 4 show the rating frequencies of satisfaction levels of occupants with the values and the impact of indoor environments on their perceived personal productivity and health, respectively. Overall, on average, occupants rated their satisfaction with energy cost saving, IAQ, thermal comfort (in summer and winter), visual comfort, and environmental protection as “moderately satisfied” or higher, but a considerable percentage of occupants rated their satisfaction with the values as “moderately unsatisfied” or lower. For example, 19.7% of the occupants are “moderately unsatisfied” or lower with energy cost saving, which is the least satisfied value. Environmental protection, thermal comfort in summer, thermal comfort in winter, IAQ, and visual comfort are rated by 15.8%, 15.5%, 13.9%, 11.6%, and 11.2% of the occupants as “moderately unsatisfied” or lower, respectively. For health and personal productivity, 27.8% and 24.8% of the occupants believe that the current indoor environment conditions have a negative effect on their health and perceived personal productivity, respectively. This is consistent with the findings of a recent study (Zalejska-Jonsson and Wilhelmsson 2013), which found that a considerable percentage of occupants are dissatisfied or very dissatisfied with their indoor environmental quality.

![Satisfaction levels of occupants with the values across AZ, IL, and PA](image)

Figure 3: Satisfaction levels of occupants with the values across AZ, IL, and PA
Figure 4: Reported impact of indoor environmental conditions on health and perceived personal productivity of occupants

The difference in the satisfaction levels across the three states was examined using Kruskal Wallis-H test which is the non-parametric version of one way analysis of variance. The results show a significant difference, across the three states, in the satisfaction levels occupants with thermal comfort in winter. Occupants in AZ are more satisfied with thermal comfort in winter, than those in IL and PA. In order to identify where the differences between the groups lie, a post-hoc pairwise comparison test was conducted. The test shows that occupants in AZ are more satisfied with thermal comfort in winter than those in PA. This difference could be explained by the different weather characteristics of the two states. Other than that, there was no significant difference in the rating of satisfaction levels among occupants across the three states. Similarly, across the three states, there was no significant difference among occupants in the impact of indoor environmental conditions on their health and perceived personal productivity.

5 CONCLUSION AND FUTURE WORK

This paper presents an empirical study to discover energy-related values of building occupants. Seven energy-related values were identified and classified into three main categories: thermal comfort, lighting/visual comfort, indoor air quality, health, personal productivity, environmental protection, and energy cost saving. The importance of these values to occupants and the satisfaction levels of occupants with these values were then investigated using a questionnaire survey. The survey focused on residential building occupants in AZ, IL, and PA. The results show that residential building occupants in AZ, IL, and PA value all seven values. On average, health was ranked highest among the values – overall and across the three states. The results also show that there is a significant agreement on the ranking of values by occupants across the three states. The ratings of the satisfaction levels with the values show that a considerable percentage of occupants (11.2% to 19.7%) are unsatisfied with the fulfillment of their values, with 27.8% and 24.8% of the occupants thinking that the current indoor environmental conditions have a negative effect on their health and personal productivity. The survey results also show that there is a significant difference in the satisfaction levels with thermal comfort in winter across AZ and PA.
In their future/ongoing research, the authors will focus on three main areas: (1) developing a semantic data sensing system (including sensors and algorithms) for automatically measuring and monitoring energy consumption, indoor climate and lighting, plug loads, and occupant location, and interactively measuring and monitoring energy use behavior (e.g., energy use patterns in terms of use of plug loads, lighting, cooling, etc.) and satisfaction with occupant values; (2) developing a semantic (computer-understandable and meaning-rich) context-aware model for representing and reasoning about the sensed data and user values and deriving contextual information about the interrelationships between user values, energy use behavior, and energy consumption to analyze human values and actions and how they impact energy usage; and (3) developing hybrid semantic and machine-learning (ML) data analysis models and algorithms for analyzing the sensed data and learning how to automatically operate building controls in a way to minimize energy consumption while maintaining the values identified in this study.

DEVELOPMENT AND VALIDATION OF REGRESSION MODELS TO PREDICT ANNUAL ENERGY CONSUMPTION OF OFFICE BUILDINGS IN DIFFERENT CLIMATE REGIONS IN THE UNITED STATES

Shideh Shams Amiri1, Mohammad Mottahedi 2, Somayeh Asadi1, 3, David Riley1
1 Pennsylvania State University, United State
2 University of Texas at San Antonio, United State
3 asadi@engr.psu.edu

Abstract: Energy consumption in commercial buildings has been growing substantially in recent years. Recently, building energy consumption estimation tools have been used to calculate energy savings and emissions reduction. Energy performance of building is complicated since it depends on multiple variables associated to building characteristics, equipment and systems, weather, occupants, and sociological influences. Therefore, the objective of this study is to develop the multi-linear regression models to predict energy consumption of an office building in five different climate regions in the United States. In order to achieve this objective, a typical commercial building was selected and the effect of 17 key building design parameters on its energy performance was investigated. To quantify building energy consumption, eQuest and DOE-2, which are building energy simulation software programs, were used to develop the building profile and perform annual energy simulation. In addition, Monte Carlo simulation technique was used to create a ten thousands comprehensive dataset covering the full range of design parameters for each studied climate region. An in-house computer program was developed to implement the Monte Carlo simulation. Statistical analysis was performed using R statistical analysis program to develop a set of linear regression equations predicting energy consumption of each design scenario. The difference between obtained results from regression model and DOE-2 are largely within 5%. In addition, standardized regression coefficient was calculated to assess the sensitivity of heating, cooling, and total energy loads to different building design parameters across five climate zones. It is believed that the developed regression models can be used to estimate the energy consumption of office buildings in different climate regions when designers and engineers consider various building envelope designs in the early stages of the design.

1 INTRODUCTION

In recent years, the contribution of modern world to energy consumption has been increased significantly. World energy consumption has increased from 524 quadrillion Btu in 2010 to 630 quadrillion Btu in 2010 and 820 quadrillion Btu in 2040, a 30 year increase of 56% (EIA 2010). The same trend was seen in the United States in which total energy consumption was approximately 97.9 quadrillion Btu in 2010 with an increase rate of 8.3% (EIA 2010). According to the EIA (2010), building sector in the U.S. consume 40% of total energy which is higher than transportation and industrial sectors. Therefore, proper tools are needed to estimate and optimize energy consumption in buildings.

Several studies have been conducted to study building energy performance. In addition, there are different methods including simple regression analysis and dynamic simulation software programs (e.g.
EnergyPlus and DOE-2 (Repice 2011) to model building energy performance (Lam et al. 2010, Broun et al. 2014, Catalina et al. 2013, Asadi et al. 2012). In a study conducted by Hygh et al. (2012), EnergyPlus software was used to perform energy simulation and calculate annual building energy consumption of a commercial building in four different climate zones. Mohammadpour et al. (2014) employed EnergyPlus to model energy consumption of three retrofit projects and compared energy consumption before and after the retrofit. Asadi et al. (2014) developed multiple linear regression models to predict building energy consumption for a typical residential building in the hot and humid climate. The effect of 7 buildings shapes as well as 17 building design parameters including HVAC schedule, orientation, building envelope, etc. on building energy performance were investigated. Results of their study showed that there is a good agreement between results of the DOE-2 and regression equations and the error was less than 5% in most cases. In another study, Catalina et al. (2013) developed regression models to investigate monthly heating load in residential building in France. The inputs of the regression model include the window to wall ratio, building envelope U-value, and building shape factor. Their analysis indicated that there is a strong relationship between building shape and energy consumption. Later, Lam et al. (2010) developed regression models using DOE-2 simulation results to determine the impact of 12 building design sensitive variables on building energy performance. The authors reported that there is a strong correlation between annual building energy consumption and design parameters in the warm climates. This paper proposes a simple and realistic approach to estimate energy consumption of a typical office building in five different climate zones. The primary objective of this study is to develop a multi-linear regression model to predict and quantify energy consumption of a commercial building in the early stages of building design.

2 MATERIAL AND METHOD

Building energy simulation models are commonly used to predict energy performance. They are powerful computational tools helping users to model a building as a system and to identify potential opportunities to reduce building energy consumption. In the present study, a comprehensive set of inputs such as internal loads, mechanical and electrical system, orientation and occupancy schedule was considered to calculate energy consumption. Also five major climate zones including cold dry, cool dry, mixed humid, warm marine and hot humid were considered in this study (Table 1).

HDD=Average heating degree-days, CDD= Average cooling degree-days (EIA, Noaa 2012)

Monte Carlo simulation was performed by randomly selecting 17 variables based on uniform distribution to generate a new input file for the simulation software. This process was repeated 10000 time to effectively examine the configuration space. The eQuest and DOE-2 software programs were utilized to calculate the annual heating and cooling consumption for each design scenario based on Monte Carlo simulation. eQUEST software, which adds an additional graphical wizards capability to DOE-2, facilitates creation of building envelope and climate zones. Using DOE-2 avoids imprecisions introduced by simplifying algorithms, and since it is a configurable tool, it can be utilized for detailed design. Based on the Monte Carlo simulation, 10,000 simulation runs were defined for each of the five climate zones, covering a complete range of design parameters. In addition, a code was written in Python's programming language to help extracting required data from DOE-2. Then, these data were used to develop the multiple linear regression equations and investigate the relationship between different parameter and annual energy consumption. Figure 1 illustrates the framework of the analysis.
2.1 Base Case Model Description and Design Variables

Table 2 shows the list of parameters that were used to build the office building model using eQuest and Table 3 represents the implemented variables in the Monte Carlo Simulation. As it can be seen in Table 2, 17 design parameters including building envelop, orientation and occupant schedules were considered. The properties of all building components including wall, roof, ceiling, foundation, and floors were defined in this study. For each parameter, set of values and ranges are selected based on AHRAE 90.1 (ASHRAE 2007). In addition, a comprehensive data set was generated based on random distribution to examine all possible configuration of building envelope. Uniform distribution was applied to each parameter ensuring that all values within the specified range are investigated equally for each design choice.

2.2 Regression Analysis

The aim of regression analysis in this study is to develop simple and accurate models to predict energy consumption in commercial buildings. A multiple regression model with more than one explanatory variable may be written as:

\[ Y = \beta_0 + \beta_1 X_1 + \beta_2 X_2 + \ldots + \beta_n X_n \]

Where \( y \) is the output, \( \beta_i \) is the regression parameters and \( X_i \) is the input variables. The least-squares method is generally used for estimation purposes in the multiple-regression model. Once regression coefficients are identified, a prediction equation can then be used to estimate the value of a continuous output as a linear function of one or more independent inputs. A comprehensive dataset was developed based on the randomly generated building parameters using energy simulation model. Eighty percent (80%) of the simulation runs were selected randomly and used to develop the regression equations. Remaining twenty percent (20%) of the runs were used to validate the developed model. The generated dataset was used to develop regression equations predicting annual building energy consumption.

3 RESULTS AND DISCUSSION

3.1 Interaction between parameters

Analysis of the Interaction between parameters represents the combined effects of the independent parameters on the dependent variable. When an interaction effect is present, the impact of one factor depends on the level of the other factor. One of the methods to determine the interaction between parameter is to identify multicollinearity. Multicollinearity is a statistical phenomenon in which two or more predictor variables in a multiple regression model are strongly correlated. It arises when two or more predictors in the model are correlated and provide redundant information about the response. Generalized variance-inflation factor (GVIF) can be used to detect multicollinearity in the regression equation. The GVIF indicates the degree to which the confidence interval for that variable regression parameter is expanded relative to a model with uncorrelated predictors. As a general rule, GVIF>4 indicates a multicollinearity problem. The GVIF results are presented in Table 4. As it can be seen in this table, the GVIF values in all cases are less than 1.3 indicating that there is no correlation between predictor variables in the multiple regression models.

### 3.2 Regression Results and Discussion

Table 5 shows the regression equations associated with each climate zone. Five different regression equations were developed for each climate zone. The $R^2$, root mean square error (RMSE) and F-Test values are shown in this table. $R^2$ measures how close the data are to the fitted regression line. As it can be seen, the $R^2$ value is more than 0.94 in all cases which indicates that the model fits with the data.

\( x_1 \) = building orientation, \( x_2 \) = top floor batt insulation, \( x_3 \) = ceiling interior finish, \( x_4 \) = ceiling insulation, \( x_5 \) = floor construction, \( x_6 \) = top floor ceiling exterior insulation, \( x_7 \) = top floor ceiling interior finish, \( x_8 \) = ground floor construction, \( x_9 \) = ground floor interior finish, \( x_{10} \) = floor interior finish, \( x_{11} \) = interior wall, \( x_{12} \) = exterior wall, \( x_{13} \) = roof absorbance, \( x_{14} \) = exterior wall absorbance, \( x_{15} \) = roof absorbance, \( x_{16} \) = occupant schedule, \( x_{17} \) = glass category.

The objective of multiple-linear regression analysis is to predict the single dependent variable (energy consumption) by a set of independent variables (building orientation, wall insulation, glass type, occupancy schedule, etc.). Multiple regression shares all the assumptions of correlation including normality, independence, linearity, and homoscedasticity. Figure 2 shows the scatter plots of residuals which allows visual assessment of the distance of each observation from the fitted line. The residuals from a fitted model are the differences between the responses observed at each combination values of the explanatory variables and the corresponding prediction of the response computed using the regression function. As it can be seen, the residuals are randomly scattered in a constant width band about the zero line and no discernable pattern, without any relationship to the value of the independent variable is observed.

![Residual scatter plots for five locations](image1.png)

Figure 2: Residual scatter for the five locations.
To demonstrate the variation in energy consumption for each climate zone, identical parameter samples were used for all locations, but the observed range and variability of total energy were unique in different locations (Fig 3). It can be seen that number of outliers is highest in Billings where the first and third quartiles makes up less than half of the range between the minimum and maximum observed. The high variability in Billings is driven by the cold winters and hot summers, which exhibits wide variation depending on the combination of the values for the design parameters.

![Figure 3: Distribution of total energy consumption for the five locations](image)

### 3.3 Regression Model Validation

Model validation is one of the most important steps in finding the best fit for the regression model. $R^2$ and RMSE values are commonly used to validate the model. In this study two thousands of simulations runs were set aside to test the regression model performance and validate the results. Figure 4 shows the validation results for each climate region. It can be observed that the results from the model are well correlated with the data from simulations with acceptable error of less than 5%.

![Figure 4: Regression model validation results](image)
4 CONCLUSION

The goal of this study was to develop simple regression models for office building in the five major climates including cold dry, cool dry, mixed humid, warm marine and hot humid. A total of 17 key building design variables were identified and considered as inputs in the regression models. The coefficient of determination R² varies from 0.94 to 0.95 indicating that 95% of the variation in annual building energy consumption can be explained by change in 17 parameters. The analysis indicates that there is a strong interaction between building location and level of energy consumption. It also shows Billings (cold-dry) with cold winters and hot summers consume the highest amount of energy in comparison with other location. On the other hand, San Jose (warm marine) with the subtropical Mediterranean climate has the least temperature variation and subsequently has the least annual energy consumption. The difference between regression-predicted and DOE-simulated annual building energy use are largely within 5%. Consequently, the developed regression models can be used for comparative energy studies to estimate the potential energy savings during the early stage of design when different building schemes and design concepts are being considered.

Climates with the least temperature variation, subsequently have the least annual energy consumption. The difference between regression-predicted and DOE-simulated annual building energy use are largely within 5%. Consequently, the developed regression models can be used for comparative energy studies to estimate the potential energy savings during the early stage of design when different building schemes and design concepts are being considered.

The models for energy consumption prediction presented in this study, will be expanded in future and will be validated using case studies on physical commercial building to better estimate the prediction accuracy.

Abstract: Construction industry has one of the highest numbers of fatalities among Canadian industries. Despite ongoing efforts to improve safety through trainings and promoting personal protective equipment (PPE), the number of construction fatalities in Canada is actually on the rise. Studies show that systematically monitoring construction sites and providing immediate feedback to workers are instrumental in improving safety. In particular, close monitoring of the real-time status of moving objects has been shown to improve the safety, productivity and performance on construction sites. Information and Communication Technologies (ICT) and automation techniques have shown strong potentials for identifying hazards. As a result, automated data collection to monitor the status of the construction sites has received researchers’ attention in recent decades. The objective of this study is to develop a model that prevents the accidents on construction sites using automated real-time location estimations. A model is developed to detect situations that can lead to fall or colliding with moving objects based on proximity of workers to these situations. The system will use the readings from UWB tracking and generates a visualization of the moving objects on the job site in real time. When the possibility of an accident is detected, the system will send an alarm to warn the involved personnel. The functionality and efficiency of the model in detecting accidents is examined. The results of these experiments shed light on the importance of addressing the time delays caused by UWB tracking in actual real-time applications.

1 INTRODUCTION

The high number of accidents in the construction industry compared to most other industries (AWCBC, 2014a) makes a construction site one of the most complex working environments. One of the main causes of accidents on construction sites has been identified as collision of the on-foot workers with moving objects, due to workers’ proximity to heavy construction equipment (Teizer et al., 2008). For example, crane operators have difficulty in relating their own position to that of the load they are moving, and this creates hazardous situations that might lead to accidents and injuries (Cheng et al., 2011). The limited spatial awareness is also the main factor of a second typical cause of accidents: falls from heights. In the United States alone, falls from heights cause the highest number of fatalities in the construction industry – almost 37% of workplace life losses in constructions in 2013 (OSHA, 2014).

Standard policies used to reduce the risk of accidents focus on increasing the training of the workers and their education about potential risks, consequences, and precautions they should take. In addition, measures that reduce hazards and provide collective protection, as well as the use of Personal Protective Equipment (PPE) are commonly required by the law. However, despite these efforts to improve safety through planning, training, and the use of protective equipment, the number of construction fatalities in Canada is actually on the rise, with a growth of about 17% since 2011 (AWCBC, 2014-b). This shows that managing safety issues only through standard safe work practices is not sufficient to avoid accidents.
This is mainly due to the dynamic nature of construction sites. The constant changes of the site during the construction phase create new hazards, and a rapid modification of the safety strategies is not always feasible. Recent studies show that systematically monitoring the work in progress and providing immediate feedback to workers are instrumental in improving the effectiveness of any safety strategy (Skibniewski, 2014). In particular, close monitoring of the real-time status of moving objects has been shown to improve the safety (Teizer et al., 2010), productivity and performance (Cheng et al., 2011 and Song et al., 2006). However, the effectiveness of manual methods is strongly affected by the safety awareness of front-line supervisors. Since the automation technologies have shown strong potential for identifying hazards and decreasing the time required for corrective actions, the development and implementation of an automatic system is receiving an increasing attention in recent years.

This paper presents part of a larger research work on improving safety on construction sites. The long-term goal of this research is to develop an accident prediction model that predicts potential accidents on construction sites ahead of time, long enough to provide perception and reaction time to the parties involved. This paper focuses only on the first step of this larger research, which is on real-time accident detection. Unlike prediction, in real-time detection an accident is detected only shortly before it occurs. An Accident Detection Model (ADM) is developed to analyze the estimated location of moving objects on the site (workers and equipment) provided by an UWB Real-Time Locating System (RTLS), and send a warning signal when a worker is getting too close to a hazardous situation. The ADM presented in this paper will be the basis for the development of an accident prediction model in the next steps of this research.

2 BACKGROUND AND LITERATURE REVIEW

Alerting workers when they are approaching a danger zone is an important part of real-time safety management. The preventative models are required for situations where the standard security procedures and PPE fail. Within real-time safety technology, the reactive and proactive safety approaches are differentiated (Teizer et al., 2010). Reactive real-time approaches collect data in real time, but require a post data processing to convert these data into information. On the contrary, proactive approaches collect and analyze data in real time, in order to alert workers of the dangers occurring in that moment.

Due to their efficiency in collecting data, different remote sensing technologies have been proposed to be used for various applications on construction sites. Radio-Frequency Identification (RFID) is one of these remote sensing technologies, largely used for inventory tracking in several industries including construction (Nasir et al., 2010). This technology has been applied also to the construction industry for position tracking, but since in principle it is not a localization technology, it requires to be used in combination with GPS to get information on the position of a tag, or with other tags of known locations dispersed through the area to cover (Saidi et al., 2011). However, previous researches showed that the estimated tags’ locations are within few meters of their actual positions; even if it might appear a high accuracy level, it is not enough for preventing potential dangerous situations in a construction site. For this reason, RFID technology can be very useful for estimating the locations of construction components, but not for being applied with a safety purpose in large construction environments (Torrent and Caldas, 2009).

Ultra Wideband (UWB) is another remote sensing technology that has been explored in the literature for applications on construction sites. By using very short pulses (one nanosecond) transmitted by each tag, UWB allows the filtering of reflected signals from the original signal, offering the possibility to measure distances at the decimeter and centimeter level. Due to this accuracy, UWB has been suggested for applications where more accuracy is required, such as monitor the workers’ positions on the site. Previous studies have shown that UWB offers an accuracy of less than one meter under conditions that are common on construction sites, such as the presence of metal objects, or tracking a large number of tags simultaneously (Maalek and Sadeghpour, 2013). In addition to accuracy, UWB offers other characteristics that render them suitable for the conditions of construction sites. For example, due to its high penetration ability, UWB tracking does not require line-of-sight. It also does not suffer from multipath distortion and interference (Gu et al., 2009). Furthermore, they have low installation and operational cost.
Ease of use, small and light (wearable) tags, and long range of operation have been identified as favorable characteristics of UWB tracking for construction sites (Teizer et al., 2008). For the aforementioned reasons, UWB seems to be suitable for safety management systems where accuracy is of high importance.

In recent years, a number of studies suggested the use of Real-time Location Systems for safety management on construction sites. Giretti et al. (2009) and Carbonari et al. (2011) proposed a predictive algorithm for the real-time identification of potential overhead hazards using UWB tracking system. They conducted experiments on actual construction sites and concluded that the capability of the system to identify hazards is affected by the time required by system to update the locations of the workers. Lee et al. (2012) developed a similar system that uses RTLS (without specifying which technology is used) to warn endangered workers. The workers’ positions are continuously monitored by a safety manager, who manually activates a warning signal when a worker is approaching a danger area. Riaz et al. (2006, 2012) proposed a conceptual model that could avoid possible collisions between equipment and workers. In this conceptual model, it is proposed that the workers who stand in the operational envelope of a specific equipment can be identified using RFID tracking. Finally, Hwang (2012) used UWB to monitor tower crane movements in real time and prevent potential collisions. Cranes’ possible movements were modeled and an algorithm was developed to predict the positions of the booms of two adjacent cranes, based only on their axial rotation. Overall, these studies showed strong potential for the application of RTLS, and specifically UWB tracking for safety management of construction sites. However, most of these models have either not been implemented, or been used for a specific study. The objective of this study is to advance the current status of research and develop a real-time accident warning system that can be implemented in any construction sites. The study will also investigate the effect of time latency in real-time systems on safety management applications that has not been addressed in the literature before.

3 A REAL-TIME ACCIDENT WARNING SYSTEM FOR CONSTRUCTION SAFETY MANAGEMENT

The proposed Accident Warning System is composed of two parts: a Real-Time Locating System and an Accident Detection Model. The RTLS will estimate the positions of workers and equipment by means of small tags installed on moving objects (e.g. workers’ safety helmets or construction equipment). The Accident Detection Model detects accidents by continuously comparing the estimated positions of tags with danger zones in real time. When the possibility of either an accident between two moving objects or a fall from heights is detected, the system will generate a warning. Due to its higher accuracy, UWB tracking is used in this study for real-time locating of the objects; however, the developed model can work with any other RTLS. The overall schematic of the system is shown in Figure 1. The aforementioned two parts of the Accident Warning System are described in this section.

3.1 UWB Real-Time Locating System

The UWB RTLS is composed of receivers (or readers), tags, and a location estimation platform (see Figure 1). To estimate the position of the tags, the readers receive the signals transmitted by the tags. One receiver is assigned as a “Master Receiver” and has two-way communications with the tags. This means that in addition to receiving signals from the tags, it can also send commands to them (e.g. activate the sleep mode when they are not moving). The other receivers are considered “Slave Receivers” and can only receive signals from the tags. Receivers are connected to each other by timing cables whose function is to enable time synchronization among them. Each receiver is connected to a Power over Ethernet (POE) switch through an Ethernet cable. Other than providing power to the receivers, this cable transfers the collected data to the platform for location estimation. When the system is activated, the tags send an UWB pulse to the receivers. Each receiver collects two types of data from the received signal: the Angle of Arrival (AOA) of the signal and the time when the signal reaches the receiver. The time difference between the arrivals of a pulse to two different receivers is referred to as Time Difference of Arrival (TDOA). As a result, the system can estimate the location of the tags through two different methods, AOA and TDOA, achieving a higher level of accuracy (Muñoz et al., 2009). When a tag starts transmitting its signal at a specified frequency, the receivers acquire the signal and transfer
the data to the platform, which estimates the position of the tag and generates a log file. Each row of the log file represents a single reading that, among other information, contains Date, Time, Tag ID, and $x$, $y$, $z$ coordinates of the tags at the time of reading.

![UWB Real-Time Tracking System](image)

Figure 1: Overview of the Accident Warning System

### 3.2 The Accident Detection Model (ADM)

The developed Accident Detection Model analyzes the information about the positions of the tags, and determines when an accident is about to happen. To achieve this goal, it utilizes the estimated locations from the UWB platform and compares the positions of the tags with the boundaries of the areas on the site that are defined as danger zones. As shown in Figure 1, ADM consists of three modules, namely Information Module, Detection Module, and Visualization Module. The function of each module is discussed in detail in this section.
The Information Module acquires the project site-specific parameters from the user (e.g. site manager), namely Site Boundary, Coordinate Origin, Danger Zones, and Safety Buffers (see Figure 1). The Site Boundary defines the physical boundaries for where the Real-Time Accident Warning System is activated (i.e. the part of the construction site monitored with the system). Coordinate Origin defines the origin of the coordinate system used by the UWB system on the construction site boundary. Danger Zones defines the location and boundary of the dangerous areas on the site where workers should not approach. Finally, Safety Buffer defines the dimensions of a virtual safety area that is assumed around the moving objects that are tracked on the site (i.e. workers and equipment). In the current status of the model, size of the Safety Buffer is taken as an input from the user. However, it is worthy to mention that the value assigned to it will play a major role in achieving the intended appropriate safety level on the site since the trigger of the warning is determined by the overlap between the Safety Buffers and the Danger Zones. The dimension of the Safety Buffer has been investigated in other studies and depends on a number of factors such as the moving speed, the type of activity conducted and vicinity to danger zones (e.g. Esmaeinejad and Sadeghpour, 2014).

The Detection Module is the analysis core of the Accident Detection Model and detects potential dangerous and accident-prone situations. The module acquires the information regarding the Site Boundary, the Danger Zones, and the Safety Buffers from the Information Module, and uses the Coordinate Origin to establish these boundaries. The module also acquires the estimated location of tags in real time from the UWB tracking system, and using the Coordinate Origin, it translates the estimated locations from the UWB RTLS coordinate system to that of the Site Boundary. For every new reading received from the UWB tracking (i.e. location estimation), the module checks whether the Safety Buffer of any of the moving objects overlaps with one of the defined Danger Zones on the site, or the Safety Buffer of another object. A detected overlap indicates an unsafe situation, and consequently a warning is issued (see Figure 1).

The Visualization Module acquires the Site Boundary, Coordinate Origin, Danger Zones, and Safety Buffers from the Information Module and generates a visualization of the site. Meanwhile, it receives the results of the analysis from the Detection Module. The translated coordinates of the tags and their safety status (whether their boundary at that instant is overlapping with another tag or a Danger Zone) are transferred from the Detection Module to the Visualization Module at every reading, and the module generates a real-time visualization of the positions of the moving objects on the site. If the status of the tag (moving object) is identified to be safe by the Detection Module, the tag will be represented in green color at the estimated position of the moving object. Red color is used when an overlap is detected to indicate a warning for a potential hazardous situation.

4 IMPLEMENTATION

The described Accident Detection Model was implemented in Processing 2, an open source Java development environment. The flowchart for the implemented tool is shown in Figure 2. At the beginning, the tool requires the parameters of the Information Module as an input (Step1). In this implementation, each worker is visualized as a circle that represents the virtual Safety Buffer surrounding the moving object (i.e. worker or equipment). The user also defines a rectangular Danger Zone through indicating four parameters: $x$ and $y$ of the top-left corner, and width and height of the rectangle. The user is also prompted for the location $(x,y)$ of the origin of the UWB coordinate system on the site. The boundaries of the site can either be drawn in the development environment or loaded from an external file.

Once the tracking is initiated, the tool acquires the location estimations from the UWB tracking system (Step 2). UWB keeps a record of all the readings, including the unsuccessful ones. The developed tool identifies these and filters through the records where the system failed to read the tag, and keeps track of only the successful readings. The $x$, $y$, $z$ of the estimated locations represent the position of the moving objects, and they are used as the centers of the circles that represent workers or equipment. The boundaries of these circles are compared with the defined boundaries of the Danger Zones, and the workers are displayed on the site plan as green or red circles, depending on whether they have a safe or unsafe status (Step 3). The tool continuously checks whether a new location estimation is available (Step 4). If this is the case, it reads the new position and repeats steps 3 and 4 (Figure 2).
5 FUNCTIONALITY AND EFFICIENCY OF THE IMPLEMENTED TOOL

The functionality of the implemented tool was tested in the Civil Engineering Concrete Laboratory of the University of Calgary, which is very similar to the work environment of a construction site (see Figure 3). Eight (8) UWB receivers were installed along the edges of the lab. The developed tool was setup for this site by taking in the coordinates of the site boundary. There is a cut in the concrete floor slab of the laboratory that is used for the movement of a lift between floors. This cut is protected by fence on three sides, therefore the fourth side is identified as a falling hazard. Hence, a danger zone was created next to the open edge of this cute. Two workers were initiated in the tool. Their safety helmets were equipped with UWB tags Two different Safety Buffers were assigned to each worker, one with a diameters of 2 meters and the other 3 meters; assuming that based on their movement speed and type of activity they carry the site manager required different Safety Buffers for each. The workers were asked to carry out their normal activities in the lab. The positions of the workers were monitored using the developed tool for two time spans of 10 and 30 minutes. The tool was successfully able to identify when a worker entered...
the Danger Zone. In other words, every time the Safety Buffer of one of the tags overlapped with the defined Danger Zone, the color of the Safety Buffer of the worker turned into red, and an alarm signal was issued by the tool, indicating an unsafe status for that worker. Otherwise, the tag was represented by a green circle, indicating a safe status for the worker. Figure 3 shows a screenshot of the tool at a moment where Worker 1 is entering the Danger Zone.

![Figure 3: A screenshot of the tool developed based on the Accident Detection Model](image)

The processing time of the developed tool was measured to examine its efficiency. This is the time difference between the acquisition of the estimated locations and the visualization of the workers’ or equipment's positions on the screen. This time difference is important because it translates into the delay caused by the tool in generating a warning signal when an unsafe position is detected. The two aforementioned scenarios of 10 and 30 minutes were used to measure the efficiency of the developed tool. In the first scenario with the duration of 10 minutes had an acquisition frequency of 3 Hz (i.e. 3 updates per second). In the second scenario, where the duration of the safety monitoring was 30 minutes, an estimation acquisition with a frequency of 8 Hz was used. The location estimation from the UWB system is recorded in a log file. Each location estimation (or “reading”) of the UWB is recorded in one line in the log file. Therefore, the number of lines, and as a result the size of the file, increases with the increase of data acquisition frequency and duration of the monitoring scenario. Table 1 summarizes the information regarding the two scenarios that were used in this study.

<table>
<thead>
<tr>
<th>Scenario</th>

Each scenario was simulated ten (10) times using the developed Accident Detection tool. In these simulations, for each reading, the processing time - i.e. the rime between when the information is read from the log file and when it is processed and a status (safe or unsafe) decision is decided by the tool - was measured. Therefore, there were 1,752 measurements for each simulation in Scenario 1 and 14,724 measurements for each simulation in Scenario 2 (see Table 1). Considering the ten (10) simulations for each scenario, 164,760 instances of the processing time were measured in total. The time measurements were conducted on a regular office personal computer (processor Intel Core i7-3537U 2.0 GHz, 8 GB of RAM, and Windows 8.1 64-bit operating system). The average processing times were less than 8
milliseconds for the first, and less than 41 milliseconds for the second scenario, which can be deemed negligible. The details of the processing time measurements are presented in Table 2.

**Discussion:** Although the measured processing times were negligible for the defined scenarios in this study, another interesting observation was made from the results. As it can be inferred from Table 2, the average **processing time** for the second scenario is 5 times more than the first scenario (40.72 ms vs. 7.77 ms). As the measurements of processing time were conducted for individual data acquisitions from the UWB, it was surprising to notice this time difference. After more investigations, it was realized that this time difference is in fact due to how UWB system operates, and not the efficiency of the developed tool. UWB tracking system saves the readings from one tracking session (i.e. from when system is activated until it is stopped) in a single log file. Therefore, and naturally, the size of the file gets larger as the time duration of the observation is longer and as more readings are recorded, making it increasingly more time consuming to process the file. From Table 1 it can be seen that the number of readings in Scenario 2 is approximately 8 times larger than the number of files used in Scenario 1 (due to the longer duration of observation and higher frequency used for data acquisition).

Although it is not possible to identify the precise correlation between the number of readings and the **processing time** using only the above two scenarios, some interesting understandings can be derived even with simplistic assumptions. If we conservatively assume a linear relationship, using the two data points from the above two scenarios, the **processing time** \( T_{\text{process}} \) (ms) can be estimated as (Figure 4):

\[
T_{\text{process}} = 0.0025 \, N_{\text{readings}} + 3.322
\]

where \( N_{\text{readings}} \) represents the number of readings acquired by the UWB system in one session.

![Figure 4: Relationship between processing time and number of readings, assuming a linear relationship](image)
This conservative equation demonstrates an interesting point. Even if the regression coefficient in [1] may seem very small, the number of readings increases very quickly with time. For example, assuming an acquisition frequency of 8 Hz, 480 readings are recorded every minute. Consequently, the processing time ($T_{\text{process}}$) would increase of 1.20 ms every minute.

For a typical 8-hour working day, with an acquisition frequency of 8 Hz, the number of UWB readings by the end of the day would be 230,400. Considering the conservative assumption of linear increase, this means that the processing time would be about 590 ms (more than half a second) towards the end of the day. To put the importance in perspective, consider a moving object with a relatively slow speed of 10 km/hr. Half a second of time delay translates into about 1.4 meters of disposition in location of that object. It means that, even if we assume no error in the estimated location provided by the UWB, in case of detecting a dangerous situation, by the time a warning is issued the moving object is 1.4 meters inside the danger zone. It should be reminded that this estimation is conservatively assuming only a linear increase in the processing time. While more experiments are needed to define the actual relationship between $T_{\text{process}}$ and $N_{\text{reading}}$, the authors speculate that it will be higher than a first degree relationship, resulting in even larger time delays at the end of an 8-hour session. This example demonstrates the importance of time delays caused by the processing time for realistic applications of RTLS for safety management systems which has been looked in the past.

6 SUMMARY AND CONCLUDING REMARKS

This paper presented an Accident Detection Model that is developed to detect hazardous situations on construction sites shortly before they occur. The model uses estimations of the positions of moving objects (workers and equipment) provided by an UWB tracking system. It compares the estimated locations for the moving objects with defined danger zones as well as the safety buffers of other objects on construction sites, and when the possibility of an accident is detected, it generates a warning signal. A visualization tool was implemented based on the model using a Java development environment, and its functionality and efficiency were examined.

The results of the experiments in two scenarios demonstrated the model’s capability to detect unsafe situations for a monitored moving object. Measurements were also conducted to evaluate the efficiency of the developed model by measuring the processing time for each data acquisition (location estimation). The results showed that the processing time for examined scenarios were negligible. However, a more in-depth investigation revealed an interesting finding. The processing time for each data acquisition increases gradually with time and the increase in the number of reading. It was identified that this was due to the fact that UWB RTLS records all the readings from a session into a single file. During a tracking session, UWB system adds a line to this file when a new position is acquired. This means that the delay in acquiring the estimated locations of a moving object is less at the beginning of a session, because the log file is smaller, and increases with time as the number of readings, and consequently the size of the file increases. Assuming a very conservative increase in the processing time, at the end of an 8-hour working day, the processing time would be more than half a second. Such delays would not be negligible for a real-time application anymore, since it translates in a considerable disposition for the moving objects.

This study shed a light on the importance of time delays in Real-Time Location Systems for safety management systems. While the research until this point has focussed on errors in location estimation caused by the RTLS, the experiments presented in this paper demonstrated the importance of time delays for realistic applications of RTLS in safety management. The future work of this study will include devising methods to acquire location estimation data directly and before it is recorded on the log file. This will not only keep the processing time at their initial negligible values, but more importantly, will mean that the processing time will remain relatively consistent for each data acquisition during a tracking session. Having a consistent processing time during a tracking session will facilitate applying corrective measures and as such, objectively accounting for it.

THE INFLUENCE OF PUBLIC-PRIVATE PARTNERSHIPS ON DESIGN FLEXIBILITY AND DOWNSTREAM DESIGN FEEDBACK IN THE PRESIDIO PARKWAY

³ Professor, University of Colorado at Boulder, U.S.A.

Abstract: Public-Private Partnerships (P3s) offer the opportunity to improve integration among project stakeholders throughout a project’s life cycle. Stakeholder integration, in turn, can enhance design decision-making process by focusing on the project’s life cycle cost. The objective of this paper is to compare and contrast design decision-making in a P3 and design-bid-build (DBB) process to explore if life cycle considerations are better optimized under a P3 delivery method. To do this, we analyzed a project that included both P3 and DBB project delivery strategies—the Presidio Parkway. We collected data through 16 open-ended, semi-structured interviews with key project participants. We analyzed the data for design decision-making processes and found mixed evidence supporting the proposition that life cycle considerations can be better optimized under a P3 delivery method. Specifically, we found that the ability of the P3 contractor to influence project outcomes depends on the timing of the integration of the designer in a P3 and the degree of design criteria and flexibility allowed. In the case study analyzed, the P3 designer was able to influence downstream life cycle considerations, such as the operations and maintenance of the project; however, given the degree of definition of the design and the timing of integration of the P3 designer, it was not possible to influence the upstream design decisions. These findings allow researchers to better understand how P3s are being integrated from a design perspective and allow the public sector to realize how the timing and degree of definition of the design in P3s influences a concessionaire’s ability to make life cycle design choices.

1 INTRODUCTION

The use of public-private partnerships (P3s) as an alternative project delivery method to deliver highway projects has become increasingly attractive over the past two decades. A P3 is defined as “a contractual agreement formed between a public agency and a private sector entity that allows for greater private sector participation in the delivery and financing of transportation projects” (FHWA 2013). P3s are a potential solution to close the increasing gap between transportation infrastructure costs and funding (Buxbaum and Ortiz 2009). Governments may use P3s to reduce pressure on government budgets, expedite financing, or facilitate innovation (AECOM Consult Team 2007), among others. Implementing P3s is commonly attributed to the improved services and better value for money achieved through appropriate risk transfer, encouraging innovation, greater asset utilization and integrated whole-of-life management (Fitzgerald 2004). Value for money is defined as the optimum combination of whole-of-life costs and quality (or fitness for purpose) of the good or service to meet the user’s requirement (HM Treasury 2006). One of the reasons a better value for money is expected for P3 delivery is because of the ability of the private partner to implement cost-saving investments during the design and construction of a project that may lower the long-
term life-cycle cost during the operations and maintenance (O&M) phase. The private partner is incentivized to use such strategies when the design and construction of a project is bundled with its O&M phase into a single contract (Blanc-Brude et al. 2009). Because stakeholders have the greatest ability to influence the long-term life cycle performance of a project during the design phase (Paulson 1976), ‘life-cycle’ decisions are expected to take place in the design phase. Of particular interest is how information from all project phases, including construction and O&M, is integrated and considered when making design decisions for the project. The flow of design information—specifically whether it flows as a sequential ‘waterfall’ from one phase to another, or whether the information is iterated back and forth in a ‘whirlpool’ fashion—is expected to greatly impact life cycle considerations.

While previous studies have focused on the comparison of P3 projects to traditionally procured projects by using initial cost and schedule performance metrics that do not extend beyond initial delivery or compare overall life cycle cost performance (Blanc-Brude et al. 2006, 2009; Chasey et al. 2012; NAO 2003; SAIC et al. 2006), this study will focus specifically on life cycle considerations in the design decision-making processes. Because most P3 projects are long-term arrangements that last between 30-99 years, the scarcity of projects available for analysis has made it difficult to draw life cycle conclusions (CBO 2012). However, by focusing on life cycle considerations in the design process, this paper can contribute to our understanding of the project characteristics or conditions that enable the enhancement of life cycle design decision-making processes. To do so, the research team analyzed the design decision-making processes in a single case study of a project that implemented both traditional DBB and P3 delivery.

2 BACKGROUND

2.1 Project Delivery Methods

A project delivery method (PDM) refers to the contract methodology used to acquire and deliver the basic elements of any infrastructure project (Miller et al. 2000). It is “a process by which a project is comprehensively designed and constructed for an owner and includes project scope definition (concept and feasibility); organization of designers, constructors and various consultants; sequencing of design and construction operations; execution of design and construction; and closeout and start-up. In some cases, the project delivery method may encompass operation and maintenance” (Touran et al. 2009 p. 4). The manner in which these PDM functional elements are structured determines the PDM strategy that the owner of the facility will implement (Miller and Gerber 2012).

PDM strategies may be broadly categorized by the bundling of the procurement of the services needed to initially deliver the facility, and to provide its intended service, the usage of facility. These two phases, the delivery and usage, can be referred to as the relative life cycle phase responsibility (Chasey and Agrawal 2013). Increasing the private involvement through allocating different responsibilities increases the amount of risk assumed by the private sector during the delivery of a facility. Note that the finance element of a project is something that occurs throughout the life of a project, and the degree of responsibility for financing might vary depending on the contract terms of a project. By assigning such key functional responsibilities, a segmented versus combined (‘bundled’) PDM strategy is determined to deliver a project, meaning the bundling of these key functional elements. P3s are typically considered to be in between this range of the traditional ‘segmented’ delivery strategies, and fully privatized ‘combined’ strategies (Miller et al. 2000).

2.2 Public-Private Partnerships

A public-private partnership (P3) does not constitute a single PDM, and there are many delivery methods depending on how a P3 is interpreted. The literature on the definition and types of P3s is also vast (Hodge and Greve 2007, 2009). A P3 has been defined as an agreement between the government and one or more private partners in which the private partners deliver the service in such a manner that “the service delivery objectives of the government are aligned with the profit objectives of the private partners and where the effectiveness of the alignment depends on a sufficient transfer of risk to the private partners” (OECD 2008, p.8). More strictly, using the appropriate terminology of PDMs discussed above, P3s for this study are classified as those whose functional life cycle phases are combined, the delivery and usage of the facility,
and for which finance is also part of the risk transferred, primarily the Design-Build-Finance-Operate-Maintain (DBFOM) type of PDM.

To put into perspective the P3 environment in the US, one of the most recent published summaries from a major projects database (PW Financing 2014) indicates that there have been only 30 transportation P3s in the US, dated from 1993 through September 2014. Out of these 30 projects, 17 are currently under operation, and the rest under construction. Also, only 21 of these projects have been carried out under this described DBFOM delivery strategy, whereas the rest are leases (i.e. Chicago Skyway) (n=5) and build-own-operate (BOO) projects (n=4), which are not considered to be P3s per the definition established for this study. Furthermore, 8 of these DBFOM transactions have been structured under an availability-based payment mechanism (DBFOM-avail) over the past few years, and the rest have been structured as direct-toll payment structures or similar (DBFOM-toll). The number of projects that would allow for the intended research on P3 projects to be conducted in this study is very limited.

2.3 Life-Cycle Design

Project stakeholders have the greatest ability to influence the long-term life cycle performance of a project during the design phase. The concept of how design decision-making influences the long-term cost performance of a project and how the level of control over those costs decreases as the project evolves has been long understood by many industries. Paulson’s well-known “cost influence curve” (Paulson 1976), shows how the level of influence that decisions made in the earlier phases of a project’s life cycle phase have a much greater influence on project outcomes, at a minimal fraction of the cost of the project’s complete life cycle cost. By the time construction is completed the influence that any decision might have on the remaining life cycle of the project is minimal, if any, and might be a considerably large capital expense at that point.

![Figure 1: A Sequential 'Waterfall' (left) vs. an Iterative 'Whirlpool' Design Process (right)](image)

The traditional DBB design process can be compared to a linear ‘waterfall’ approach in which, given the segmented approach of each functional element, each phase is optimized for personal benefit (Thomassen 2011). The concept of a waterfall design process has emerged from the discussion of software development processes (Royce 1970). The general idea of such processes is that it can be considered to be an extremely inflexible design process, where inflexibility is characterized by frozen outcomes and sequential processes (Weisert 2003). As shown in Figure 1, this suggests that ideas and feedback for design decisions only flow to downstream activities but may not be fed upstream; furthermore, the inability of starting later phases in which other project participants get involved and may provide valuable life cycle feedback to the design process, alters the design.

Alternative PDMs on the other hand, such as design-build, and even more so in what can be considered to be a fully ‘combined’ PDM strategy, such as P3s, control of the design is removed from the engineer and given to the entire team. As opposed to the waterfall model, working in a complete linear fashion, in a P3, the design process is considered to be iterative ‘whirlpool’ process, with significant “over-the-shoulder” design reviews by the contractor, financier, operator, and, to some extent, the owner (Hatem and Gary...
The ability of having input into the design by other project stakeholders involved in different phases of the project life-cycle, provides the opportunity to better optimize the functionality of the project to improve a project’s overall life cycle performance.

3 RESEARCH METHODOLOGY

The research methodology for this study was an *embedded single-case study design* methodology (Yin 2009), as shown in Figure 2. The case study methodology was selected because the case study selected, the Presidio Parkway project discussed further below, was a *revelatory case* (Flyvbjerg 2006), meaning that it was a P3 project with a unique contextual setting that allowed for the opportunity to study the design process under special circumstances. Specifically, the case allowed for a side-by-side comparison of two delivery strategies—design-bid-build and P3—implemented to construct the Presidio Parkway Project in the US. This research analyzed the design decision-making processes within each of the two phases of this project, delivered under each respective PDM.

![Figure 2: Embedded, Single-Case Study Design](image)

### 3.1 Case Study Setting and Unit of Analysis

There have been limited transportation P3 projects in the US in the last 20 years, with only 21 existing projects delivered under a DBFOM-type of P3. To select the appropriate projects for this study, P3 projects whose design phase was on-going or recently finished were targeted. The Presidio Parkway Project, located in San Francisco, CA, was selected as the case for this study. This particular project was split into two phases delivered under different PDM strategies: Phase One was delivered as a traditional Design-Bid-Build (DBB), and Phase Two was continued as a P3 (DBFOM-type). The P3 developer for this project also assumes operations and maintenance for both phases after initial delivery of the project for a contract term of 30 years. This particular case became a project in which two design processes were considered under each respective delivery mode, and therefore the design processes were chosen for analysis to compare the influence of PDM strategy on design decision-making. Data was collected during the spring of 2014, when the design of the project was almost complete. The design processes were treated as *embedded units of analysis within a single case, given that they were part of the same project*.

The project’s condition can be considered to be a ‘hybrid’ project, meaning that it is not a brownfield nor a complete greenfield project since it is adding a significant amount of structures as well as the replacement of most of the existing facility. The project is approximately a 1.5 mile long road with a significant amount of structures, with four cut-and-cover tunnels, six bridges, and three interchanges split between the two phases. Furthermore, the P3 delivery of the project was structured as an availability-based payment mechanism, as opposed to a toll-revenue P3 mechanism.
3.2 Data Sources

This research collected data from project participants by conducting semi-structured interviews. This research analyzes the data collected from the interviews, which were the most in-depth source of data. A total of 16 on-site interviews were conducted, with 20 different participants. The interviewees were targeted to represent a broad spectrum of all stakeholders involved in the project, particularly those that could have the knowledge to discuss design issues experienced in this project. Table 1 lists the organizational role and project role for each of the participants.

The research team conducted exploratory, semi-structured, in-depth interviews. The format employed was meant to develop ideas and research hypotheses rather than to gather facts or statistics. Determining the number of interviews to conduct was dependent on reaching theoretical saturation, when new information was no longer mentioned. As a result, quality was preferred over quantity (Oppenheim 1992). As Oppenheim (1992, p. 67), explains, “the job of the depth interviewer is thus not that of data collection but ideas collection.” Using this approach, interviewees were asked about the design decision-making process on each phase of the project and conditions that may have enhanced or constrained life cycle considerations in the design. The semi-structured interviews began by asking directly how the choice of project delivery method had influenced the life cycle design decision-making process, particularly, characteristics of life cycle design were explored, including the integration of life cycle functional properties (Design, Construction, O&M, Reconstruction and/or End-of-Life properties).

3.3 Data Analysis

The research team used QSR Nvivo software to organize and analyze the data. The interviews were audio-recorded, transcribed into text, and imported into the software. Over 17 hours of recorded audio time for the interviews shown in Table 1 resulted in over 215 pages of text, after all audio files were transcribed word-by-word. The data was systematically coded to identify significant patterns following the coding process described by Miles et al. (2013). The coding process was primarily driven by two ‘cycles’ that allowed the researchers to draw conclusions from the interviews regarding the life cycle design decision-making process as experienced in this case. The first cycle of coding was an organizational, or structural approach to sort appropriate data into macro-categories for further analysis. Following this process, a more explicit identification of the content in the interviews allowed for more a ‘substantive’ and ‘theoretical’ description of the data to be analyzed more in line with the research objectives. For example, one of the interviewees, when discussing the life-cycle design considerations in phase two: “I think this project has not had as much leeway for innovation as what I think of is a typical P3, or a typical design-build project might,
because we have been more confined by what was done in phase one of the project with respect to the design. So in some ways I sort of feel like there has been a little bit less innovation on this project than I would have expected.” This section of the interview was coded to themes of ‘innovation’ and ‘design flexibility’.

Following the initial coding, the data was then further analyzed. During this process, we focused on explanation building (Yin 2009). Specifically, we focused on how the theoretical proposition of this study was either supported or challenged from the data collected. The theoretical proposition was: Design information in a segmented PDM strategy flows one-way, downstream in a sequential design process in which no downstream design feedback may be incorporated into upstream design activities. In a combined PDM strategy, an iterative overlapping design process allows for a two-way information exchange between upstream and downstream design activities, thereby allowing for life cycle design to be better optimized. This paper describes and explains what has happened in this single case, regarding the stated proposition. This includes interpreting and mapping the results from the case study to this proposition in order to understand it from this single case (Eisenhardt 1989).

4 FINDINGS

The Presidio Parkway had a significant amount of overlap between phase one (DBB) and phase two (P3). As a result, while the project provided an ideal laboratory setting for analyzing two different delivery methods under similar settings, the overlapping sequence of processes also created constraints for attributing differences and similarities solely to one PDM strategy employed. However, the researchers were able to identify project characteristics that influence life cycle design decisions under a P3. These characteristics are explained as the timing of implementing a P3 in a project during its development, and the design flexibility of the project. Furthermore, as part of using this case study to explain the life-cycle design decision-making process under a P3 delivery strategy, examples of downstream design feedback are also discussed. These examples are related to the design feedback that benefited constructability and the O&M phase of this project.

4.1 Timing of P3 Implementation

When the interviewees were asked about design decisions, all participants indicated that the unique phasing of the delivery methods limited the ability of the P3 designer to influence the design and consider life cycle aspects. In this case study, the P3 developer entered the project after many design decisions had been made. As Hayes shared, “just because phase one was already built, a lot of ground work was done for the P3 group, the developer, and in the contract we have some language that phase two has to be similar to phase one. So pretty much it takes the innovation out of the developer.” Other interviewees indicated that, if a P3 project is to benefit from the private sector's innovations, the P3 developer has to have the ability to alter the design and be able to provide value engineering input. As a result, the definition of the design requirements and its implications for design flexibility must be given thoughtful consideration upfront by the public sponsors. A recent report (Parsons Brinckerhoff et al. 2013) indicated that the private sector may be able to best define and incorporate design alternatives based upon life cycle considerations in a highway project prior to the conclusion of the environmental clearance process. On the other hand, a ‘post-environmental clearance’ P3 procurement may reduce the ability of the P3 developer to propose alternative technical concepts (ATCs) that will influence life cycle design optimization decisions significantly.

4.2 Design Flexibility

Interviewees’ also indicated that contract specifications limited the design flexibility of the project. These contract specifications are the contract documents in which the owner communicates a project’s requirements and how conformance with those requirements will be measured, as thus, determine the amount of flexibility allowed in the design (Loulakis 2013). The degree of specifications varies from performance-based specifications (PBS) that describe the final product based upon operational characteristics, and thus offer the P3 contractor a greater degree of flexibility in how to achieve the final product; to ‘prescriptive’ specifications that explicitly describe the final product in terms of component materials, dimensions, tolerances, weights, and even required construction means and methods, thus
giving the owner maximum control of the project (FHWA 2004). For this project, the P3 design process was considered to be relatively prescriptive. As McAllister indicated, “I think it [this project] is rather prescriptive for a P3 project because it is supposed to mimic the look of the other side so there isn’t really a lot of flexibility… innovation is probably coming from the means and methods, but in terms of appearance there isn’t really a lot you can play with.”

Because the P3 delivery finished a project half-built under a DBB, the design specifications had to be prescriptive for this project: “You don’t want to be too prescriptive, in fact you don’t want to be prescriptive at all; however, in this situation there has to be some prescription… using these contract documents is a challenge. You don’t want to restrict things too much but then, at the same time, you want to make sure what they are going to build is a mirror image of what is already there.” From a life cycle design perspective, the ideal setting for a P3 is when ‘degrees of freedom’ are given to the P3 designer to meet a functional need without limiting the design parameters that the designer might propose. Overall, the timing of the P3 and the contractual specifications of the project greatly affected the P3 developer’s design flexibility. One interviewee, Green, indicated that the limitations inherent in brownfield projects may always limit design flexibility and that the optimal conditions for considering lifecycle within the design are Greenfield projects: “Maybe the most beneficial application of a P3 is where you have more of a Greenfield project where there is a lot of flexibility, so as what the franchise can do meeting a fundamental need, but flexibility to kind of start from scratch as to what it is they can do and innovate more”.

4.3 Downstream Design Feedback

The timing of P3 implementation and the design requirements for this project limited the ability of the P3 developer to alter the early, upstream design. However, downstream from the design phase, particularly constructability issues and O&M processes benefitted from the life cycle considerations used by the P3 team.

4.3.1 Constructability

Within the P3 delivery strategy, the developer subcontracted the design and construction of the project. As previous studies have shown (SAIC et al. 2006), constructability reviews are typically incorporated into the design phase on P3 projects, thus enhancing the construction phase of projects. Within this project, we compared the approaches taken to construct the piles for the project’s viaducts. In phase one, under the DBB approach, the project sponsors were ‘conservative’—they did not want to take any risks in having the piles fail and therefore ‘over designed’ the piles. One of the project sponsors, Waller, explained their approach in phase one for this particular example: “we designed it a full depth casing because [the department] didn’t want to take a risk, if we had historic buildings next to our new bridge, we couldn’t do any pile driving because we would collapse the building, so we said ‘let’s drill down a full depth casing…’ we took an extremely conservative route plus we didn’t want to have a 12 foot diameter hole collapse on us.” Under this phase the sponsors did not try to optimize or make the design and construction process more efficient, from an economical perspective. In comparison, under the P3 delivery, phase two, the contractors chose a different design to eliminate the need for casings, as Ellis indicated: “we didn’t have the permanent case because our designers didn’t think that we needed that, we added rebar, and we did something to eliminate the need for permanent casings.”
This specific example shows how a project component was approached differently under different PDM strategies. The following excerpt from one of the interviews with the public sponsors, Clayton, highlights how this difference is reflected by their ‘motivations’: ‘We were under pressures, but different pressures, so it is kind of interesting because, okay, this is Doyle drive, this is kind of a high profile job in the Bay Area in the State of California so we were both under pressure but for different reasons. We want to get to seismic safety, we didn’t want to delay the P3, it costs us money to delay plus we don’t get the seismic safety traffic switch which is important for public safety. They had different reasons, they want to get done, they have a banker, their financier’s saying ‘hey when are you going to get done, pay us back?’ So that is kind of interesting, we have pressures but for different reasons.” Looking at this comparison, the motivations that drive these particular design decisions can be appreciated. In one phase, ‘safety’ drove the decision to build the piles with a permanent casing. Phase one’s more ‘conservative’ design approach can be argued to be driven by an underlying motivation to reduce all risk of potential failure which may delay the achievement of seismic safety, given the importance of this particular arterial road in the region for public safety. In phase two, the decision to eliminate permanent casings can be argued to be driven by an underlying motivation that resulted in a more economically efficient design, and that significantly reduced the time to construct the second high viaduct, given the financial pressure that the P3 team experienced.

4.3.2 Operations & Maintenance

During the construction of phase two, the O&M provider began operations for the scope of work delivered in phase one. As a result, there was in-depth integration of the O&M service provider with the P3 design-build team in phase two, allowing the O&M team to provide significant feedback to the designer as they began the operations of the complex facility. As discussed, the overlapping of the project phases (phase one and phase two) allowed for the O&M phase to begin during the construction of phase two. “In most projects you don’t normally get that and [the P3 designer] would tell us all day long, ‘we never really get to talk to the end user and how they want it configured, how they want it to function, you know, do you want it to do this? or do you want it to do this?’ And those are all the conversations that we have on a weekly basis” commented one of the O&M contractors, Eddy. “So those are the things that we are pushing for and we are getting on this project, but those things may not have been thought of in phase one, because hey guess what? In most cases, in most typical delivery, you never really talk to the end user, and say ‘I like your design, but me getting out there to access or do what I need to do out there could be done in a little different way, it isn’t going to cost more money, it’s just a little different way to do it and you can take into account what my needs are at the end of the day.’”
This particular response has been provided to show the type of conversations that the O&M provider is having with the P3 designers in order to benefit the O&M phase of the project for both phase one and phase two scopes of work. Phase one might have not considered the operability as in-depth, including the systems that were installed for traffic management in one of the tunnels, as much as phase two was able to incorporate. The ‘systems’ of this project, considering the fact that this project is more a ‘tunnel’ project than it is a road project, were a very important component. Having four tunnels that the O&M contractor is responsible for, which carry over 100,000 vehicles, average daily traffic, and this being the main artery connecting the North Bay to the San Francisco through the Golden Gate Bridge shows the importance of the systems in this project. This same interviewee, Eddy, commented: “a lot of times I think phase one was built as a roadway project and not necessarily a tunnel project which has a lot of more intricacies in terms of how traffic is managed, how the systems in the tunnel are managed, everything from the lights system to the fire alarms to the CCTV cameras and how that all talks and communicates together… but I think the real benefits are in the systems and devices and how that is used and that is I think something that is kind of in the back, that a lot of people don’t understand. That is where your bang is, your bang for your buck is there. In terms of the systems and how they operate, how they all intercommunicate together and how we get things off the roadway.”

This second example shows the O&M phase, being a downstream phase from a life-cycle perspective, being enhanced by the P3 strategy in this project. Having the O&M operator being closely aligned with the P3 designer, specific design input regarding the systems of the tunnels, for example, were design feedback that was incorporated to improve the operability of the project. This in turn, enhances the long-term performance of the project overall from an operations perspective.

5 CONCLUSIONS AND FUTURE WORK

This study explored and presented initial findings from how life cycle design decision-making processes are influenced by project delivery methods in the embedded case study of the Presidio Parkway project. P3s are considered to be the most integrative and ‘combined’ project delivery strategies to deliver infrastructure projects. Through the analysis of interviews conducted with project participants we found that the timing of P3 implementation, the degree of design flexibility, and the degree of overlap between the O&M and design-build team influences the ability to consider life cycle perspectives and private sector innovations during the design.

These initial findings are limited to the single case study of this project. Ongoing work will extend these findings by analyzing life cycle considerations in the design phase on two additional P3 transportation projects in the US, and by conducting a cross case comparative analysis. To conduct this analysis, we will select projects to analyze based upon characteristics such as the technical complexity of the project (i.e. structure-heavy project vs. a road project), the DBFOM payment mechanism (i.e. direct tolls vs. availability payment), the project condition (i.e. greenfield vs. brownfield), and the organizational structure of the project (i.e. a fragmented vs. integrated structure, and financial leverage).

BRAZILIAN AND CANADIAN OIL&GAS INDUSTRIES – SIMILARITIES, DIFFERENCES, CHALLENGES AND PERSPECTIVES FOR A SUSTAINABLE INDUSTRY

Rodrigo R. Aragao1,2,3 and Tamer El-Diraby1
1 Department of Civil Engineering – University of Toronto, Canada
2 Petróleo Brasileiro S.A – Petrobras, Brazil
3 r.aragao@mail.utoronto.ca

Abstract: The Brazilian and the Canadian Oil and Gas industries are facing similar challenges now: both countries are developing huge oil fields; as a result, companies, governments and policy makers have started to invest escalating resources in projects and regulations. These efforts have provided both countries with a significant increase in their oil production. Brazil discovered the Pre-Salt field, located off its Southeastern coast, what resulted in complex technical researches whose outcome will guarantee a safer and more environmentally friendly production. The oil sands in the western Canada, along with the shale formations, despite the abundance, have been utterly criticized by environmentalists who report the possible impacts of the methods used to extract the oil. This paper aims to analyze the similarities, differences and challenges that both countries have to confront. In addition, as many companies in other sectors, the oil and gas industry has taken the initiative to demonstrate that their activities are in accordance with the best practices of sustainability by seeking the optimal efficiency in water consumption, energy and waste management; as well as minimizing carbon emissions to reduce the greenhouse effect. Nevertheless, the oil and gas industry still has to face the common sense that their activities cannot be innovated to reduce environmental impacts and therefore be aligned with the best sustainable practices. Analogous to the movement that has led the AEC industry to create the “green buildings”, two proposals on how to address the sustainability of these projects is presented.

1 INTRODUCTION

Despite the recent fall in oil prices, which have been striking the oil and gas industry, some projects in Brazil and Canada will be postponed or even canceled and yet many will still continue to the next phases. Brazilian and Canadian oil and gas industries are in continuing evolution and are expected to maintain it for a long time. Nevertheless, in today’s environment, more and more corporations are willing to demonstrate that their activities are in accordance with the best practises of sustainability so as to guarantee the optimal efficiency in water consumption, energy and waste management as well as to minimize carbon emissions and hence reduce the greenhouse effect. This is much expected from the Brazilian and Canadian oil and gas industry because of the reliance of global oil demand on their non-conventional oil and gas resources, as noted by Kerr (2011; 2012a; 2012b). Furthermore, sustainable development also involves an appropriate balance between environmental solutions, and social and economic issues. As a result, stakeholders, clients, investors and government parts have been demanding dramatic changes in the way companies are investing in new projects.
Aiming for better sustainable results, the oil and gas industry has a key role by addressing new practices that have been widely used to develop sustainable rating systems like the ones that have been extensively utilized to assess the green buildings such as LEED and BREEAM. However, the specific characteristics of the oil and gas industry do not permit a full application of building rating systems into industrial projects. Although many rating systems are vastly used to analyse the sustainability of green buildings, few attempts to assess the sustainability of oil and gas projects has been adopted so far. Compared to buildings, industrial projects are typically larger, have a longer lifetime, take longer to construct and consume more energy and water overall.

As part of industrial projects, the oil and gas industry has to challenge the common sense that its projects cannot be designed to reduce environmental impacts and therefore comply with the best practices of sustainability. Thus, despite the outstanding initiatives of the sector, the oil and gas industry should incorporate in its projects the valuable concepts of green buildings projects. In this work, we present two different proposed researches on how to address the sustainability of oil and gas projects. The first is the development of a universal green rating system framework that could be implemented in the oil and gas sector. The second proposal focuses on the main causes of the climate change. A method using BIM – Building Information Modelling to calculate and optimize the embodied energy and corresponding emissions of oil and gas projects is proposed.

2 CURRENT SCENARIO OF MAIN BRAZILIAN AND CANADIAN OIL AND GAS PROJECTS

A comparison between the Brazilian and Canadian oil and gas projects is structured below according to subareas of the oil and gas industry such as upstream (oil); downstream (refining); and natural gas, liquefied natural gas (LNG) and transportation.

2.1 Upstream – Oil

Brazil is the eleventh oil producer of the world (EIA, 2013), with a daily average production of 2.6 millions of barrels of oil equivalent. The Brazilian oil and gas industry is comprised of many players, with the state-owned Petrobras as the largest one. Founded in 1953, the company is already present in seventeen countries. It is controlled by the Ministry of Mines and Energy of Brazil and has operations in exploration and production, refining, oil and natural gas trade, transportation, petrochemicals, retail distribution, electricity, biofuels and renewable resources among others (Petrobras, 2014a). Located in the Atlantic ocean off the southeastern coast, the Pre-salt province discovered in 2006 (Petrobras, 2014c) has already increased Brazilian proven reserves to 15.6 billions of barrel (ANP, 2014), and it is expected to double until 2022 (Folha de Sao Paulo, 2014). The Pre-salt and other domestic demands have caused a boom in the number of proposed offshore projects in Brazil: 38 platforms (including drillships), of which 7 are already in operation, 49 vessels and 20 waterway convoys among others (Petrobras, 2014b).

Canadian crude oil reserves is the third largest in the world with 173.6 billions of barrels (EIA, 2014), just behind Saudi Arabia and Venezuela, thanks to the oil sands located in the western provinces, accounting for 167 billion barrels or nearly 96% of overall Canadian reserves. As opposed to Pre-salt in Brazil, the potential of oil sands has been widely known for decades, but they became economically viable just when oil price reached around sixty US-dollars at the beginning of the 2000’s. This permitted massive investments in in-situ and pit mining projects, increasing the Canadian daily oil production from slightly over 2 million barrels at the early years of last decade to 3.7 million in 2014 (NEB, 2015). Besides the oil sands projects, Canada has also seen investments in the offshore fields along the Atlantic coast and Western Union Sedimentary Basin. However, the offshore projects do not seem to represent a significant increase in the current level of oil output compared with the potential of oil sands (EIA, 2014).

Despite the difference of size of both national reserves, the main similarity of the Brazilian and Canadian oil reserves relies on the fact that many experts anticipate a delay in global oil peak, alleging the potential of these future oil prospects and others. They call this type of oil production non-conventional, since it cannot be produced by the well-known conventional extraction methods. However, some authors are skeptical regarding the future of the oil and gas industries of these countries, as the increase in their production will heavily depend on developing technologies and a relatively high breakeven oil price that
justifies new investments (Sorrel et al., 2010; Sorrell et al. 2012). Furthermore, the expected improvements in technologies are not only to implement oil outcome but also to guarantee a safe and environmental friendly operation.

2.2 Downstream – refining

As the Pre-salt is expected to boost the Brazilian production to about four million barrels per day until 2022, the surplus of oil should be either processed or exported. As a result, four new refineries and revamps have been proposed, which will increase the Brazilian refining capacity from currently 2.1 million to 3.3 million barrels per day (Petrobras, 2014d). One refinery, Rnest, located in the state of Pernambuco, is already under operation since December 2014. Two other projects are on hold. Brazilian downstream projects have been demanding a great effort from the owner and contractors, as refining projects are very capital intensive, require high-skilled workers, demand excellence in quality assurance and therefore a remarkable supply chain. The last refinery had been constructed more than thirty years before Rnest started up.

As opposed to the Latin American country, Canada opts to export its oil surplus to the U.S., where the actual installed refining capacity is larger, underused and more suitable to process the viscous and heavy sand oil (MacLellan, 2014). This strategy is highly controversial, as opposers argue that new refineries would generate more post jobs, more investments; and reduce the price of fuels and the international dependency on processed products, such as gasoline and diesel (Mendleson, 2013). One of the few exceptions is North West Redwater Partnership, a refinery that is under construction in Alberta and with startup expected to late 2017 (North West Redwater Partnership, n.d.).

2.3 Natural gas, liquefied natural gas – LNG and transportation

Brazil has already concluded some of the major projects considered strategic for the natural gas pipeline network. Concluded in 2010, GASCAC, or Cacimbas/Catu gas pipeline, is a 954-kilometer-length stretch, which permitted the integration between the southeast and northeast gas pipeline networks. As a result, natural gas that is imported from Bolivia can also supply the region Northeast of the country.

Brazil has also opted to construct three LNG import terminals. These facilities permit the import of natural gas on ships, opening new import markets and, consequently, reducing the dependency on the current inland natural gas imports.

Canada is already a natural gas exporter with the U.S. as the only buyer of the Canadian gas. With the significant findings of shale gas in the U.S. and Canada in the last years, Canadian market is shifting the strategy and seventeen LNG export facilities were proposed, entering the regulatory process (Natural Resources Canada, 2014). However, due to the recent fall in oil prices, only two projects sponsored by Chevron/Woodside Petroleum and Shell respectively may proceed, with the former expected to start up in 2021 (Hussain, 2015). Both projects are located in the Western Coast, British Columbia.

In Canada, there are also proposed improvements in the transport network such as Keystone XL. Under lively debate because of the allegedly environmental impact, Keystone XL pipeline, with 529 km in Canada, is expected to increase the offer of the crude oil produced in Alberta to the U.S Golf Coast refining system, whose refineries are considered more suitable to process the viscous and heavy sand oil. However, the issuance of a U.S. presidential permit has delayed its construction (TransCanada, n.d.).

2.4 Summary of projects

Table 1 provides a summary of the main projects of the Brazilian and Canadian oil and gas industries. The projects presented in this work and on the table below were selected based on their level of relevance as well as the similarities between both countries. Thus, the main goal is to illustrate the current general status of the oil and gas industry in both countries and the correlation with future challenges concerning sustainability that will be presented later. It is not intended to list all current oil and gas projects in Brazil and Canada.

3 TOWARDS A MORE SUSTAINABLE INDUSTRY

3.1 Green buildings vs. the oil and gas industry

Green buildings are designed to minimize the potential impacts of constructions on the environment, to contribute to the reduction of the emissions of greenhouse gases and thus to a long-term sustainable development. The concept of such buildings aims for environmental responsibility throughout its whole life cycle, from the design until the demolition. The main consolidated issues covered by sustainable designs are (Building Research Establishment n.d.; US Green Building Council n.d.):

- Energy efficiency
- The efficient use of water
- The environmentally efficient use of materials
- Impacts of construction methods
- Indoor environmental quality
- Operation and maintenance
- Waste management

With the advent of green constructions, the necessity of developing sustainable rating systems have been arisen so as to assess how sustainable and environmentally friendly these new projects are. Rating systems are benchmarking codes and one important step to be taken by corporations that intend to demonstrate to society that its projects are effectively green. Sustainable rating systems are structured, decision-making tools in support of measuring environmental performance throughout the project life cycle and verified by third-parties (Poveda, 2014).

Examples of factors that should be considered when developing a rating system assessment throughout the life cycle of projects should include the project size, kind of industry, surroundings, codes, standards, regulations and the stakeholder’s requirements. The majority of rating systems have been developed considering these aspects. The most popular rating systems worldwide are ATHENA (Canada), BEAT 2002 (Denmark), BREEAM (UK), CASBEE (Japan), LEED (USA, Canada, Mexico), DGNB (Germany),
NABERS (Australia), HQE (France), ENVEST 2 (Netherlands) and others. In Brazil, more recently, the ratings systems AQUA (Vanzolini Foundation, n.d.) and LEED Brazil have been launched.

Adaptation from a green building rating system to industry has no efficacy, since the specific characteristics of industrial projects do not permit a full and integrated application of building rating system. Moreover, the impacts on the environment of industrial projects are far more critical than in buildings, including the phases of demolition and disposal at the end of the economic life of the project.

Although engaged in several remarkable sustainable projects, the oil and gas industry should advance and incorporate the green philosophy already found in the building industry. As one of the first precursors, Poveda (2014) developed a rating system to measure the environmental performance of oil sands and heavy oil projects in Canada, called the WA-PA-SU project sustainability rating system. However, due to the large variety of projects of the oil and gas sector around the globe, a full application of Poveda’s framework, which was based on the oil sands in Alberta, should be carefully verified before extended to other oil and gas projects.

### 3.2 Is ISO 14000 series enough?

Many oil and gas companies in Brazil and Canada are certified ISO 14001, the most popular environmental management standard; and also demands the use of this code from its subcontractors. Based on the PDCA (Plan, Do, Check and Act) cycle, however, ISO 14001 is an environmental code that certifies the corporate management processes and does not ensure the quality of the final product since it does not define goals and indicators, which should be established, planned, measured and controlled by the certified entity. Rondinelli and Vastag (2000) point out that ISO 14001 does not measure the actual environmental performance of a plant or company. In fact, it ensures that the company has a management system to deal effectively with its environmental impacts, meet regulatory mandates and go beyond legal requirements to achieve continuous environmental improvements, but there is no way of externally verifying that such improvements actually occur.

### 3.3 Building Information Modelling (BIM) and Sustainable Engineering

Building Information Modelling (BIM) represents the development and use of n-dimensional models to simulate the planning, design, construction and operation of the future facilities (Azhar, 2007). BIM carries all information related to the model including its physical and functional features and project life cycle information as "smart objects". According to Azhar (2007), a building information model can be used for the following purposes:

- 3D visualisation of the model
- Detailed design drawings for construction and purchasing of the different facilities such as MEP systems
- Code reviews, like those done by fire departments
- Forensic analysis by simulating potential failures, such as leaks, evacuations plans etc.
- Operation/maintenance of facilities, including the use of the model for planning renovations and maintenance operation
- Cost estimating (materials quantities are automatically extracted and changed when any changes are made in the model)
- Construction sequencing (used to create material ordering, fabrication and delivery schedules for all project components)
- Conflict, interference and collision detection, for models are created in 3D space, hence all major systems can be visually checked for interferences.

More and more, for projects pursuing green certifications, designers have to conduct in-depth sustainability analysis based on a building’s form, materials, context, and mechanical-electrical-plumbing (MEP) systems, as the most important decisions regarding a sustainable project are made during the design and planning stages (Azhar et al., 2011). BIM is also a powerful tool used to optimize the use of passive solar energy for lighting, ventilation, heating and cooling and therefore reduce overall energy use
of the building. In addition, BIM is also employed to perform life cycle energy assessment simulations so as to provide designers, owners and engineers with valuable information on energy, emissions and impacts over the lifetime of the project.

3.4 Embodied energy of industrial projects

According to Harvey (2010:35), buildings account for more than one third of total energy use in world, whereas industry also represents at least one third of total energy consumption. Agriculture and transport sectors are responsible for the remaining one third. Although buildings and industry demand approximately the same amount of energy, most works involving sustainable design are just related to buildings. This is probably due to the higher level of complexity of industrial processes, more complex design and the immense variety of materials used in industry. All these aspects make it difficult to create a unique and standard green code, such as LEED, for industry.

Embodied energy is the total primary energy used to extract, process, manufacture, deliver and construct materials, assets, equipment or facilities; and should also include the feedstock energy, which is the energy value of energy commodities that eventually are incorporated in the final product (Harvey, 2010:331). Yung et al. (2013) published a literature review of 38 works involving 206 cases and concluded that the initial embody energy represents from 7.5 to 7.8 years of the total energy use in buildings’ life. It can be an indicator of the overall environmental impact of projects, since energy use produces carbon dioxide and therefore contributes to the greenhouse effect. Embodied energy approach considers only the total primary energy spent until the point in which the installation is commissioned and ready to start-up, not including the operation or decommissioning. As of this phase, the facility is operational and all energy use is classified as process energy, whose efficiency is examined by the related process engineering.

Contrary to the embodied energy approach, the life cycle assessment evaluates all the impacts over the whole life of a material or element (from cradle to grave). Although the main goal is to reduce the embodied energy of an installation, one of the most important observations derived from the embodied energy perspective is to consider embodied energy over the whole lifetime of a project, since an increase in the embodied energy might lead to a reduction in the operational energy over the lifecycle and therefore a reduction in the total energy use of the project. This trade-off relationship will depend on the percentage use of recycled materials, the performance of the individual systems, the avoidance of wastes, construction methods and many other aspects that can influence the operation and maintenance of the facility. In this sense, this method resembles the preliminary study of economical viability of the project, with energy instead of cost.

Likewise sustainable rating systems, the embodied energy analysis has been already in use by the building industry, although a great effort is still necessary to fill up the existing research gaps (Ariyaratne and Moncaster, 2014). In most works, BIM was utilized as the main tool to calculate embodied energy and respective carbon footprint. Articles, works or case studies related to the use of the embodied energy approach by the oil and gas industry could not be found until the conclusion of this work.

4 DISCUSSIONS

Based on the situation cited earlier, two proposals were identified to address the sustainability of oil and gas projects. These proposals are presented below.

4.1 Universal oil and gas green rating system

As observed earlier, the complexity and the variety of the industry do not permit a full application of current green building codes. Contrary to the industry, the building sector is a more standard-based sector. In the oil and gas industry, besides the variety of projects (plataforms, refineries, power plants and much more), the list of regulatory requirements is often longer, which demands more resources and effort to be met. In addition, most of these projects are located in remote areas, posing a higher potential impact on the environment when compared with buildings.
A universal framework of a green rating system for the oil and gas industry that could cover all types of projects around the globe is desirable. This would permit the comparison of similar projects by means of a quantitative analysis. As mentioned earlier, Poveda (2014) concluded a valuable research project about a sustainable rating system that can be applied on the oil sands and heavy oil industry in Canada, the WA-PA-SU. However, further analysis is necessary in order to evaluate the applicability of the proposed framework into other types of projects and in other parts of the globe. In addition, Hunt (2005) developed a sustainable rating system for bridges based on the LCA and replicating several existing criteria of the LEED certification. Envision 2.0 (Graduate School of Design – Harvard University, n.d.), a rating system for sustainable infrastructure covers civil infrastructure projects such as roads, bridges, pipelines, railways, airports, landfills and others. These previous works suggest that the academic community have already identified promising improvements in the effort of the industry to become more sustainable, and that a green rating system for each sector may be a coherent evolution.

4.2 The use of BIM to optimize the carbon footprint of oil and gas projects

Instead of looking for a green rating system that would address all concerning dimensions of sustainability, as the ones already mentioned in section 3.1, another proposal is to focus on the carbon footprint of oil and gas projects. The challenging emission levels, which perhaps will be agreed on the next United Nation Climate Change Conference in November 2015 by attending nations, will not tolerate the current emissions provided by business as usual – BAU. As a result, carbon caps or tax will be probably levied in many nations and therefore the lifecycle energy in industrial projects should be taken even more seriously than nowadays. This issue will be considerably more challenging in developing countries, such as the BRICS – Brazil, China, Russia and South Africa, where the current infrastructure is still under development, demanding huge amounts of equipment, construction sites and energy intensive materials, such as concrete, steel, aluminium and copper.

As seen in the AEC industry, BIM as a tool to perform a lifecycle energy analysis in oil and gas projects will play an important role due to its ability to integrate geometric features of the model with non-geometric attributes. In addition, BIM also has the ability to generate schedules and simulate the construction site, which will also interfere in the overall embodied energy of the project. All these features facilitate changes in the model, which are accomplished in a consistent and automatic way.

4.3 The role of project management in sustainable engineering

With so many requirements to be fulfilled by green projects, the role of project management has to be stressed, since the project team also have to meet the planned cost, conclude it on schedule and guarantee the quality requisites in order to be considered economically viable. One of the main complaints of owners is that green buildings normally lead to cost overruns and schedule delays. Figure 1 illustrates the main aspects discussed in this work, showing the main categories of projects (building; energy, in which oil and gas projects are included; and infrastructure) and the role of the best practices of project management to ensure that green projects will not only achieve the goals of sustainability but also guarantee their compliance with cost, schedule and quality requirements agreed with the owner and other stakeholders.

The additional sustainable requirements make projects even more challenging than traditionally they are, and only benchmarking practices of project management can assure green projects will be supported, sponsored by owners and therefore will have the chances of success of the project maximized. Once the various constraints are incorporated in the preliminary design, such as the ones mentioned in items 4.1 and 4.2, in both proposal (not only on the lifecycle energy assessment), the model can be implemented in a BIM system, for example, and used as an optimization tool in order to find the most suitable conditions allied with cost, schedule, quality assurance and sustainable indicators.

The choice for one of the proposals presented above and the respective research development is part of first author’s Ph.D. program, and further findings will be partially published later on.
5 CONCLUSION

Although the recent fall in oil prices, many oil and gas projects around the world are expected to advance to the next phases. Regarding Brazil and Canada, oil and gas specialists and corporations are growing expectations due to the potential contribution of their national oil outcomes to maintain the global oil demand in the near future. In fact, even with the claims to reduce the fossil fuel dependency and with the restrictions that can arise with international agreements at the end of 2015, the oil and gas sector will still have an important role to guarantee the global energy offer for a long period.

In this sense and despite the recognizable performance of the sector, the oil and gas industry has to go further and adopt new concepts such as the green philosophy that is more mature in the building industry, for industry and buildings are responsible for equally energy emissions and energy use. Two proposals on how to address the sustainability of oil and gas projects were presented. They will be deeply analysed on a Ph.D program and published later on. The first is an attempt to develop a universal green rating system for the oil and gas industry. The framework proposed by Poveda (2014) will be considered as an initial point. The second is the use of BIM to assess the initial embodied energy and respective carbon footprint of oil and gas projects. The latter is more closely related to climate change due to the carbon emission goals that may likely arise soon, whereas the former deals with all dimensions of sustainability more broadly. In both proposals, the role of the best practices of project management has to be underlined, for green projects still have to comply with cost, schedule and quality requirements in order to be considered viable.

Finally, the challenges of the oil and gas sector are not few, since the industry has to confront the common sense that the exploration and production of oil and gas cannot occur without reducing environmental impacts and therefore without complying with the best practices of sustainability. However,
based on notable actions, the sector has demonstrated to be open to new changes; willing and aligned with the society to evolve to achieve benchmarking results in sustainability, thereby contributing with the global efforts to guarantee the climate stabilization and the sustainable development.

DESIGN AND VALIDATION OF THE FIRST PHASE OF THE NEW CHRONOGRAPHICAL STANDARD PROTOCOL FOR CONSTRUCTION PROJECT SCHEDULING

Fabian A. Ardila¹ and Adel Francis², ³

¹Department of Construction Engineering, École de technologie supérieure (Éts), Canada
²Department of Construction Engineering, École de technologie supérieure (Éts), Canada

Abstract: Graphical modeling is considered to be a suitable approach for displaying project data because of its ability to communicate information clearly and effectively through graphic means such as shapes, connectors, colours and textures. However, current methods and software do not propose a standard protocol for the graphical representation of the scheduling. Little research has been undertaken in this area and therefore, it has been up to the individual planner to set his or her own standard. We have developed the first phase of a new standard protocol for construction project scheduling compatible with Chronographical Modeling. This first phase consists of the development and validation of a graphic convention including textures and colours. The present paper discusses the validation phase of this convention. Its main objective is to validate a range of textures that represent the construction activities. This validation was performed through a case study with the participation of 15 planners, as well as graduate and undergraduate students. It consists of several tests including the application of the various textures of the proposed convention to a building scheduling. The results of the case study were used to assess the suitability of the protocol and its visual clarity while simultaneously seeking to diminish the mental effort necessary for finding information. Future phases are designed to integrate other graphic elements to the protocol, such as shapes, symbols and codes.

1 INTRODUCTION

Graphical modeling is considered to be a suitable approach for displaying project data because of its ability to communicate information clearly and effectively (Tory and Moller, 2004). However, little research has been undertaken within the domain of construction project planning to develop new approaches for the graphical modeling of non-linear project schedules. Indeed, Gantt charts combined with the precedence logic still dominate among visualization techniques, despite the fact that finding and monitoring information on the schedule can be difficult (Russell and Udaipurwala, 2002). In addition, current methods and planning software do not offer a graphic standard for schedule representation. Chronographical Modeling (Francis, 2004; 2013) addresses this issue with one of the specific goals being to propose a standard protocol for graphical representation of construction project planning.

The first phase of this protocol involves the development and validation of a graphic convention of textures and colours representing construction activities, resources and locations which was then validated through a case study with the participation of 15 professionals, graduate and undergraduate
students from within the construction industry. The study included several tests and the application of the texture convention to a construction project schedule. The results allowed us to evaluate the intuitiveness, the suitability and the visual clarity of this convention. They also demonstrate that using of textures on a schedule aids with the data search process.

2 RESEARCH MOTIVATION

Effective communication of information depends in large part upon the way that data is graphically represented and how we perceive and interpret this information. According to Encarnacao et al. (1994), the development of new visualization systems must take into account the following three approaches:

- Technology-driven: what can be done with current technology;
- Perception-driven: what makes sense considering the constraints on human visual;
- Task-driven: what the user wants.

Considerable effort has been put forth towards the Technology-driven approach, where advancements in terms of information technology are remarkable. However, little attention has been given to the Perception-driven and Task-driven approaches. Tory and Moller (2004) argue that it is necessary to think about how we analyze and interact with graphic variables and how it can affect the information visualization. Indeed, the brain is able to perceive multiple graphic elements simultaneously, but it cannot process them in parallel. Our vision focuses on small areas of the visual field and watches one element after another in an unintended sequence named "Attention" (Rodrigues et al., 2008). Ware (2013) divides the Attention process into three sub-processes:

- The Pre-Attention Process: quick parallel process where one chooses the graphic elements to be analysed;
- Visual Perception: slow series of processes where one analyses the graphic properties of the visual element comparing correspondence, differentiation, relationships, understanding and meaning;
- Interpretation: process in which one interprets the analysed information and obtain results.

Rodrigues et al. (2008) assure that the design of visualization systems should seek to maximize the impact on the pre-attentive process. According to these authors, textures and colours are among the graphic elements that encourage this. Bertin (1977) places texture third, right after colour, in terms of its effectiveness in the encoding of nominal information. Because of their separation properties, these graphic elements are extremely useful for encoding such information.

Several areas have implemented graphic standards including colours and textures. For example, a standard manual of traffic signals was already in place in the infrastructure sector in 1935 (Hawkins, 1992). The geotechnical sector uses abbreviations, textures and colours to represent soil types according to ASTM D2487-11. Urban planning, somewhat related to the construction industry, has used a standard convention of colours for the classification of land use since 1965 (APA, 2013). However, current methods and existing planning software do not offer any standard for schedules. Chronographical Modelling (Francis, 2004; 2013) addresses this issue, with one of its goals being to propose a standard protocol for the graphical representation of construction project planning.

3 RELATED LITERATURE

3.1 Using textures

Textures can be very effective for encoding information in construction schedules (Carrier-Fraser, Francis and McGuffin, 2013) since they favor data interpretation by association allowing for a search in parallel. Thus, the interpretation and learning processes are more easily carried out. However, their use has some limitations and must follow certain guidelines in order to facilitate the pre-attentive process.
Tufte (2001) and Wilkins et al. (1984) argue that streaked textures have very strong terminations and contrasts. This can cause visual discomfort and symptoms from simple fatigue to headaches. According to Healey (1999), a combined use of graphic variables such as colour and texture may not favor the pre-attentive process causing a move from a search in parallel to a search in series. Moreover, if the background brightness resembles the texture, the texture visualization will require more time and visual memory and thus be more difficult to interpret. According to Carrier-Fraser, Francis and McGuffin (2013), in order to stay within the pre-attentive process limits and ensure that the data search will be performed in parallel; the information represented by textures must be independent from that shown by colours. This facilitates the search for only one data type, but not both.

The American National Standards Institute (ANSI) and the International Organization for Standardization (ISO) proposed standards for the use of textures. The BSI standards BS 8888 (2002) and BS 308-1 (1993) compile a set of guidelines for the use of hatching. Suggestions of hatching applicable to construction can be found in the standards BS 1192-3 (1987), BS 5930 (1999) and BS 8541-2 (2011). The National Institute of Building Science (NIBS) in collaboration with the American Institute of Architects (AIA) developed the US National CAD Standard or NCS (NIBS, 2005). This document compiles hatching, objects and symbols commonly used in Computer Aided Design.

3.2 Graphical modeling in construction projects planning

Graphical modeling is not widespread in construction project planning. Tory et al. (2013) present a visual comparison tool for construction schedules. Their research addresses three main components: the graphical representation of constraint types (Echeverry, Ibbs and Kim, 1991; Koo, Fischer and Kunz, 2007), the interactive representation of precedence networks, and the comparison of different planning alternatives. Stott et al. (2005) were inspired by a subway system, representing the project planning using lines, colours and shapes. Aigner et al. (2005) propose a graphics system called Planning Lines to represent uncertainty in the time attributes of activities. This system also incorporates the concept of probability in time representing two values: the minimum and the maximum duration.

The modeling approach of the Chronographic Method (Francis, 2013) studies the graphical representation of the project in the spatial dimension (Francis, 2004; Francis and Miresco, 2011). This approach proposes classifying all the elements that make up a building project into five entities (Table 1). Chronographical Modeling analyzes the visual interface, the graphic elements and the parameters associated with these elements. The goal is to establish a standard protocol for the graphical representation of construction project planning. Textures and colours are examples of graphic elements used by this protocol. Carrier-Fraser, Francis and McGuffin (2013) propose guidelines for the use of these graphics in modeling the physical entity. According to these authors, activities can be represented by textures, and colours can be linked to resources and locations.

4 PRESENTATION AND VALIDATION OF THE TEXTURE CONVENTION

4.1 Presentation of the texture convention

According to Chronographical Modeling (Francis, 2013), activities can be represented by textures. Our texture convention aims to facilitate finding, interpreting and memorizing information on a construction schedule. The following approaches were taken into account in the development of this convention:

- Prioritizing the use of standard graphics.
- Using a minimum of graphic elements through a generic convention that adaptable to the needs of construction industry and to individual users.

The texture convention includes two levels or layers in order to accommodate the demands of building projects. The base level of this convention represents construction divisions or summary activities. Several types of graphic elements were used to elaborate the textures on this level: hatching, objects, symbols, lines, shapes, and in some cases text. Most of these are standard elements (hatching, objects and symbols) that are listed in the US National CAD Standard (NIBS, 2005) and commonly used for the graphical representation of information in construction. In addition, the texture convention has been structured according to the divisions proposed by the MasterFormat Classification System (CSI, 2012). Furthermore, the US National CAD Standard (NCS) also uses MasterFormat as reference for classifying the information.

The second level of this convention uses shapes and lines to represent building elements. These elements have a generic denomination which allows users to customize their application in order to adapt to the needs of each activity and each project. Figure 1A shows a 3D view of the convention levels and the information represented. Figure 1B is the result of the superposition of these levels within the same work plane.

![Figure 1: 3D and plan views of the texture convention levels](image)

4.2 Validation of the texture convention

We conducted a case study to validate our concepts and evaluate the achievement of our goals. The design and realization of this case study followed the steps recommended by Lam et al. (2012). These steps correspond to: i) setting a goal; ii) picking suitable scenarios; iii) considering applicable approaches; iv) creating evaluation design and planned analyses. Lam et al. (2012) also identified seven evaluation scenarios according to the methods commonly used in evaluation of information visualization, as follows:

- EWP: Evaluating environments and work practices;
- VDAR: Evaluating visual data analysis and reasoning;
• CTV: Evaluating communication through visualization;
• CDA: Evaluating collaborative data analysis;
• UP: Evaluating user performance;
• UE: Evaluating user experience;
• AEV: Automated evaluation of visualizations.

Our case study has two parts: in the first part, we evaluate the visual data analysis and reasoning (VDAR) in order to assess the suitability of the texture convention and its visual clarity. In the second part, we evaluate communication through visualization (CTV) with the intention of validating if the texture convention helps to diminish the mental effort necessary for finding information on the construction schedule of a building.

4.2.1 Evaluating visual data analysis and reasoning

This part of the case study evaluates the suitability of the texture convention and its visual clarity. It was conducted using a questionnaire consisting of eight questions. The first four questions tested the intuitiveness and simplicity of this convention. First, we asked participants to intuitively associate the meanings of the graphic elements presented in each question. The purpose of this exercise was to assess whether our texture convention could be understood intuitively and without any prior explanation. After each question, we presented the answer. Then we asked the participants to repeat the exercise again in order to evaluate the ease of memorization of this convention.

Table 2 shows the success rate for questions 1 to 4. According to this table, more than half of the participants were able to intuitively identify the meaning of textures using hatching. Nearly 90% of the participants succeeded in memorising the meaning of these textures after knowing the answer. In the case of textures using objects and symbols, the results were lower compared with those of textures using hatching. While most of the objects and symbols used are listed in the NCS and are commonly associated with the proposed divisions, this result may be influenced by other factors such as occupation, specialty and overall experience of the participants. However, despite the results in terms of intuitiveness for this part of the texture convention, almost 70% of the participants were able to remember the meaning of textures after knowing the answer.

Figure 3 shows the second level of this convention where shapes are used to represent the construction elements. Dotted lines are used to indicate a pre-construction stage; for example, the preparation and approval of workshop drawings. The straight lines indicate that the element is in construction. These elements have a generic denomination which allows users to customize their application in order to adapt to the needs of each activity and each project.

4.2.2 Evaluating communication through visualization

In this part of the case study, we applied the texture convention to the construction schedule of a building. This schedule presented the planning of the design and procurement stages, the construction of foundation, structure, finishes, facility systems and site works. Then participants in the study responded to 16 open questions regarding information that could be obtained from the prepared schedule.

The schedule was presented as a Gantt chart and was available to participants in PDF format in order to avoid influencing their performance through the use of an unfamiliar method or planning software. Participants could graphically interact with the schedule by performing simple actions, such as zooming in and out, and moving throughout schedule. Some information, such as names and durations of activities, was removed in order to ensure the use of the texture convention to obtain the requested information. To answer the questionnaire, participants had no prior training and had to use only the knowledge gained in responding to the questionnaire used in the previous section of case study (VDAR) as outlined above. They could work individually or in teams consisting of a maximum of three people.

Table 4 presents the questions asked about the schedule using the texture convention and summarizes the results. Three people worked individually and twelve people worked in teams: i) two teams of three; and ii) three teams of two. Despite the fact that participants had to use only the knowledge acquired during the first part of the case study, almost 70% of the questions were resolved correctly. If we also consider the questions that had an approximate answer, the success rate reaches 84%.

We also analyzed the impact of the use of teams on the results (Figure 4). The number of people per team does not appear to have had a significant impact in relation to the performance of the group. However, people working as a team were able to establish group discussions which positively influenced the accuracy of their responses compared with those who did so individually.

The first phase of the new protocol for the graphical representation of construction project planning includes the development and validation of a texture and colour convention. The texture convention uses different graphic elements such as hatching, objects, symbols, lines and text to represent major construction divisions. This convention provides a second level of information through a convention of shapes and lines. Test results show the intuitiveness of this convention, with particular regard to textures using hatching. These tests also indicate that experts have a fairly positive perception in relation to the meaning and graphic quality of the textures and graphic elements used. These experts had the opportunity to propose suggestions for improvement which have helped to refine the initial concept.

We also tested the texture convention in relation to the ease of finding information on a construction schedule where the activity names have been removed. Note that the participants had no prior training and no documentation was permitted. The results show that nearly 70% of the questions were resolved correctly. The success rate reaches 84% if we also consider the questions that had an approximate answer.

The results have therefore validated both levels of this convention: the textures that represent major divisions and the convention representing construction elements. This demonstrates clearly that the use of textures and shapes helps simplify the information search process on a schedule. Future developments are planned with other graphic elements as well as a wider consultation regarding the validation and application of the texture convention on other types of projects.

Abstract: Recycled glass cullets in asphalt shingles may be utilized as a cool roof strategy to reduce the harmful effects of Urban Heat Island (UHI). A Three-Dimensional (3D) transient Finite Element (FE) model was developed and validated to quantify energy savings provided by the proposed recycling process under various climatic conditions. Simulations were carried out for three cities located in three climate regions in the United States representing different climatic conditions. The three cities representing each region were Kansas City (Missouri) for Zone 3, Charlotte (North Carolina) for Zone 4, and Miami (Florida) for Zone 5. Results for each of the climatic zones were quantified. Results showed that the annual energy savings ranged from $35.37 in cold climatic regions to $92.58 in hot climates.

1 INTRODUCTION

Building sector in most countries represent about one third of the total energy consumption. It is projected that the building’s energy demand will be increased 110–150% by 2050 and 160–220% until 2095 from its 2005 level. Several factors including design and building characteristics, occupants, and people who work and live in buildings can significantly contribute to the success of energy efficiency measures. HVAC systems account for the largest amount of energy consumption in both commercial and residential buildings. As a consequence, the thermal barrier (or building envelope) that controls the heat flow of building is responsible for up to 40% of residential energy use and 55% of commercial energy use. In addition, cooling load in residential building shows an increasing trend worldwide and is one of the main concerns not only for countries that are characterized by hot climatic conditions but also for cities suffering from the heat island effect. The lower albedo of urban surfaces and the replacement of vegetation by building structures are considered as contributing factors to the heat island effect. Due to this effect, the ambient temperature in urban areas is usually several degrees higher (e.g. 1°C−6°C) than that of their surrounding suburban and rural areas. Increased ambient temperatures result in thermal discomfort and increase cooling energy consumption, energy demand, and energy prices (Hassid 2000; Santamouris 2007). In recent years several experimental studies have been conducted to investigate the energy saving effects of urban heat island mitigation measures such as high albedo coatings and urban greening (Akbari 2005; Akbari 2001; Sailor 2007; Taha 1988). In parallel, important simulation studies have been carried out to identify the heat island mitigation potential of cool roofs (M. Jacobson 2012; S. Menon 2010; Savio 2006). These studies found that the precise energy benefits depend on the local climate and more significantly on the specific building characteristics.
Intensive research has been carried out on the heat island effect and cool roofs, the impact and the significance, as well as its qualitative and quantitative characteristics. Recent studies found that there is a relationship between building energy consumption and heat island effect (Hassan 2013; Hassid 2000; Yukihiro 2006). Noteworthy among these publications are the works of Akbari et al. (Akbari 2001) who found that changing the roof albedo of a residence in Sacramento, California from 0.18 to 0.73 results in energy savings of approximately 2.2 kWh/day. It was also found that increasing the urban albedo by about 20% reduces cooling load between 2.9% and 21% for Toronto and 62% for Sacramento (Akbari 1992; Taha 1994) which indicates that energy benefits differ largely as a function of the climatic conditions and the characteristics of the building. In another study conducted by Synnefa et al., several types of cool materials have been identified and tested to assess their performance in reducing heat island effect in Athens, Greece. They studied the optical and thermal properties of the selected materials and results revealed that these materials can be classified as “cool” with the ability to maintain lower surface temperatures. They defined and studied two scenarios of modified albedo including a moderate and an extreme increase in albedo scenario. The results indicated that large-scale increases in albedo could reduce ambient air temperatures by 2°C (Synnefa 2008). Within this context, Akbari and Konopacki (Akbari 2004) carried out a field study to predict the energy-saving potential of several UHI mitigation measures in Toronto. Their results indicated that the level of savings in energy varies depending on the mitigation measures and building types. However, that study did not consider the temperature distribution in the urban area.

This study investigates the application of recycling of broken and waste glass cullet in the production of asphalt shingles in order to reduce energy consumption in residential buildings and to mitigate heat island effects by increasing the solar reflectance index (SRI) of the roof asphalt shingles. To achieve this objective, laboratory characterization of glass cullet was conducted and asphalt shingles prepared with and without glass cullet were tested in the laboratory. In addition, Three-Dimensional (3D) transient Finite Element (FE) model was developed and validated to quantify energy savings provided by the proposed recycling process under various climatic conditions.

2 EXPERIMENTAL PROGRAM

Conventional and recycled-glass modified asphalt roofing shingles were prepared in the laboratory by varying the amount of glass cullet and conventional materials used in asphalt roof shingles, and acceptability was based upon the standard specifications described in ASTM D 3462. A full description of the laboratory experimental study has been presented elsewhere (Kiletico 2014). Three different colors of recycled glass cullet including green and two sources of clear glass were collected from Construction and Demolition (C&D) processing plant to prepare the asphalt shingles. Since the size of the collected glass cullet was large, a high performance mixer was used to reduce particle sizes. The ground glass cullet was then used in lieu of conventional mineral aggregates as surface granules, filler material, and backdust.

The preparation of asphalt shingles in the laboratory consisted of three steps including preparation of the formwork, preparation of the asphalt blends, and aggregate preparation. The dimensions of the prepared asphalt shingles were 76mm x 76mm x 3mm. In the first step, the metal forms containing a fiberglass mat substrate were prepared. In the next step, asphalt binder was poured in the prepared forms. A white pigment powder was used in the fabrication of the asphalt shingles. The powder consisted of 98% pure titanium dioxide (TiO2) and was added at 8% by weight of the top surface granules. To add the TiO2 pigment powder to the surface granules, two grams of powder were mixed with 23 grams of surface granules, saturated with water, and then oven-dried. The filler material was then homogeneously mixed with liquefied asphalt binder for each sample, which was heated to 204°C. After mixing the filler material, 36 grams of asphalt coating mixture was reheated to become liquefied at 230°C. The asphalt coating mixture was then poured in the metal formwork of each shingle and then placed into the oven at 204°C for impregnation of the fiberglass for 1 hour. Then, the samples were removed from the oven and firm pressure was applied on the top surface granules in order to achieve 100% surface coverage. A forced heat gun was used to separate the shingles from working surface. Finally, the backdust particles were applied to the back surface while keeping the underside heated. The new shingles are patented under Provisional Patent 61/952515 “Method for the Manufacturing of Energy Efficient Shingles using TiO2
Coated Recycled Glass Cullets. The color appearance of all the prepared asphalt shingles is shown in Figure 1.

Figure 1. Asphalt shingle with/without glass cullet

2.1 Solar Reflectance Index (SRI)

SRI incorporates both solar reflectance and emittance into a single value and is a measure of the constructed surface’s ability to stay cool in the sun by reflecting solar radiation and emitting thermal radiation. It is defined such that a standard black surface (initial solar reflectance 0.05, initial thermal emittance 0.90) has an initial SRI of 0, and a standard white surface (initial solar reflectance 0.80, initial thermal emittance 0.90) has an initial SRI of 100. Materials with the highest SRI values are the coolest choices for roofing. To calculate the SRI of the prepared asphalt shingles with and without glass cullet, their solar reflectance and thermal emittance were measured in the laboratory. The SRI of the asphalt shingle with and without glass cullet was calculated according to ASTM E 1980. The following formulas were used to calculate the SRI:

\[ SRI = 123.97 - 141.35X + 9.655X^2 \]

\[ X = \frac{((\alpha - 0.02\varepsilon)(8.797 + h_c))/((9.5205\varepsilon + h_c))} \]

Where \( \alpha \) is the solar absorptance and \( \varepsilon \) represent for the thermal emissivity of the prepared asphalt shingle samples. The calculation was conducted for three convective coefficients \( (hc) \) that correspond to low, medium, and high wind conditions \( (5, 12, \text{and} 30 \text{ W·m}^{-2}·\text{K}^{-1}) \), respectively. Table 1 shows the SRI of some of the available asphalt shingles in the market (EETD 2014).

3 CLIMATE REGIONS IN THE UNITED STATES

In order to estimate the effect of the application of glass cullet asphalt shingle on the residential building energy load, simulations were carried out for three cities located in three climatic regions including Zones 3, 4, and 5 in the United States. US Energy Information Administration (EIA) categorized the climate regions in the United States into 5 main categories based on the last 30-year average heating degree-days (HDD) and cooling degree days (CDD) (EIA 2011; NOAA 2012). A HDD is a measure of how cold a location was over a period of time, relative to a base temperature of 65 °F (18.3 °C). On the other hand, a CDD is a measure of how hot a location was over a period of time, relative to the same base temperature of 65 °F (18.3 °C). Zone 3 is defined as the region with less than 2000 CDD and less than 4000-5499 HDD; Zone 4 is defined as the region with less than 2000 CDD and less than 4000 HDD; Zone 5 is defined as the region with 2000 CDD or more and less than 4000 HDD. Figure 2 shows the 3 main studied climate zones in the United States. Table 3 also provides the latitude and the longitude of the selected cities for this study.

4 FINITE ELEMENT MODEL

ABAQUS 6.13 software was used in this study to develop a three dimensional transient finite (FE) element model. Two FE models were developed to simulate the heat transfer mechanisms and evaluate energy consumption in the house with conventional asphalt shingle and house with glass cullet asphalt shingle in different climate regions in the United States. The developed FE model considered all the heat transfer mechanisms that may occur within the space. It is worth mentioning that many factors affect the calculated temperature distributions and the heat flux in the roof. The inputs to the FE model include the emissivity of asphalt shingle with and without glass cullet, emissivity of insulation, attic flow rate, longitude, latitude, and time zone of the locations. Although the physical model was symmetric, the amount of solar radiation differed from one side of the roof to the other depending on the surface orientation and inclination. Thus, in order to conduct an accurate analysis, the entire configuration of the roof was simulated in the FE model. It is worth mentioning that in order to attain reliable and accurate results; a mesh convergence technique was conducted using different mesh sizes. Final mesh size was selected after considering both computational efficiency and accuracy. To model the conduction heat transfer mechanism in the roof and the ceiling, approximately 49,000 DC3D8 elements were used. Featuring a hexahedron shape with eight nodes, these linear heat transfer elements were used for all the materials except the air. To model the advection, that is, bulk motion of the air in the attic, the convection/diffusion option in ABAQUS was utilized by means of eight-node DCC3D8 elements with forced convection/diffusion capabilities. The total number of aforementioned elements was approximately 73,000. In addition, forced convection inside the roof was simulated by means of the mass heat transfer option in ABAQUS. A full description of the model has been presented elsewhere (Asadi 2012). In addition, hourly climatic data, including ambient air temperature, solar radiation, wind speed, wind
direction, and relative humidity were used in the simulation. The metrological data was obtained from the Typical Meteorological Year 2 (TMY2)(NREL 2014). Figure 3 shows the finite element mesh of the model.

Figure 3. Finite Element Mesh

Figure 4 shows the operation of the conventional and reflective roofs. During daylight hours, a roof is constantly subjected to solar energy striking its surface. A reflective roof with high SRI would have a lower surface temperature as compared to a conventional roof. In the case of a reflective roof, a lower surface temperature translates into less heat gain into the attic space or living space below the roof, which result in a cooler living space and lower cooling/heating energy consumption.

The building used in the simulation is a single story residential building with a tilted roof with area of 148.6 m2. The attic had two pitched roof sections, two vertical gable-end sections, and one horizontal ceiling frame. The thermostat set point temperature for cooling and heating was set to 26 and 21°C, respectively.

Figure 4. Operation of conventional and reflective roofs
5 RESULTS AND DISCUSSIONS

Model validation was necessary to demonstrate the precision and the viability of the FE model. Therefore, the developed models were validated based on experimental data collected in Zackary, LA. To validate the FE model, a site-located weather station was placed on the roof to measure the actual weather parameters and collected data was used in the model. Figure 5 compares the results based on FE model and experimental data for a typical day in the summer. The results showed that there is a good agreement between experimental data and FE model and error was less than 5%. The obtained results demonstrate that the finite element model could be applied with success even for more detailed situations and with better precision on the results.

![Figure 5. Model validation](image)

In order to investigate the performance of the glass cullet asphalt shingle to reduce building energy consumption, the heat flux were calculated for the control house and the house with asphalt shingle containing glass cullet in different climate regions in the United States. It should be noted that the values mentioned in this part of the study depend on the building characteristics. As expected, increasing the roof SRI resulted in reduced summer cooling loads particularly in hot climate regions. Figure 6 shows the required cooling and heating loads in the house with and without asphalt shingle containing glass cullet. For the building chosen and the climates examined in this study, it was found that the potential savings are greater in hot climate regions such as Miami, FL. It was found that the application of asphalt shingle containing glass cullet in the roof can reduce energy consumption from 7.8 kwh/m² to 6.9 kwh/m² in June in Miami-FL and save approximately $16 in this month. Results showed that increasing the SRI of a roof is clearly more advantageous in hot climate regions where cooling load dominates most of the year. This study provides further evidence that roof asphalt shingles containing glass cullet are effective strategies for urban heat island mitigation. The increased SRI of these roofs effectively reduces their surface temperature and decreases sensible heat flux into the urban atmospheric system.
6 CONCLUSIONS

The present study evaluated the application of waste glass cullet in the production of asphalt shingles in order to reduce energy consumption in residential buildings and to mitigate heat island effects by increasing the SRI of the roof asphalt shingles. Laboratory tests were conducted to determine the solar reflectance and thermal emittance of the prepared asphalt shingle samples with and without glass cullet. Based on the laboratory results, it is concluded that glass cullet can be successfully blended with conventional materials to produce a sustainable asphalt shingle that has a solar reflectance of that is significantly greater than conventional asphalt shingles. Results show that a typical black ceramic coated asphalt shingle has SRI of 0. In order to achieve cool roof attributes, the addition of a white pigment mixed together with the top surface granules increased the SRI to 30 for clear glass.

A FE model was developed to calculate and quantify the energy consumption reduction in the house with and without glass cullet. The developed model was successfully validated with measured experimental data collected in Zachary, LA. Annual models were run for three cities in five climate regions in the United States. For the building studied and the climates considered in the simulation, it was found that the potential savings are greater in hot climate regions such as Miami, FL. Results indicated that the application of asphalt shingle containing glass cullet in the roof can reduce energy consumption from 7.8 kwh/m2 to 6.9 kwh/m2 in June in Miami-FL and save approximately $16. Results showed that increasing the SRI of a roof is characteristically more advantageous in hot climate regions where cooling load dominates most of the year. This study provides evidence that roofs covered with asphalt shingles containing glass cullet are effective strategies for urban heat island mitigation. The increased SRI of these roofs effectively reduces their surface temperature and decreases sensible flux into the urban atmospheric system.

TEACHING ENGINEERING LITERACY TO NON-ENGINEERING STUDENTS IN FORMAL LEARNING ENVIRONMENTS

Mounir El Asmar¹, Abbas Chokor¹ and David Grau¹, ²
¹ School of Sustainable Engineering and the Built Environment, Arizona State University, USA
² david.grau@asu.edu

Abstract: Since enrollment rates in American college engineering programs have been constantly dropping, formal and informal processes to teach and learn engineering are on the rise. An opportunity actually exists to formally teach engineering to construction students in US colleges and universities. If non-engineers understand how science and technology work, they can better interact with scientists and engineers in the workforce and make informed decisions about when technology can be a solution to a problem, or when other solutions maybe more adequate. To this date, higher engineering education has been repeatedly investigated through the lenses of engineering programs and degrees. This paper investigates engineering literacy for non-engineering students, by comparing the performance of engineering and non-engineering students when gaining engineering literacy. The methodology of this study consists of analyzing the performance of construction management (CON) and civil and environmental engineering (CEE) students in comparable courses taught in both programs: introduction to geotechnical engineering and geotechnical applications. Data is collected over four distinct semesters. The results reveal that CON students scored significantly higher grades when the course was offered from a non-engineering perspective rather than from an engineering perspective. The results of the study highlight the need to develop clear and consistent teaching methods and techniques that take non-engineering students’ diverse backgrounds into consideration.

1 MOTIVATION

Over the last decade, enrollment rates in American college engineering programs have been dropping constantly. The U.S. ranks well behind other countries in the percent of students earning their first university degree in engineering or science. In the U.S., 15% of undergraduates receive degrees in natural science or engineering compared to 38, 47, 50 and 67% in South Korea, France, China, and Singapore, respectively (AIAA 2003). Given that technological innovation is a key ingredient to economic growth and high paying jobs, the U.S. is in critical need of more engineers, especially with the acceleration of engineers’ production in countries such as China (NSF 2010). Because the U.S. is losing its competitive advantage in science and technology, leading business organizations set a goal of doubling the number of bachelor’s degrees in science, technology, engineering and mathematics (Business Roundtable 2005).

Engineering affects all disciplines in many ways. Since many managers, directors, and policymakers are making decisions related to key technology-based issues, it makes sense to provide them with a conceptual framework of technology (Mina 2007). Because the decisions that engineers make regarding infrastructure and consumer products involve almost everybody, even students enrolled in non-engineering curricula can benefit from examining engineering issues (Dyrud 2001).
world, engineering teams frequently comprise key individuals with non-engineering Science, Technology, Engineering, and Math (STEM) backgrounds. While not yet common, some engineering departments offer service courses for non-engineers (Krupczak and Ollis 2006). Examples of such science and technology programs that require engineering literacy include programs in computer technology, informatics, construction, environmental and biomedical sciences, aeronautical, industrial, architecture or graphic design. These science and technology programs, and many others, require students to learn engineering and design principles. The National Academy of Engineering is advocating that all Americans need to better understand all types of technology, not just computers and information technology (Pearson and Young 2002). A survey of the literature shows a positive perception towards engineering content (Krupczak et al. 2005). Scholars addressed the success of several programs and courses across the U.S. in attracting non-engineering students to engineering fields (Nahapetian 2011). These programs provided technological awareness and an understanding of technical issues to non-engineering students to develop basic literacy in engineering. Mina (2007) summarized the main incentives behind students enrolling in engineering courses: (a) to better understand the role of engineering in society and the interactions of engineering with their major field of study; (b) perform simple calculations and estimations using engineering methods; (c) make cost-benefit and risk-benefit analyses; (d) appreciate the importance of the underlying assumptions used to produce the cost-benefit and risk-benefit analyses presented by engineers; (e) make informed decisions about the desirability of engineering activities by weighing the benefits of those activities against their environmental risks; (f) understand the interdependence of the economic, environmental, and sociological aspects of technological change; (g) assess the validity and possible weaknesses in predictions of economic, environmental, and sociological consequences of technological change presented by others; (h) attain a basic understanding of the engineering design process; (i) achieve a survey-level understanding of why particular materials and processes are used to produce simple engineering devices and systems; and (j) understand the capabilities and limitations of basic manufacturing processes and engineering systems.

The inclusion of non-engineers on an engineering service learning project can significantly alter the manner in which the participants view the impacts of an engineering project. In general, engineers tend to seek quantitative solutions to a given problem, while non-engineers, particularly those who are from the liberal arts, will seek more qualitative solutions, most often addressing the impacts of the proposed engineering solutions (Polito 2005). However, the non-engineering students need specially-developed courses that take their backgrounds and skills into account. Developing and teaching non-engineering courses requires a different approach from the traditional way courses are taught to engineering students (Sadiku and Yantorno 1997). If non-engineers understand how science and technology work, they can better interact with scientists and engineers in the workforce and make informed decisions about when technology can be a solution to a problem, and when other solutions may be better. It is important that non-engineers understand enough about science and engineering so that they can apply technology where it is most useful to society (Nickels and Giolma 2000). Hence, it is the responsibility of engineering faculty to develop such courses with the intended audience and desired course outcomes in mind (Mahajan et al. 1996).

So far, the challenges associated with providing a solid engineering professional development framework for non-engineering degree seekers have not yet been tackled. To this date, higher engineering education has been repeatedly investigated through the lenses of engineering programs and degrees. However, creating an inclusive environment so that the significant mass of students in multiple technology and science programs can effectively learn core design and engineering principles has yet to be tackled. This paper aims to act as a first building block by comparing the performance of engineering and non-engineering students when gaining comparable engineering literacy.

2 RESEARCH METHODOLOGY

A statistical analysis on student performance on two parallel undergraduate courses in introduction to geotechnical engineering applications serves to compare the performance of engineering and construction management students. Indeed, two separate classes, with common learning and performance outcomes, are taught each semester for both engineering (civil engineering) and non-engineering (construction management) students by two instructors with PhD degrees in civil engineering
and with similar backgrounds. Students who successfully complete both courses have a broad understanding of soil mechanics principles related to construction. Some of the topics discussed include: rocks/geology/soil formations, deep foundations, soil classification, USCS & AASHTO, site investigations for construction, soils reports, consolidation, settlement, compaction, stresses in soils, surface loading, shear stress and Mohr’s circle, lateral soil loads, retaining walls, overturning, bearing capacity, and shallow foundations. Moreover, the performance of students in the two classes will be assessed similarly. The grade will consist of homework assignments on the various topics, a project paper, and three exams.

The methodology of this study consists of collecting anonymous performance scores of construction management (CON) and civil and environmental engineering (CEE) students enrolled in the course over four distinct semesters. For each class, the anonymous data was provided by the Academic Advising office, which keeps grade records for all classes. First, the paper compares student characteristics. Second, the paper compares the performance of CON and CEE students and tests the statistical significance of the results using an unpaired t-test with unequal variances. The tested hypothesis is that the average grade of CON students \( x \) is equal to that of CEE students \( y \). This assumption is tested, at a 95% confidence level, for the null hypothesis \( H_0 \) or its alternative \( H_1 \) as follows:

- \( H_0: x = y \) if p-value is greater than 0.05; the null hypothesis is engineering and non-engineering student performance is similar;
- \( H_1: x \neq y \) if p-value is less than 0.05; then we have evidence to reject the null hypothesis.

Third, the paper examines the factors that could affect student performance in different semesters and tests the statistical significance of the differences using ANOVA tests. The paper ends with a discussion of the results and raises several critical engineering education questions for future studies.

### 3 RESULTS AND DISCUSSION

This section presents the results of the comparison between engineering and non-engineering students enrolled in the geotechnical course, and leads to a discussion of the potential parameters that could explain the differences in performance between both groups of students. Of the 381 students, 255 are engineering students and 126 are non-engineering students (see Table 1). Figure 1 illustrates comparable percentages for CEE and CON students in the four studied semesters.

</tbody>
</table>

Next, Figure 2 shows a difference in female and male student percentages between the CEE and CON students. While only 10% of CON students are females, this percentage is three times higher for CEE students. The number of women studying engineering and technology is quite low relative to other previously male-dominated professions such as law and medicine. The low percentage of women in CON in this current study is comparable to national percentages.
For example, the percentages of electrical and mechanical engineering degrees awarded to women in 2009 were also very low, sitting at just 11.5% and 11.4%, respectively (American Society for Engineering Education 2010).

Figure 2: CEE and CON students’ female/male distribution

Figure 3 provides a graphical illustration of the differences in grades between CEE and CON students, in the form of boxplots. CON students seem to score slightly higher grades, and the statistical testing of the results confirms this difference in performance. The top of Table 2 shows the t-test p-value is smaller than 0.05, which leads to rejecting the null hypothesis. Therefore, the observed differences in performance are statistically significant.
For a better understanding of the parameters that might affect the performance of CEE and CON students in the studied course, a closer examination of the grades for each semester is needed. After conducting ANOVA tests on the data and checking the significance of the differences, the results are illustrated in Figure 4 below. Except for one semester, CEE and CON student performance was similar. One of the reasons that explain the difference in CON students’ performance between semesters 1, 2, 3, on one hand, and semester 4 on the other hand, is the manner in which the course was taught. Table 3 summarizes the covered topics when the course is offered from: (i) an engineering perspective (semesters 1, 2, 3) by focusing deeply on quantitative engineering and design principles; and (ii) from a non-engineering perspective that offers a broad understanding of engineering principles with an emphasis on the practical and contractual points of view (semester 4). CON students performed much better when the course was offered from a non-engineering perspective, which catered to the students’ diverse and often non-quantitative backgrounds. While the difference in teaching methods justifies the variance in the results, other interrelated factors also may have major impacts on the performance of non-engineering students in engineering courses, including: student background, instructor background and experience, program pre-requisites, interactive teaching tools and support. The results of this study lay the foundation for a future study to explore the combination of reasons behind this noticeable variation.

This study also raises several questions: (1) What teaching methods and techniques are appropriate for ensuring non-engineering students gain adequate engineering literacy? (2) How can we ensure engineering instructors are best prepared to teach engineering courses to non-engineering students? (3) What are the key learning barriers for non-engineering students to become engineering literate? Additional research is needed to answer these critical engineering education questions.

Figure 4: CEE vs. CON students’ grades per semester
4 CONCLUSIONS

If non-engineers have a good understanding of science and engineering concepts, they can better interact with scientists and engineers in the workforce and make informed decisions when it comes to engineering solutions. This paper compared the performance of engineering and non-engineering students in the introduction to geotechnical engineering and geotechnical applications course over four semesters. A deep examination reveals a significant variation in non-engineering students’ grades depending on the way the course was taught. Non-engineering students performed better when the course was offered from a non-engineering perspective, catering to students’ diverse backgrounds, rather than focusing on a quantitative engineering perspective. The results of this study highlight the need to develop clear and consistent teaching methods and techniques to ensure non-engineering students gain adequate engineering literacy. Although this paper highlights the effect of an important factor on the performance of non-engineering students in engineering courses, this preliminary study has limitations that need to be addressed in a larger research effort focusing on the topic: the sample size used in this study is limited to 381 students; the study investigates student performance in two specific courses and within one university; and the paper studies one specific factor out of several that can impact student performance. The preliminary findings of this study are currently being strengthened improved by investigating a larger sample of students and courses, and also considering including additional factors that affect the performance of non-engineering students in engineering courses.

Abstract: Implementation of sustainability rating systems for buildings had a recognized effect on the increased level of sustainability adoption in the construction industry. However, there is still a need for objective quantifiable evidence that the concepts adopted by the sustainability rating systems and implemented in projects lead to optimum positive impacts on resource consumption and the environment. The objective of this paper is to present research conducted to assess the actual environmental impact saved by implementing credits of both LEED (Leadership in Environmental and Energy Design) and QSAS (Qatar Sustainability Assessment System) using Life Cycle Analysis (LCA) approach. The impact of implementing LEED and QSAS credits under the categories of energy, water and urban connectivity on a selected project in Qatar was analyzed using LCA. The results of this analysis manifest the objective quantifiable benefits behind applying the respective sustainability credits and how the impact of an international rating system differs from that of a system developed for the specific region where the project is located. The relative weights allocated to these credits were also analyzed in light of the corresponding LCA results in order to evaluate the significance of such weights and how they can be reconsidered to achieve optimum reduction of impacts.

1 INTRODUCTION

The construction industry is distinguished, among other industries, by the large number of materials, processes and technologies that are incorporated within its activities. Warnock (2007) explained that the complexity of building construction is demonstrated by the various physical components used in projects, which significantly increases resource consumption and highly impacts the environment. The United Nations Environmental Program (2002) revealed that this industry consumes 40% of Europe’s energy in addition to its large contribution to the emission of greenhouse gases in the United States. Also, it is estimated that one-third of energy end-use is consumed for heating, cooling, lighting, appliances and general services in buildings whether residential, commercial or public (Ardenta 2008). Therefore, due to the referred incontestable significant impacts, achieving sustainability in construction projects has been the target for various initiatives, among which is development of sustainability rating systems.
Rating systems are used to evaluate construction projects through set of categories where each category encompasses a number of measurable targets that are evaluated under relevant credits. The objective of adopting these systems is to improve the performance of construction projects from sustainability perspective by appreciation of reducing resource consumption or harmful emission. Various rating systems have been developed in the last two decades in different countries. The use of some of these systems has gone beyond the boundaries of the countries where they were developed and are being applied internationally. Leadership Engineering and Environmental Design (LEED), for instance, was developed by the US Green Building Council (USGBC) and is currently implemented in many developed and developing countries (Kyrkou and Karthaus 2011). Building Research Establishment Environmental Assessment Method (BREEAM) has a long track record as the main rating system in UK (Fowler and Rouch 2006). In Australia, Green Star is implemented to assess environmental performance of construction projects (Lockwood 2006). Comprehensive Assessment System for Building Environmental Efficiency (CASEBEE) is the widely established as sustainability evaluation system used in Japan, (Reed et al. 2009).

2 BACKGROUND

The declaration of Qatar 2030 visionary plan endorsing environmental development as one of the four main pillars of Qatar’s National Vision (GSDP 2008) has led to various nation-wide initiatives and efforts to adopt sustainability in construction activities. One of these initiatives is the development of Qatar Sustainability Assessment System (QSAS) by the Gulf Organization for Research and Development (GORD) forming a tool to benchmark construction projects with respect to their environmental performance. However, similar to other rating systems being implemented all over the world, the current practices being adopted and supported by these rating systems do not provide sufficient quantifiable evidence that they lead to optimum saving to the environment. Rather, they have evolved from a consensus-based understanding of environmental issues. This understanding, in some cases, has been based on conventional environmental wisdom that does not always stand up to objective analysis (Trusty 2003).

One of the most powerful tools to address this issue is Life Cycle Analysis (LCA), which is a methodology used to analyze the “Cradle to Grave” impact of using a specific product or process on the environment. According to ISO standard 14040 issued by the International Standards Organizations (ISO 2006), the analysis takes into consideration the impact of all processes involved in the life cycle of such materials on the environment starting from extraction, through manufacturing, transportation, installation, operation till disposal. The Objective of this paper is to present utilization LCA as an objective assessment tool to hold a comparative evaluation between internationally recognized and locally developed rating systems with regard to their actual positive impact. The following sections of the paper demonstrate the methodology adopted to hold this comparative evaluation, the results of this application on a project in Qatar, comments on the results obtained leading to conclusion and finally, future suggested research work.

3 METHODOLOGY

As introduced in the previous sections, this paper presents research carried to utilize LCA to evaluate the efficiency of international versus local rating systems in the state of Qatar. The international rating system selected for this study is LEED and the local one is QSAS. To enable comparative evaluation of the two rating systems, the methodology proposed by Attallah et al. (2013) is implemented on a commercial center at Alshamal City, which is a project currently under construction in Qatar using the comparable credits under the two rating systems. Implementation of the methodology is described under this section and briefly illustrated in Figure 1.
3.1 **Step 1: Selection of comparable credits under LEED & QSAS**

Since the rating systems are developed in different countries and under by different organizations, they tend to be dissimilar in terms of their development of the evaluation procedures and the prioritization of credit, which is reflected in the relative weights assigned to each credit. However, since the most significant elements of the construction projects affecting the environment are basically the same anywhere in the world, we can still claim that similar language can be detected under different rating systems. For example, the water and energy consumption credits are typically of the highest relative weights under any rating systems. This is due to the established consensus among practitioners and experts that water and energy consumption are of high significance due to the processes involved in securing both, which are characterized by high resource consumption and heavy emissions.

The target here is to compare the impact of implementing two different rating systems. Therefore, we have selected the credits under LEED and QSAS that are of comparable nature and identified their relative weights in order to understand the relative contribution and consequently the relative efficiency. Table 1 shows sample of selected comparable credits under the two systems and their relative weights towards certification.

</tr>
</tbody>
</table>
3.2 Step 2: Content analysis of rating system documentation

The second step in the methodology is to analyze the contents of the respective working documents forming the basis of implementing credits and achieving the targeted certifications. The first set of documents is commonly the design guides or manuals created to provide the project participants with various ideas or approaches to improve the building performance in respect to the environmental issues addressed under each credit. These documents typically refer to relevant sections of standards or codes which are used in assessing the savings achieved. In the case of QSAS, design manuals are available for those who procure license from GORD or companies applying for project certification. For LEED, the reference for our research here is the document titles “LEED 2009 for New Construction and Major Renovation”, which is open to public. The later document was used as one single source of reference since it included the information required to carry out the analysis in the case of LEED.

The second set of documents typically refers to how the score for each credit is calculated using the relevant calculation sheets or toolkits. Designers or concerned stakeholder change parameters under each credit to come as close as possible to the reference target figures in the design manuals. The score is typically calculated by comparing the project parameter planned for the project with the set standard or reference. Assessment manuals for QSAS were obtained to complete this task. The third set of documents is the calculation tools, the form of which can be extensively different from one rating system to another as they are very specific to the nature and scope of credits under each system. The calculation tools assist the users or applicants to feed the relevant project input and perform computations for self-evaluation before submission for certification. For QSAS, set of calculation excel sheets and tool kits were obtained along with the design and assessment manuals to complete this task. As explained, the objective of this research step of the presented methodology is to establish a thorough understanding of the adopted sustainability approach, the assessment criteria, and the build-up of scores for each credit.

3.3 Step 3: Defining project parameters for achieving sustainability credits

A very critical step in the adopted methodology, linking the conceptual phase of evaluation with the quantification phase, is to determine the critical project parameters that have to be appropriately addressed and changed in order to reach the target score. Extensive analysis for each credit, which is carried out through exploring the design and assessment manuals, reveals what are the options the designer has in order to achieve the target points. The holistic approach followed under some credits, which leads to unclear intangible parameters, forms the biggest challenge for implementing this methodology on all credits. The parameters identified for each comparable credit under QSAS and LEED are shown in Table 2.

</tr>
</tbody>
</table>

3.4 Step 4: Analysis of project data

Upon identifying the critical parameters for each credit, these parameters are then converted into LCA inventory data in order to quantify the associated LC impacts. To do this, we have selected a project currently under construction in Qatar to apply the concept with actual quantities derived from available drawings, specifications and other project information. The project is targeting 3 stars on the QSAS scale, which is at 50% of the maximum certification. For the comparison purpose, the LEED certification targeted is taken as 55 points corresponding to 50% on of the maximum achievement (silver level). According to this presumption, the obtained project data were explored in order to translate the change in the identified parameter (i.e. saved impact) to inventory. The following two sections provide more details on the inventory analysis and impact calculation steps.

3.5 Step 5: Project inventory assessment

The changed parameters result in saved impact on the environment and/or saved resources. In order to quantify this saved impact, we first calculate the amount of resources saved or emissions reduced due to implementing the considered credit. In some cases, the parameter is itself a quantity that can be traced through the LCA database to calculate the associated saved environmental impact. Water consumption credits in any rating system is an example, where the score is based on the amount of savings in consumed water annually due to the implementation of some strategies and the use of economical fittings or systems that reduce consumption. Nevertheless, in other cases like vegetation credits under the QSAS, the parameter identified is the area planted in relation to the project overall area. In this case, project drawings and specifications are used to identify the type of plants used and calculate the approximate annual saved CO2 due to this planting scheme. Deriving the inventory saved based on the changed parameters is the most critical step in this methodology as it requires careful reading and interpretation of the project technical data. The changed parameters to achieve certain scores can usually be measured from the project drawings. Specifications are usually required to determine the technical features of the identified parameters. Table 3 shows the calculated inventory for some QSAS and LEED credits based on the selected commercial building project.

</tbody>
</table>

3.6 Step 6: Calculation of LCA impact using Simapro

The LCA impact involves lengthy calculations of all processes involved in throughout the whole life cycle of the project components. It is well established among LCA practitioners that while the products under study are used in certain countries, portion of the life cycle impacts could be generated in other countries. For construction products like wall cladding systems, ironmongery, and carpentry, there are usually imported components from industrial countries that are not themselves the origin of the raw materials. This leads to having several locations worldwide where the traceable environmental impact could be recorded. For this reason, the LCA approach has a cross-borders nature, which justifies why an international database can be used for LCA studies even in countries different from the one where data for this database was collected. One of the available LCA databases was targeted to identify the LC impact for each saved inventory. The last step is to perform weighting of the LCA impact in order to reach a single score representing the total impact and to enable comparison of results. Weighting is done here based on the built-in figures in Simapro.

4 RESULTS

We chose the SimaPro software with application of eco-indicator 99 database built-in the software to calculate the impacts. Table 4 in the results section shows an example of the impacts as an outcome of the Simapro software after weighting. The unit Pt used in this table represents the unit adopted in the database of eco-indicator 99, which is a dimensionless unit that reflects the single-score environmental impact after applying weighting as an interpretation technique. The comparison graphs, sample of which is presented in Figure 2 highlight the relative contribution of comparable credits for the certification and as per LCA calculation as well.

</table>

Using results as presented in the sample comparison graph in fig 2, the contribution of each of the QSAS towards certification by 3 stars along with its associated LCA single score can be compared to the contribution of corresponding comparable LEED credits towards silver certification and their associated LCA results. The LCA score for each credit under study was calculated by multiplying the score achieved to target the required certification level (2 for QSAS and 0.5 for LEED) by the assigned weights for each credit. The product was then multiplied by a ratio of 1000 for the purpose of graph presentation (to have the same primary scale). These values are referred to as the certification score in Figure 2. The objective here is to check the performance of comparable credits to reach optimum potential saved impact on the environment under different rating systems, in this case a locally developed versus international one. To illustrate the results presented in Fig. 2, the blue column represent the certification score achieved for each of the subject credits while the blue columns represent the scores recorded through LCA calculations.
5 DISCUSSION & CONCLUSION

Comparison of the E1 (QSAS) and EA1 (LEED) shows consistent trend in terms of the LCA results as opposed to the certification scores. Both contributions to certification and LCA score of E1 are higher than those of its comparable LEED credit EA1. On the other hand, while the LCA score for QSAS E3 credit is higher than the LCA score of its comparable credit EA2 under LEED with a huge difference (more than 6 times), the contribution of E3 towards certification exceeds that of EA2 with much less difference than the one noticed for LCA. Taking into consideration that these two comparable credits are essentially addressing the same environmental issue, both contribution to certification and LCA score were expected to be comparable. Since this is not the case, it can be deduced that either QSAS is underestimating the percentage allocated to E3 or LEED is overestimating the score assigned to EA1. In other words, if we assume, for the sake of clarification, that LEED's distribution of weights assigned to credits are reflecting actual benefits to the environment as it's a more developed rating system being internationally used by professionals around the globe, then QSAS developers should be considering assigning higher percentage to E3 to reflect the impact in light of the discussed LCA study. It's also noticed that, comparing E1 and E3 under QSAS, shows that the LCA score of E3 is higher than that of E1 while its contribution for certification is less than that of E1. That could also be considered a basis to reconsider the weights assigned to both credits. Higher weight should be assigned to E3 in order to reflect more realistic saved impact on the environment.

According to the above sample analysis of the results, it is perceived that although implementation of sustainability rating systems on construction projects has clear positive effect on reducing burdens on the environment, rationalization of these rating systems using fair quantifiable measures is still required. This paper presented application of a quantification methodology on two rating systems, QSAS and LEED, to explore their relative efficiency through comparing similar credits using LCA approach. As discussed, results show possible superiority of some credits over others although the relative contribution towards similar certification levels is not indicating this. Future works on this research is envisaged to be addressing all credits of these two systems whenever quantification is feasible in addition to credits of other systems especially those which tend to be used on an international scale.

HAZARDOUS PROXIMITY ZONE DESIGN FOR HEAVY CONSTRUCTION EQUIPMENT

Ibukun G. Awolusi, Eric D. Marks, Nipesh Pradhananga and Tao Cheng

Abstract: The construction industry continues to be among the leading industries for workplace fatalities in the U.S. After experiencing 824 fatal injuries in 2013, the construction industry continues to rank as one of the most dangerous work environments when compared to other private industrial sectors in the U.S. Conditions of construction sites often produce hazardous proximity situations by requiring ground workers and heavy equipment to operate at close proximity. The gathered injury and fatality statistics indicate that current safety practices of construction workers have proven inadequate. The objective is to design hazard zone around pieces of heavy construction equipment in which ground personnel should not enter during construction operations. The scope is limited to construction sites and equipment at a horizontal grade and hazards between heavy construction equipment and workers-on-foot. A framework for creating the hazard zone around any piece of construction equipment is presented including detailed methodology discussions for each step. The hazard zone for a dump truck, excavator, and backhoe are shown using the created framework. Construction resource tracking data was used to validate the created hazard zone around a dump truck. Results indicate that hazard zones for ground workers can be created around construction equipment to increase hazard awareness for workers. Furthermore, additional safety standards can be formulated based on the ability to design and eventually implement hazard zones on construction equipment.

1 INTRODUCTION

Construction environments are typically comprised of multiple resources that perform dynamic activities in a specific space. This often requires construction resources, such as ground workers and heavy equipment, to operate at close proximity to each other creating potential hazardous proximity situations. The risk of injuries and fatalities increases as contact collisions between ground workers and heavy construction equipment occur.

A majority of past research efforts for hazardous proximity situations have collected and analyzed statistics for injuries and fatalities resulting from contact collisions between heavy construction equipment and ground workers (CFOI, 2011). Safety standards for hazardous proximity situations between heavy construction equipment and ground workers include Personal Protective Equipment (PPE) and equipment back-up alarms (OSHA, 2014). These regulations signify the hazards associated with ground workers and construction equipment working at close proximity, but have proved inadequate to prevent incidents from occurring.
A review of current construction worker fatality statistics resulting from hazardous proximity situations between heavy construction equipment and ground workers is completed. The created framework for designing a hazard zone for a piece of construction equipment is presented and followed by a discussion of identified limitations, benefits, and recommendations. Position tracking data of a dump truck on an active construction site was used to validate the created hazard zone. Future research work on proximity detection and alert systems for the construction industry is also addressed.

2 LITERATURE REVIEW

Construction sites are dynamic in nature and each site typically has a unique size and set of working conditions. The movement and resulting interaction between various construction resources including ground workers and heavy equipment can create hazardous proximity situations. A multitude of movements of construction resources coupled with the densely populated nature of construction sites can account for safety concerns resulting from proximity issues (Cheng et al., 2011). The following review covers current fatality incidents associated with proximity issues in the construction industry and current safety practices of construction workers with regards to hazardous proximity issues.

2.1 Construction Accident Statistics

The construction industry experiences one of the highest accident fatality rates per year when compared to other industries in the U.S. In 2012, the Bureau of Labor Statistics (CFOI, 2011) reported the construction industry experienced 806 fatalities of which 17% (136 fatalities) resulted from workers coming into contact with objects or construction equipment. Fatalities resulting from workers being struck by pieces of construction equipment accounted for 3% of the total workplace fatalities experienced in 2012 by the U.S. private industry sector (CFOI, 2013). Since 2003, the construction industry has averaged 191 fatalities resulting from construction equipment or other objects striking workers per year (BLS, 2013). Figure 1 provides the total construction fatalities and those causes by ground workers contacted with objects or equipment between 2003 and 2012 (CFOI, 2013).

![Figure 1: Construction fatalities caused by contact with objects or equipment (CFOI, 2013)](image)

One longitudinal study identified minimal significant change in fatalities resulting from contact collisions between construction equipment and ground workers between 1985 and 2009 (Hinze & Coates, 2011). Although the number of fatalities resulting from contact collisions decreased during this duration, the ratio when compared to total construction fatalities remained largely unchanged. Even in highway work zones, more worker fatalities are caused by struck-by events from pieces of construction equipment rather than commuting vehicles (Pegula, 2010). Member companies of the Construction Industry Institute (CII) also reported that a significant portion of their worker fatalities were caused by struck-by incidents.
2.2 Human-Equipment Interaction

A majority of previous research in hazardous proximity situations is largely concentrated in worker behavior. One study identified two general problems resulting in hazardous proximity issues between heavy construction equipment and ground workers (Fosbroke, 2004): (1) Workers and equipment operators - Outdated or never implemented policies, a lack of knowledge of existing specific risk factors, and repetitive work tasks, (2) Incident investigation - All incident causation data is collected after-the-face resulting in no or limited real-time incident information.

Standards and regulations required by the Occupational Safety and Health Administration (OSHA) are imperative to enhance safety in construction (OSHA, 2013a). As per OSHA regulations, construction equipment must provide alerts when moving in the reverse direction (OSHA, 2013b). Research has found that these alerts can desensitize workers to existing hazards (Duchon & Laage, 2011). Other OSHA regulations require construction site personnel to wear hard hats, reflective safety vests, and other personal PPE (OSHA, 2013b). Safety training and education, other required safety regulations, can increase the awareness of hazards associated with proximity issues between construction equipment operators and ground workers (Goldenhar et al., 2001; Huang & Hinze, 2006). Construction accident statistics indicate that back-up alerts and PPE are incapable of preventing contact collisions between workers and construction equipment.

2.3 Equipment Operator Visibility

Equipment operator visibility has impacted the overall safety of construction sites (Fosbroke, 2004). One of the leading causes of contact collisions between ground workers and heavy construction equipment is limited operator visibility (Fullerton et al., 2009). Data from an OSHA fatality database from 1990 to 2007 to shows that approximately 5% of construction fatalities during that period were caused by some type of equipment-related visibility issue (Hinze & Teizer, 2011). Table 1 shows the breakdown of visibility-related fatalities and pieces of construction equipment involved. Hazard zones were created for pieces of construction equipment that were most cited for each visibility-related fatality.

3 OBJECTIVE AND SCOPE

The primary objective is to present and test a methodology for creating hazard zones around pieces of construction equipment in which ground personnel should avoid during construction operation. The hazard zone is created for several pieces of construction equipment to demonstrate and test each step of the methodology. The scope is limited to construction sites, equipment, and personnel at a horizontal grade and hazards between construction equipment and workers-on-foot. The consideration of interactions between other construction resources (such as equipment-equipment or equipment-material interaction) is out of the scope of this work.
4 METHODOLOGY

Several variables and situations must be considered when calculating the hazard zone around a piece of construction equipment for a ground worker. These variables include equipment travel speed, equipment travel direction, equipment physical dimensions, equipment turning radius, equipment rotational capabilities, operator reaction time, and equipment braking distance. To create a process for determining the hazardous zone around a piece of construction equipment, a hierarchy was designed to assure each variable was considered. Figure 2 presents the methodology implemented to determine the hazard zone for any piece of construction equipment. A typical three-axle, tandem rear axle, 23,586 kg haul capacity dump truck is used as an example to demonstrate how each step is calculated and how the resulting hazard zone is determined (Harwood, 2003; Peterbilt, 2014).

Step 1: Equipment Footprint - The outermost position from the centroid of the piece of construction equipment should be determined for all of the equipment components. To determine the equipment footprint, the outermost extension at any height for each point 360 degrees around the equipment should be projected onto a 2D (two dimensional) horizontal plane. The equipment footprint for a typical three-axle dump truck is shown in Figure 3. This footprint is derived from the equipment dimensions of a typical three-axle, tandem rear axle dump truck (Harwood, 2003; Peterbilt, 2014).

Step 2: Initial Safety Boundary - The initial safety boundary is a 2-meter distance extended from the equipment footprint that performs as a safety factor in the event that other hazardous zone design steps fail to provide protection. A parallel line 2 meters offset from the equipment footprint calculated in step 1 creates the initial safety barrier (see Figure 4). The initial safety boundary was assigned a 2 meter value to account for a ground worker that may have body parts (e.g. limbs) horizontally extended (e.g. a worker with an outstretched arm). This safety boundary extends beyond the length of a person’s horizontally extended arm or leg as well as a person bending horizontally at their torso. This initial safety boundary zone can be modified depending on a unique set of working conditions.

Figure 3: Equipment footprint for a three-axle dump truck

Step 2: Initial Safety Boundary - The initial safety boundary is a 2-meter distance extended from the equipment footprint that performs as a safety factor in the event that other hazardous zone design steps fail to provide protection. A parallel line 2 meters offset from the equipment footprint calculated in step 1 creates the initial safety barrier (see Figure 4). The initial safety boundary was assigned a 2 meter value to account for a ground worker that may have body parts (e.g. limbs) horizontally extended (e.g. a worker with an outstretched arm). This safety boundary extends beyond the length of a person’s horizontally extended arm or leg as well as a person bending horizontally at their torso. This initial safety boundary zone can be modified depending on a unique set of working conditions.
Step 3: Equipment Function - The hazard zone must be designed to align with the specific function of a piece of construction equipment. For example, the equipment function of a hydraulic excavator with tracks and resulting hazard zone mainly follows a circular pattern with the maximum hydraulic arm reach as the circle's radius. Other pieces of construction equipment such as a dump truck or scraper will have a hazard zone largely based on their turning radius and maximum speed on a construction site. The equipment function is taken into consideration to determine the hazard zone for a typical three-axle dump truck as shown in Figure 5. Most pieces of construction equipment provide specific details about turning radius in the equipment specifications (Peterbilt, 2014).

Step 4: Operator Reaction Distance - This metric is used to determine the travel distance of a piece of construction equipment during the period in which a construction operator reacts to the identification of a hazard. An equation typically used for commuter traffic driver reaction time is implemented to determine the equipment operator reaction time (see Equation 1). An average operator reaction time of 2.5 seconds...
to a recognized hazard is utilized (MUTCD, 2013). The resulting reaction distance is plotted at intersecting points along the existing hazard zone from the previous step 3.

[1] Reaction Distance = 0.278Vt  where V = velocity and t = time (2.5 s)

Step 5: Braking Distance - The braking distance of the piece of construction equipment is added to the operator reaction time as an additional factor in determining the hazard zone. To calculate the braking distance, an equation typically used to measure the braking distance of commuter traffic (including semi-trucks) is used and shown in Equation 2. After the operator identifies a hazard, a separate reaction time is required for the operator to apply brakes to stop the equipment. The same average operator reaction time of 2.5 seconds is used as was discussed in step 4 (MUTCD, 2013). The resulting braking distance is plotted at all locations extended outward from the reaction distance calculated in step 4.

[2] Braking Distance = 0.039(V^2/a) where V = velocity and a = acceleration (3.41 m/s^2)

Step 6: Determine Hazard Zone - To determine the resulting hazard zone, steps 1 through 5 should be calculated and compared to identify the maximum calculated distance for each point around a piece of construction equipment. It is important to note that each step of determining the hazard zone builds from the previous step. For example, the initial safety boundary calculated in step 2 is added to the maximum extent of the equipment footprint for each point calculated in step 1. The maximum calculated hazard distance along the centerline of forward travel for the dump truck is the combined reaction time and braking distance of 6.3 meters. This value was added to the equipment function and initial safety boundary and equipment footprint that were calculated in step 3 and step 2 respectively. The resulting hazard zone for a typical three-axle, tandem rear axle dump truck is presented in Figure 6.

![Figure 6: Hazard zone of a typical three-axle, tandem rear axle dump truck](image)

5 HAZARD ZONE

The hazard zone for several pieces of construction equipment was created using the methodology presented in the previous section. Dimension values for a typical backhoe loader were used to create a hazard zone for ground workers. The backhoe loader used was a single tilt loader and was equipped with a multi-purpose 1.0 m³ (1.3 yd³) front loading bucket (Caterpillar, 2011). The resulting hazard zone for the backhoe loader is presented in Figure 7.
The hazard zone for an excavator was also created using the previously discussed methodology. The excavator used was a typical three teeth digging 0.018 m$^3$ (0.29 yd$^3$) capacity bucket (Caterpillar, 2011). The resulting hazard zone for the excavator is displayed in Figure 8.

The resulting hazard zone area data was also calculated based on the creation of the hazard zone for the dump truck, backhoe loader, and excavator. The net hazard area is calculated from subtracting the area occupied by the equipment (B) from the full hazard zone area (A). This net hazard area is the region that should be avoided by construction ground workers during equipment operation. The resulting hazard zone data is shown in Table 2.

6 HAZARD ZONE DEPLOYMENT

Location tracking data of construction resources (including personnel and equipment) was used from a previous study (Pradhananga & Teizer, 2014). For this study, an active construction site was selected with an earthmoving operation involving excavators, dozers, rollers, dump trucks, and construction ground workers. Position-based data was collected using GPS identification devices calibrated to a frequency of 1 Hz mounted on various surfaces on pieces of construction equipment and to the hard hats of workers. The data was filtered using an existing filtering process (Vasenev et al., 2014).

Figure 9 shows the result of verifying the proposed hazard zone with location-based data from the construction site. Tracking data for the trajectory of one trip cycle of a single dump truck starting from the point it entered the construction site and ended when the truck passed the exit point. A hazard zone was created around the truck for its position every second based on the previously prescribed methodology.

The tracked dump truck is expected to stay within the computed hazard zone. The equipment footprint of the dump truck with respect to hazard zone computed for its immediate previous position was checked for compliance with the hazard zone (i.e. did the dump truck remain in the zone after movement). The boundary of the equipment footprint should completely lie inside the hazard zone if the computed hazard zone is adequate for the equipment (truck). In Figure 9, the portion of the truck lying inside the hazard zone is plotted in blue and the portion that extended beyond the hazard zone is plotted in red. The gray area represents the hazard zone.

Instances in which the dump truck remained static were excluded from the analysis. A total of 106 location data points were assessed. Among those points, the equipment footprint was found to cross the hazard zone boundary 33 times. This implies that the computed hazard zone was able to envelope the dump truck’s movement approximately two thirds of the times. Figure 9 also shows that red areas were
only present in cases where the truck performed forward sharp right turns. Following the analysis, a recommendation on extending the hazard zone to include very sharp right turns can be implemented. The same methodology for creating hazard zones can be used to iterate through each step to optimize the hazard zone for an equipment.

7 CONCLUSIONS

The safety practices currently used in the construction industry for ground workers and heavy equipment operating in close proximity has proven inadequate by the continued injuries and fatalities resulting from workers being struck by equipment or objects. The purpose of this research was to create and test a methodology to design hazard zones around construction equipment. These hazard zones are areas that should be avoided by ground workers during construction operation. The methodology created includes six steps that include the following: 1) equipment footprint, 2) initial safety boundary, 3) equipment function, 4) operation reaction time, 5) equipment braking distance, and 6) creation of the hazard zone. The hazard zone was created for three pieces of construction equipment (dump truck, backhoe loader, and excavator) using the presented methodology. Results of the created hazards zones indicate that hazard zones can be designed and used to increase awareness of dangers around construction equipment for construction site personnel. Location-based data for a dump truck was used to evaluate the created hazard zone methodology. By creating hazard zones around construction equipment, ground workers can be informed of and avoid dangerous areas around heavy equipment on construction sites.

The presented methodology for creating a hazard zone for pieces of construction equipment is founded singularly on construction safety considerations. The hazard area accounts for potential movements of a piece of construction equipment which in some situations can result in a rather large hazard area. The created hazard area may not be feasible on select compact construction sites or working conditions. Further research is required to understand the hazard zone’s impact on other topics within the construction industry including productivity, economic feasibly, and sustainability.

Several limitations were cited during and after creating the methodology and designing hazard zones for construction equipment. The proposed methodology only allows for a horizontal plane hazard zone and doesn’t address three-dimensional hazards (i.e. crane applications and sloped conditions). The methodology presented currently addresses independent hazard zones for each piece of construction equipment, but future research could address the dynamic activity of all pieces of equipment on a construction site simultaneously. The created hazard zone could also be used to optimize the calibration of proximity detection and alert systems. Future research efforts can create a tool for automatically creating the hazard zone around a piece of construction equipment for safety managers. Future research should also address the implementation of these hazard zones. This includes a strategy to educate workers on where hazard zones are located and how to avoid them during construction operation.

Abstract: Educating building design and construction students about sustainability is critical to the development of a future workforce that is capable of making a positive impact on future sustainable buildings. Prior research has leveraged emerging computing technologies to remove some of the educational hurdles that are common among new engineering students, related to visualization and design assessment. In this prior work, an augmented reality (AR) based simulation game, called \textit{ecoCampus}, was developed to allow students to design an exterior wall for an existing building on their campus to improve sustainable performance. After users created designs in \textit{ecoCampus}, they were able to view a virtual mock-up of their design at full-scale with AR and then assess the performance of that concept using the basic simulation game interface. Using this technological approach to design, students were able to resist the tendency toward design fixation as compared to students who were not provided with the computerized \textit{ecoCampus} interface. This paper further explores the AR component of \textit{ecoCampus} to understand how students' learning is affected when the design activity is completed out of the context of the physical building. In this work, students who used \textit{ecoCampus} to design a new exterior wall concept for an existing building did so in a lab space where they were not able to physically explore the existing building for which they were designing the concept. Instead, they could only view the existing building through a single photograph that was projected on a screen. Students completed the same assessments as prior student cohorts and were allotted the same amount of time. After analyzing the collected data it was observed that, while students still employed beneficial design behaviours as compared to prior cohorts using paper-based design strategies, the process that they employed to arrive at their final design concept included fewer considerations of different design alternatives than students who used \textit{ecoCampus} in the existing building. This suggests that there may be additional value in using AR in the physical context of a space for building design and assessment learning tasks, especially when design creativity is advantageous.

1 INTRODUCTION

There has been a growing concern for the environmental impact of buildings, and subsequently, a shift in recent years to embrace more sustainable design and construction strategies. As the Architecture, Engineering, and Construction (AEC) Industry continues to adopt more aggressive sustainability standards, it becomes increasingly important for students pursuing AEC careers to understand the sustainability performance implications of the buildings they design and build. This paper extends prior research that explored how mobile computing technology can help to remove traditional barriers to
sustainable building design education to allow newer students in AEC disciplines to develop, visualize, and assess the sustainable performance of different design concepts.

A prototype mobile computer application, called ecoCampus, was developed in prior work to challenge users to design a new exterior wall for an existing building in an attempt to make it perform more sustainably (Ayer et al. 2014a). Through an augmented reality (AR) based simulation game interface, ecoCampus allows users to: design an exterior wall concept; visualize their designs using augmented reality; and assess the performance of the designs with a basic simulation game interface. ecoCampus was implemented with students at The Pennsylvania State University enrolled in courses in Architecture, Civil Engineering, and Architectural Engineering. The prior work compared the behaviour and perceptions of students who completed the same sustainable design challenge using either ecoCampus or one of two paper-based versions of the design activity. One of the paper-based design activities included a purely open-ended design activity, where students were only supplied with blank sheets of paper on which to illustrate their design concepts (Ayer et al. 2014b). The other paper-based design activity included printed images of the existing building’s exterior wall on which students would illustrate their design concepts to help provide them with a sense of scale and limitations on design requirements (Ayer et al. 2013a). From these prior implementations of different sustainable design activities, several beneficial learning behaviours were observed related to the students’ design process when using ecoCampus (Ayer et al. 2013b).

One of the research questions that these prior implementations did not explore was related to the extent to which the augmented reality (AR) component of ecoCampus affected student behaviour. In prior implementations, students who completed the design activity, regardless of format, were physically located inside the existing building for which they were designing a new wall for improving sustainable performance. This placement of students in the actual, physical building for which they were designing was hypothesized to allow the AR component of ecoCampus to add value by letting students visualize their design concepts at full-scale and in the context of the physical space. This paper explores this hypothesis by implementing the same design activity out of the context of the physical building. Instead, students involved in this work used ecoCampus in a laboratory setting, which required them to visualize their design concepts from a projected still image of the physical building. This effectively eliminated their ability to view a full-scale mock-up of their design concept through AR and also eliminated their ability to physically explore the existing building to gather information that could influence their design. By removing this component of physical location in the targeted building, this implementation served to provide an understanding of the benefits and drawbacks of using AR out of the context of a physical space.

2 BACKGROUND

Situated learning theorists suggest that the best way to educate students about content that will eventually be applied to a particular context is to learn that content in its corresponding context (Lave and Wenger 1991). This can be especially relevant for students in engineering disciplines because of the problem-based nature of their work that requires them to apply mathematics and physics concepts to an engineering context to create viable solutions (Johri and Olds 2011). For new students learning about sustainable building design and construction, situated learning theory would suggest that the best way for students to learn these concepts is in the context of a design or construction scenario. This can be a challenging scenario to create for newer students because many new students have had little, if any, design experience in the early stages of their academic career. This challenge of creating a design scenario for new students is complicated further because the traditional means for communicating design and construction information relies on the use of 2D drawings. These can be challenging for students to understand and the mental models they create from their understanding of the drawings can be prone to errors (Johnson 1997).
The potential challenge with presenting this learning content in the context in which it will eventually be applied offers some synergies with AR visualization technology, which presents virtual content in its physical context. AR is a subset of the broader “mixed reality” which involves the merging of real and virtual components along a continuum ranging from completely virtual (computer models) to completely real (what can be seen by unaided eyes) (Milgram and Kishino 1994). AR allows users to see a predominantly real world view of a space with some virtual content superimposed to “augment” their view, similar to the yellow “first-down” line on televised American football games (Azuma 1997). This superimposition of content allows AR to present virtual content in the context of a physical space. In a building design context, AR allows hypothetical or planned design models to be visualized on top of an existing building or construction site, which allows users to visually compare planned versus existing building content.

In addition to the visualization capabilities that can be afforded through AR, simulation game technology further facilitates learning by situating students in a learning context where they may experiment in an engaging way (Gee 2005). Simulations are models that attempt to approximate a situation, environment, or set of events to predict, teach, or entertain (Prensky 2004). Games, on the other hand, are defined as: having rules; having variable and quantifiable outcomes; having value assigned to possible outcomes; requiring player effort; requiring a player to become attached to the outcome; and having negotiable consequences (Juul 2003). Simulation games are, therefore, defined as contests between individuals that move toward specific goals under sets of conditions and constraints that will sufficiently model a real-world situation (Gredler 1994; Jacobs and Dempsey 1993). Prior work using simulation games applied to construction engineering educational contexts have identified pedagogical benefits enabled through the use of the technology (Nikolic et al. 2010).

In prior work conducted by the authors of this paper, these educational approaches involving AR visualization, simulation games, and situated learning environments were applied through the development and implementation of ecoCampus (Ayer et al. 2013b). ecoCampus is a mobile computing application (or “app”) that was created to challenge users to create a more sustainable exterior wall design concept for an existing building on Penn State's campus. The performance and behaviours of the students using ecoCampus was compared to other first-year students from prior semesters who completed the same design activity using non-computerized formats (Ayer et al. 2013a, 2014b). In these prior studies, all students completing the exterior wall design challenge, regardless of format, were physically present in the building for which they were designing wall concepts. This consistent educational setting allowed the researchers to vary the format of the design activity between paper-based and computerized activities, which allowed for direct comparison of findings, but also lead to additional research questions. Specifically, it was still not clear from the prior works the extent to which AR’s presentation of virtual content in its physical context affected student behaviour. This paper removes the “physical context” component of AR to specifically focus on this question.

3 METHODOLOGY

The research presented in this paper extends prior work that involved the implementation of ecoCampus. For this work, first-year engineering students enrolled in an architectural engineering course were tasked with creating an exterior wall retrofit design concept for an existing building on campus to make the building perform more sustainably. Unlike prior implementations, this implementation of ecoCampus task students with completing this activity in a lab space that was not in the same location. This eliminated the students’ ability to physically explore the existing building to gather additional information that could potentially affect their design process.
Students completed their design work in the Immersive Construction (ICon) Lab at the Pennsylvania State University, as shown in Figure 1. The ICon Lab features three, large (1.8m by 2.4m) projection screens. During implementation, an image of the building targeted in this design challenge was projected onto the center screen, which is also shown in Figure 1. This image was taken with a fiducial marker hung in the appropriate position on the wall to allow the tablet computer camera to track a user’s position and display accurately positioned and scaled AR content. Therefore, in the ICon Lab setting, students could use ecoCampus’s AR interface to see their design concepts overlaid onto the projected image of the physical space.

Figure 1: Students used ecoCampus in a lab (left) where an image of the building wall was projected (right).

Other than the modified activity setting, the research steps completed by the students remained consistent with the different prior design activity implementations. Students were able to self-direct their work to determine for themselves how to approach the design challenge. Additionally, students completed the same assessment activities, before and after designing, to generate data that could later be analyzed to assess their performance.

3.1 Pre-tests

Before beginning the design activity, each student completed a pre-test assessment. This pre-test determined baseline knowledge of sustainability and building design concepts for each student. Additionally, the pre-test gathered responses from the students related to their levels of motivation, confidence in their building design abilities, basic demographic information, and familiarity with mobile computers and the technologies incorporated into ecoCampus. All responses to pre-tests were made anonymous using experimental identification (ID) numbers, which were not known to the course instructor or researchers, to encourage candid responses from the student participants.

3.2 Design Activity

After completing the pre-tests, students were given tablet computers equipped with ecoCampus. They were given a brief, five-minute, introduction to the application, which explained the workflow. The workflow involved three main user interfaces with which a student would interact as shown in Figure 2. These included: a touch-based design interface where students would develop wall design concepts; an AR interface where students would visualize their concepts in the context of the projected image of the physical space; and a basic simulation game interface where they would receive performance data for assessment of their design concept.

After students were introduced to the application, they were asked to input their experimental ID number to link their design work to the other assessments. At each of the main user interfaces, students took screen-captured images of their work to serve as a record of what they designed. These screen-captured images were also submitted as part of their assignment for research analysis as shown in Figure 2.
Students were given approximately 40 minutes to complete the design activity using ecoCampus. They were required to complete a minimum of one design concept. As with students who completed other formats of the activity, they were also allowed to create as many additional design iterations as they felt were necessary during the class time.

![Figure 2: ecoCampus screen-captured images taken by student participants.](image)

### 3.3 Post-tests

After completing the design activity, students were given a post-test assessment where they were asked similar sustainable design understanding questions to the pre-test assessment. Additionally, they were asked questions to elicit responses related to their perception about the activity. These questions sought to understand their perceptions related to the benefits of the activity to their education, the appropriateness of the amount of time allotted to this activity, the level of enjoyment they experienced while completing the activity, and the level of interest generated in building design and sustainability from completing the activity. Using the same approach as the pre-tests, the responses to the post-test were also made anonymous through the use of experimental ID numbers.

### 3.4 Analysis

After all design activity documentation was received, the documents were reviewed and analyzed. Specific attention was given to the design process that students completed to arrive at their final design. Additionally, students’ perceptions about the value of this activity was also examined to understand if completing the ecoCampus design activity out of the context of the physical building had any observable differences from the data collected from students in prior semesters who were physically located inside the building.

### 4 RESULTS

ecoCampus was implemented in the Fall semester of 2013. During this implementation, 27 students completed all assessments and consented to allowing their responses and design submissions to be used in this research. All students who completed the design activity during this implementation were enrolled in the same first-year architectural engineering course (AE 124S), which was also the same course that was targeted in prior semesters’ implementations.
4.1 Student Perception of Activity

The responses to the post-test assessments were collected and analyzed to understand the perception that students had about completing this format of ecoCampus. The responses collected were compared to prior semesters to identify similar trends or shifts in perceptions. In this comparison to prior semesters, only data from students enrolled in the same architectural engineering course were examined to allow for consistency in comparison. The responses to the different assessments were analyzed and compared to students who completed: the same version of ecoCampus where students were physically in the existing building; a paper-based approximation of ecoCampus, where students would illustrate design concepts on top of printed images of the actual building; and a purely open-ended activity where students were given the design challenge description and blank sheets of paper on which to illustrate their concepts. Table 1 shows a summary of the findings related to student perception of the activity.

Table 1: Students’ self-reported perceptions about different design formats.

The findings from the implementation in the ICon Lab were generally consistent with the responses from prior semesters. Students generally enjoyed completing the activity and also generally felt that it increased their interest in building design and sustainability (see Table 1). The main difference observed between the computerized ecoCampus design activity formats and the paper-based versions related to the perception about the amount of time allotted to complete the design activity. Students who completed the paper-based format were more likely to feel that there was not sufficient time provided to them to complete design. This echoes the findings of prior ecoCampus versus paper-based design format comparisons (Ayer et al. 2014b).

4.2 Design Behaviour

In addition to exploring student perceptions regarding the activity, it was also of interest to study the process they employed while performing the design activity. The screen-captured images taken by the students were analyzed and their design behaviours were documented. In prior work, one of the most noteworthy findings related to the design process employed by the students was related to the number of design iterations and materials that were considered by students during the design session (Ayer et al. 2013b). This prior work showed statistically significant increases in the number of iterations as well as building materials that were considered by students during design.

The results from this implementation of ecoCampus in the ICon Lab also indicated significant increases in the number of iterations completed as compared to students who completed either of the paper-based design activity formats (p<0.001). Additionally, the design activities submitted by the students who used ecoCampus in the ICon Lab considered more building materials over the course of the design activity.
session as compared to the students who completed either of the paper-based design formats (p<0.001). This is consistent with findings from prior ecoCampus implementations.

Perhaps the most noteworthy finding related to this implementation of ecoCampus in the ICon Lab related to the students’ design behaviour was in the comparison between the students who used ecoCampus in the ICon Lab (a virtual setting) and those who used it in the actual building. There was a statistically significant increase in the number of design iterations that students considered when they were physically located in the building (p<0.001). There was also a statistically significant increase at the 95% confidence level in the number of building materials that students considered when completing the activity in the actual building (p=0.017).

4.3 Discussion

Students who used ecoCampus in the ICon Lab to develop improved exterior wall retrofit design concepts for sustainability did so through the creation of more design iterations and considered more possible building materials than students from prior semesters who used paper-based approaches. This finding was not surprising as it echoed the findings of prior work (Ayer et al. 2013b). This behaviour of considering multiple design concepts before finalizing on a chosen concept suggests that students were successfully able to resist the tendency toward design fixation. Design fixation has been defined as adherence to a set of arbitrary rules or constraints that effectively limit creativity (Jansson and Smith 1991). Therefore, this research also reinforces this prior conclusion that an AR-based simulation game interface can help students to break the tendency toward design fixation.

The more noteworthy finding from this work relates to the finding that students used ecoCampus differently based on where they completed the activity, which affected the way that AR would function in ecoCampus. In other words, students enrolled in the same first-year seminar course, using the exact same version of ecoCampus, demonstrated a statistically significant difference in the number of design iterations and building materials that they considered in the same amount of time.

This finding was further explored to determine if there could be a separate factor that might have affected the students’ behaviour. Pre-tests were compared between the different implementations of ecoCampus to determine if the different groups of students had differing levels of experience with mobile computing technology or different levels of motivation for completing the activity. Substantial differences in these metrics could potentially cause a change in students’ design processes.

Table 2 shows the responses related to these topics from students who used ecoCampus in the lab and also those who used it in the actual building. The students in both implementations of ecoCampus responded with similar levels of motivation in the activity pre-tests. This does not suggest that their levels of motivation or experience using mobile computing technology affected their design behaviour.
Table 2: Perceptions between students using ecoCampus in different implementations.

5 CONCLUSIONS

This work explored the use of an AR-based simulation game called ecoCampus that presents sustainable building design learning content to students through an interactive design challenge. From prior semesters, several beneficial learning behaviours were observed through the use of ecoCampus. This paper presents a follow-up study to further explore the prior semesters’ implementations. In this work, students were tasked with completing the same exterior wall re-design activity, but they were not physically present in the building for which they were designing this wall. Instead students were tasked with completing this design challenge in front of a projected image of the physical space. This meant that the AR component of ecoCampus did not offer a virtual 1:1 sense of scale. It also meant that students were not able to physically explore the existing facility to gather additional information that could affect their design choices, such as what materials felt the most thermally insulated from the cold outdoor air or which materials worked best aesthetically based on the rest of the building’s design.

The findings of this work generally backed up the findings of prior research that compared ecoCampus design behaviours to paper-based design format behaviours. In this work, it was observed that even when students were taken out of the physical building for which they were designing, ecoCampus was still able to help students to break the tendency toward design fixation by considering more possible design concepts and building material options than students who completed paper-based design activity formats. The perceptions of the activity among students were also largely similar between the different ecoCampus implementations, regardless of location, which further supports prior findings.

The findings related to this work differed in comparison to prior studies when the performance of students using ecoCampus in the physical building were compared to the students who completed their work in the ICon Lab. Students who completed their design work in the context of the ICon Lab did so through the creation of fewer design iterations as compared to the students who completed their design in the building. The group of students completing their design in the ICon Lab also completed their work by considering fewer different building material choices. Both of these findings suggest that using the AR component of ecoCampus in the actual building context can increase motivation to be creative and curious during design and analysis. While this conclusion is supported by empirical evidence related to the students’ behaviour, it was not supported by their self-reported levels of motivation. The responses to these perception-based questions were not largely different between the two groups. This could potentially be due to the fact that students only completed one version of this activity. Had the experiment been conducted by offering students the opportunity to complete both formats of the activity and subsequently rate their perceptions of which one was more engaging, interesting, and valuable, a difference may have been observed.
Future work will explore how human behaviour may be influenced by augmented reality and simulation games in other contexts. This future work will explore how these technologies can influence student learning about building design and construction, but it will also be tested in industry use-cases. It is possible that the same beneficial behaviours that are exhibited by students learning these skills could be observed by industry practitioners when determining the best approach to an actual building design scenario. Finally, additional use-cases for this technology will be explored to study how tasks may be improved related to training professionals in the AEC disciplines.

EFFECTIVENESS OF AUTOMATED MACHINE GUIDENCE TECHNOLOGY IN PRODUCTIVITY IMPROVEMENT: CASE STUDY

Ehsan Rezazadeh Azar¹,², Gabriel Agnew¹ and Andrew Parker¹
¹ Lakehead University, Canada
² eazar@lakeheadu.ca

Abstract: Automated machine guidance (AMG) systems are a relatively new solution to enhance the precision and improve the productivity of heavy civil operations. These systems process 3D computer models of the earthwork together with the spatial information of the end-effector of the machine, and display the relative location of the end-effector and design levels in real-time for the operator. This paper presents a case study of two large earthmoving projects to compare the performance of equipped bulldozers and excavators with non-equipped machines under similar conditions. The studied operations were summer reclamation and highway excavation for bulldozers and excavators, respectively. The results show that the automated machine guidance technology improved the productivity by 6% to 34% for bulldozers and 19% to 23% for excavators. The variation in improvement rates for bulldozers were due to different site conditions, because unstable soil conditions negatively affect the operation regardless of using automated machine guidance system. In addition to productivity improvement, application of automated machine guidance could reduce the need for surveying; the surveyor team was present 21% to 30% of the working hours for conventional operation of excavators whereas this figure was only 5% for the equipped machines.

1 INTRODUCTION

Construction is often regarded as a traditional industry that is slow to adopt productivity improvements. Historical data demonstrates that the productivity rate in US construction industry remained relatively unchanged from the 1960s to 2009 (Eastman et al. 2011). This performance is well below the increase rate of other non-farm industries. A recent study, however, showed that this inferior performance is not valid for the entire construction industry, because a considerable portion of construction operations have been moved into manufacturing setting and the productivity of off-site operations is higher than that for on-site activities (Eastman et al. 2011; Eastman and Sacks 2008).

Despite all criticisms, earthwork operations are among the pioneers of adopting new technologies to improve productivity and accuracy (Navon 2005). Earthmoving operations depend on heavy equipment, and technical advancement in various features of these machines could improve their performance and help them remain economically viable (Tatum et al. 2006). Some of the areas of improvement include efficient engines with lower fuel consumption and emissions, lower service and maintenance costs, better electrohydraulic systems, and integrated monitoring and control systems.

In addition to the evolution of the machines, a number of add-ons have been developed to enhance the performance of the operations. On-board diagnostic system (OBD), automated machine guidance (AMG) technology, weight sensors, and rear-view cameras are among the main new add-on products. AMG
technology is one of the major advancements that gives the machine operator real-time visual information about the location of the end-effector with respect to the design level, such as the location of grader’s or bulldozer’s blade, excavator’s bucket, or screed of pavers. AMG systems mostly use high accuracy GPS systems, such as real-time kinematic (RTK) GPS, to localize the end-effector. Since these antennas capture data under harsh condition (such as jittering), the signals are filtered for better results. Then, the system emulates the movement of the machine in a virtual environment which also contains the geographical data of the design. The whole process is visualized in a graphical user interface (GUI) in real-time. For example, Figure 1.a shows a dual GPS antenna system installed on the blade of a bulldozer and Figure 1.b depicts a typical graphical view of the operation displayed in the cabin. This way, the operator is able to guide the machine with more confidence than in the conventional approach; it also requires less staking and related interruptions during the operation, because these heavy machines sometimes knock down the stakes during operation (Barrett 2008; Han et al. 2006; Han et al. 2005). Moreover, application of an AMG system could reduce the possibility of rework. These products have become popular in the last decade and several companies fabricate a wide range of product lines for different machines, varying from a simple 1D depth estimation device to a full 3D AMG system.

AMG technology has been the subject of some research projects, such as the evaluation of accuracy of GPS-based systems for road pavement (Peyret et al. 2000) and excavation operations (Bernold 2002; Huang and Bernold 1997). In addition to accuracy, the effectiveness of AMG devices is a key factor in improving productivity. For instance, project planners and cost estimators need to adjust their productivity estimations based on the rates that could be achieved through the use of AMG systems (Han et al. 2005). It is also important for the decision makers to be able to estimate the payback rate of these relatively expensive systems before purchase. Therefore, a few research efforts used simulation methodology to compare the performance of the conventional earthmoving with GPS-based operation (Shehata et al. 2012; Han et al. 2008; Han et al. 2006; Han et al. 2005). In addition to simulation, some of the machine control companies provide case studies about the productivity improvement of their products. These case studies, however, are mainly carried out to promote the product and may not adhere to the basics of scientific approach. Therefore, there is a need for an independent scientific field study to evaluate the performance of the AMG technologies regardless of their make. The outcome could be useful for construction planners and decision makers, as well as for comparison with future studies.

This paper explores the productivity benefits achieved through the use of GPS-based AMG systems on bulldozers and excavators. This study examines the productivity rates in conventional and AMG-based operations, as well as the required surveyor time in both methods.

Two types of automated machine guidance devices are investigated in this research: 3D dual antenna grade control for bulldozers and 3D pose estimation system for excavators. The first system uses two RTK GPS antennas installed on both sides of a dozer’s blade (see Figure 1.a) to calculate location (x, y, z) and angles (pitch, yaw, roll) of the blade. It is also possible to implement this system using only one GPS receiver which has lower accuracy compared to dual GPS. Then the system processes the 3D locational data together with the 3D CAD model of the design profiles and displays them together in a monitor installed in the cabin for the operator. These systems usually have the options to show virtual plan and side view of the operation (see Figure 1.b).
The 3D solution for excavators is more complicated than for bulldozers, because extreme working conditions prevent tracking the end-effector using a GPS antenna. There are a variety of products for excavators in which the high-end solution (full 3D) uses a combination of two RTK GPS antennas installed on the cabin for localization of the machine and estimation of the yaw angle of the boom, and a series of angle sensors attached on the arm, stick, and the bucket to monitor the pose of the articulated arm (See Figure 2.a). The samples studied in this research were equipped with this type of 3D system.

Figure 1: a) Dual GPS antennas for bulldozer, b) virtual in-cabin display of bulldozer and blade relative to design levels

Figure 2: a) Dual GPS antennas + angle sensors for excavator, b) virtual display of excavator’s end-effector relative to design levels in cabin
A practical approach to evaluate the effectiveness of these automated machine guidance technologies is to compare the performance of equipped with non-equipped machines under relatively similar working conditions. The job conditions include the same location, same type of soil, same skill level of operators, and the same machine capacity. In addition, the job quantities should be large enough to capture the effectiveness of the system over the long term, which would provide satisfactory comparison data.

2 CASE STUDIES

Two large earthmoving operations were selected for this field survey, and both operations were carried out by a large construction company. There were two main reasons to choose these two cases: First, the contractor used same capacity machines for the same work zones, and some of the plants were operated conventionally while the rest of the machines were equipped with AMG devices. This provided the opportunity to compare their productivity rates. Second, this company uses an effective monitoring system to track the required data for productivity measurement, including working hours, operation locations, and work quantities of each machine, with high accuracy.

2.1 Bulldozer Study

A summer reclamation project in Northern Alberta, Canada, was studied to assess the performance of a 3D grade control system for bulldozers. This project included reclaiming land that was previously used for mining operations. This land had to be restored to its natural contours and pre-mining site condition. The bulldozer production rates were tracked based on time and material being placed. The total volume of earth material moved to the designed grade for the months of June and July 2013 was 181,950 bank cubic meters. The total bulldozer time allocated to the placement of cover-soil materials was 822 hours for the bulldozers without automated machine guidance and 561 hours for the equipped machines. The specified cover material included sub-soil, low-sodic soils, topsoil, and muskeg material with lifts of 70 cm, 50 cm, 30 cm, and 50 cm, respectively. Materials were hauled by off-highway dump trucks to the cover soil placement areas. Then the bulldozers spread out the dumped stockpiles to the required placement thickness and design grades.

Summer reclamation is not as efficient as reclamation in cold months due to large settlements on the placement area. Thawing of the frozen ground in the summer season causes these settlements, which result in unstable ground condition. Therefore, lightweight bulldozers would be more useful during summer reclamation as heavy bulldozers could float over the unstable material.

The average length of the earth-fill sections for this case study was 45 meters, which was an inefficient length. This was mainly due to the fact that haul trucks were not able to move the dump material over the areas where cover-soils were being placed. Nine Caterpillar D6Ts and two Caterpillar D8Ts were used during this case study. Four bulldozers were equipped with AMG including three CAT D6T bulldozers and one CAT D8T. The data was collected using transaction reports, surveying data, and site supervision notes. The transaction report is the company’s internal form of tracking hours assigned to each specific cost code to track time allocated to each task. Working hours of all bulldozers, even those without AMG systems, were tracked using mobile hour recorders. This method provides accurate machine hours. The construction supervisors tracked the work zone of each bulldozer. Onsite project coordinators compiled these records at the end of each day to ensure the acceptable productivity was achieved for each task and for each machine. An accurate survey of the work area of each bulldozer was completed after large sections of work were inspected and approved by a client representative. This inspection/approval procedure followed every two days on average, and the bulldozer would typically wait for an approval before starting work on a new zone. The bulldozer assigned to a specific area would not be moved until the completion of the cover soil in that particular zone, as a way to minimize downtime due to bulldozer relocation. These monitoring processes provide working hours, specific working areas, and approved bank volume of material associated with each bulldozer. These measurements allow for tracking the productivity of each bulldozer based on the actual work volumes with little interpolations required for production estimation of each machine. Figure 3 presents the average of production rates with regards to each month, material type, and bulldozer type.
Application of AMG systems on three CAT D6Ts resulted in 30% increase in average productivity in June subsoil placement. The productivity improvement for the equipped CAT D8T, however, was only 6% in the same operation. The much lower productivity improvement for the CAT D8T compared to CAT D6Ts was due to placement conditions. The D8T had floating issues on the placement areas, causing non value added (NVA) hours which diminished the overall productivity improvement of the automated machine guidance system. The productivity improvement for CAT D6Ts was significant; because the smaller bulldozer causes less ground pressure than a D8T (Caterpillar 2014), the D6Ts experienced less downtime and operated on the placement more efficiently.

June Topsoil placement was done using only CAT D6T bulldozers and the results demonstrate an overall productivity increase of 34%. July muskeg placement was also performed by CAT D6T bulldozers due to material conditions. Muskeg is an unstable type of earth material and related earthwork should be performed by skilled operators with lightweight equipment. As presented in Figure 3, the productivity of CAT D6T bulldozers in placing Muskeg was lower than any other cover soils. The overall productivity increase in placing muskeg with AMG was about 28%. July Topsoil placement was completed using both CAT D6T and CAT D8T bulldozers. There is a substantial difference between the productivity rates of topsoil placement in June and July for CAT D6Ts; rainfall at the end of June saturated the soil and therefore diminished the performance in July. Summer reclamation is highly weather dependent; for example, extreme precipitation could slow down the operation. The improvement rate for the equipped CAT D6T bulldozers in July Topsoil placement was about 28% which was lower than 34% improvement in June, but this figure was still higher than the 20% improvement for the equipped CAT D8T.
These results demonstrate that the productivity improvement rate obtained by the use of automated machine guidance technology is not constant in every scenario. This value also depends on the working situation, namely soil condition, and the AMG systems for bulldozers are more effective in suitable working conditions.

2.2 Excavator Study

This part of the study compared the productivity rates of similar excavators, equipped with a 3D AMG system and without such technology, in a large highway twinning job in the province of Ontario, Canada. This project included large volumes of excavation to accommodate the large cuts and fills of this highway design. The collected data covers the period of June – July 2013, when a total of 101,686 bank cubic meters of earth material were excavated. Total working excavator hours are broken down to 337 hours of conventional operation and 436 hours using AMG technology. In this project, excavators worked on the benches above the material to be excavated while the dump trucks were on the bottom of the other side of the bench being loaded. This case study excluded rock excavation which required extra operation, resulting in much lower productivity rates than the soil excavation. Seven excavators were assigned to the earth excavation task, and two were equipped with a full 3D automated machine guidance system. The machines working on earth excavation included three CAT 345DLs, one CAT 345D, two CAT 336Es, and one LinkBelt LBX700. The LinkBelt LBX700 is similar in size and power to a CAT 345. One CAT 345DL and one CAT 336E were equipped with AMG technology.

The data collection process was similar to that described above for the bulldozers, included tracking of machine hours, work areas, and detailed surveying data of each machine’s work zone to measure excavation quantities. Data recording units installed in all working equipment (even equipment without AMG) recorded working hours. The work zones specific to each machine were tracked by site supervisors and the excavation quantities were jointly measured and approved by the surveyors of the contractor and client. In addition to these three types of data, the time allocated for surveyors guiding the operators of the equipment was also tracked.

Figure 4 presents the compiled productivity rates; the operation with the use of AMG outperformed the conventional approach. The average productivity improvement rate was about 23% for the CAT 345 excavator compared to other non-equipped similar excavators while 19% productivity improvement was observed with the CAT 336 excavator compared to other non-equipped CAT 336.

![Production Rates of Excavators](image)

**Figure 4:** Graphical presentation of excavator productivity rates
The productivity improvement rates for the excavators were less variable than the bulldozers, possibly due to the stationary operation of excavators. Because of the nature of their function, excavators are less susceptible to the negative effects of unstable ground.

In addition to the productivity improvement, application of AMG system on an excavator results in more savings due to the reduced surveying time. Contractor’s surveyors must carry out some grade checks to ensure that the excavation correctly proceeds based on the designed grades. However, a conventionally operated excavator requires more frequent supervision and grade checks, because it requires some visual stakes during the excavation. Moreover, during conventional operations, some visual markers disappear or are knocked down and must be reset. Figure 5 presents allocated surveyor hours versus total working hours of each of seven excavators during the time of study. Surveyors helped the operators of the AMG-equipped excavators in only 5% of the operation time while this value varies from 21% to 30% of time for conventionally operated machines. It should be mentioned that the utilization of survey time in the conventional approach also depends on the number of excavators performing work. A job with a few excavators might require greater surveyor time per excavator, as the surveyors need to spend the time among few work zones.

![Equipment hours vs. surveyor team hours for different excavators](image)

Figure 5: Equipment working hours vs. surveyor hours for all seven studied excavators

The survey times allocated to cover-soil placement areas in the bulldozer case study were not tracked, but the use of grade control systems for bulldozers could reduce the need for this labour-intensive task as well (Han et al. 2006; Han et al. 2005). Another important factor in effectiveness of GPS-based automated machine guidance systems is the GPS signal loss, which was not studied in this research, but it could be problematic in areas with natural obstacles (such as trees and narrow valleys) or human-made obstacles (such as urban canyons) (Meguro et al. 2009).
3 DISCUSSION

The results from these case studies demonstrate that the use of AMG systems increases productivity between 6% and 34% for bulldozers and between 19% and 23% for excavators. This field study revealed that the productivity improvement for bulldozers depends on site conditions. The findings of this study could be compared with the outcome of the simulation-based studies on the use of GPS-based machine control technology in earthmoving projects. Table 1 provides these results.

4 ECONOMIC ANALYSIS

The productivity improvement rates are useful during the scheduling and planning of major heavy civil construction projects. To help exemplify the noticeable benefits of the implementation of AMG systems, a simple scenario is presented. This case examines operating costs and payback based on increased productivity for a D8 bulldozer. Operating costs for the machine and the operator were obtained using OPSS 127 (Ontario Ministry of Transportation 2014) and Statistics Canada (2014), respectively. Based on these sources, the hourly rate of a D8 bulldozer is 243.5 CAD (= $218.8 for machine + $24.68 for the operator). An initial investment of $60,000 Canadian is considered for the 3D automated machine guidance system. It was assumed that the bulldozer has an average productivity of 165 bank cubic meters per hour and the productivity improvement rates of 20%, 25%, and 30% were used in this analysis. As presented in Figure 6, the operation cost of a machine with an AMG will be lower than an unequipped bulldozer after a certain point. For example, in the case of 25% productivity improvement, the initial investment will pay for itself after 203,000 cubic meters of earthmoving, and the subsequent operations would have a larger profit margin than the conventional operation.
5 CONCLUSION

This research project investigated the effectiveness of machine control technology on bulldozers and excavators using systematically collected data from two large earthmoving projects. The results demonstrated overall increases in productivity by using AMG technology in both types of equipment. The rate of productivity improvement, however, is not consistent in all cases and depends on the site conditions, more specifically soil condition. The observed productivity improvement rates for bulldozers varied from 6% to 34% in different conditions and the improvement rate varied from 19% to 23% for excavators. In addition, the required survey time for excavators was also tracked, and showed considerable reduction for equipment with AMG. The equipped excavators required surveyors only 5% of the time, while this value was 21% to 30% of the time for the conventionally-operated excavators.

HYBRID OBJECT DETECTION AND MARKER RECOGNITION SYSTEM TO MONITOR PERFORMANCE OF THE HAULING DUMP TRUCKS

Ehsan Rezazadeh Azar1,2
1 Lakehead University, Canada
2 eazar@lakeheadu.ca

Abstract: Various sensing technologies have been developed for real-time monitoring of the earthmoving fleet on construction and surface mining jobsites. Computer vision-based methods are among the most recent techniques employed to track earthmoving machines in a construction field. All the research efforts in this area investigated computer vision algorithms to detect and track different types of equipment, but they were unable to identify individual machines within the fleet. This paper introduces a hybrid system which uses a combination of an object detection method and a marker recognition algorithm to identify individual dump trucks using specific markers attached on them. Background subtraction and Histogram of Oriented Gradients (HOG) algorithm were used to detect candidates in the video frames and then the system zooms on the detected bounding boxes to obtain a better resolution for marker detection. Next, the marker recognition module searches the zoomed frame for a marker and in case of successful identification; it verifies the detection and records a trip for that individual truck. The results showed promising performance, in which the system identified 83% of the hauling trips made by the marked machines without producing any false positives.

1 INTRODUCTION

Real-time monitoring of the construction equipment is beneficial for proactive equipment management and productivity measurement and, in addition, the collected productivity data can be used for simulation, planning, and cost estimation of future projects. Manual monitoring is costly, labour-intensive, and non-real-time, therefore, different automated data collection systems have been developed to monitor earthmoving machines, namely GPS, which has been the main tool for locating the equipment fleet in construction and open-pit mining fields. The GPS-based systems can only provide spatiotemporal data, i.e. time and location, which cannot precisely represent machine actions.

Computer vision-based monitoring systems are among the most recent techniques tested for monitoring construction equipment performance. It has been argued that the vision-based techniques are
appropriate options as they are not intrusive, cost-effective, and can successfully operate in open field jobsites where clear sightlines could be selected. A number of research projects studied the feasibility of using cutting-edge image and video processing algorithms for recognition (Memarzadeh et al. 2013; Rezazadeh Azar and McCabe 2012a; Rezazadeh Azar and McCabe 2012b; Chi and Caldas 2011), tracking (Rezazadeh Azar et al. 2013; Park et al. 2012; Brilakis et al. 2011; Gong and Caldas 2011), and activity identification purposes (Golparvar-Fard et al. 2013; Rezazadeh Azar et al. 2013; Gong and Caldas 2011). All the mentioned research efforts, however, have a major shortcoming as they cannot identify a certain machine among the in-class equipment. The developed recognition methods are only able to distinguish machine types, e.g. backhoe and dump truck, and fail to identify individual machines, e.g. dump truck # 8. Therefore, these vision-based monitoring systems are unable to track the productivity of individual machines, which is a major disadvantage compared to radio-based sensing technologies such as GPS and UWB. As a result, a main research gap is to investigate vision-based identification methods to address this problem. Vision-based identification is an evolving field of computer vision and can be grouped into model- and marker-based identification. Model-based identification algorithms try to recognize a certain target based on the unique visual features of that individual. Face identification is the most active topic in this area that is heavily used for security purposes, and related algorithms use certain features of the existing model(s) of the target to identify it in surveillance videos and images. The model-based methods are exclusively useful for identification of the targets that have unique visual features within its class, e.g. human face. This approach, however, is impractical to identify individual machines in a mining or construction jobsite, because most of in-class machines are completely similar in shape, unless they are painted in different color which is uncommon in most large heavy construction and mining jobsites.

Therefore, the second identification approach—marker-based method— is the practical choice to identify individual machines. There are several robust marker recognition techniques that are able to identify tags under challenging visual condition. These algorithms use a specific type of markers, called fiducial markers, which are made of a set of easy-to-detect features for robust recognition performance. For example, ARToolkit (Kato and Billinghurst 1999), ARTag (Fiala 2005), and AprilTag (Olson 2011) are the popular marker recognition algorithms, which are mainly developed to facilitate augmented reality generation processes. This research project aims in utilizing a fiducial marker-based approach to identify labeled dump trucks in real-time construction videos, and estimate their hauling trips. This paper introduces a pipeline framework to monitor construction equipment using attached markers. First, it describes the architecture of the system, and then it explains the modules of the framework. Next, the performance of the system is evaluated using a number of test videos and finally, the potential applications and shortcomings of this hybrid system are discussed.

2 SYSTEM ARCHITECTURE

A straight-forward approach is to simply search for the attached fiducial markers using a marker recognition algorithm in real-time frames. This brute-force approach, however, has several shortcomings: 1) markers should have a certain resolution (in pixels) to be robustly detectable in frames. This requires optical zooming on the work zone, which limits the field of view and eventually results in missing the big picture of the operations and in addition, the work zones often change and someone should adjust the viewfinder accordingly. 2) This brute-force approach is computationally-intensive.

Therefore, a pipeline framework is developed to detect the most probable candidates, and then zoom on these potential targets to get a high resolution view for the marker recognition process. Next, it passes detected machines to a tracking module which monitors the truck until it exits the view. This way, the system would be able to count hauling trips of individual dump trucks. Figure 1 shows the entire process of this system, in which different modules of the framework are highlighted by color.
First, the system grabs 1280x960 (pixels) frames and creates a 640x480 (pixels) resized copy of each frame. The higher resolution frame is kept and only used for marker recognition, and the lower resolution 640x480 frame is used for other processes, including background subtraction and object recognition. The background subtraction module isolates moving particle (see Figure 2.a) and checks whether any of moving particles are larger than a certain size, which triggers the object recognition module. The object detection module searches frame for dump trucks (Figure 2.b) and detection of a dump truck triggers the zoom control element, which changes the focal length of the lens to optically zoom on the target (Figure 2.c). Afterwards, the system applies an autofocus function to obtain a high contrast view (Figure 2.d), and then employs the marker recognition module to search a high resolution 1280x960 frame for a marker (Figure 2.e). Successfully identified dump trucks are passed to the tracking module, which will be tracked until they exit the scene. This confirms the trip of that individual dump truck. Details of each module are described in next section.
3 MODULES OF THE SYSTEM

As described before, this system is made of several components which are described in detail in the following subsections.

3.1 Background Subtraction

Background subtraction methods are used to isolate moving particles from a static background in the videos captured by a stationary camera. Mixtures of Gaussian (Stauffer and Grimson 1999), a Codebook-based method (Kim et al. 2005), and a Bayesian Model-based (Li et al. 2003) were tested in construction videos, in which the Codebook-based and Bayesian-based methods showed promising performance in detecting moving objects in construction videos (Gong and Caldas 2011). Therefore, the Bayesian-based background subtraction method was selected as the first filter of this pipeline framework. In addition, a process, called connected-components analysis (Bradski and Kaehler 2008), was used to remove random noise from the filtered frame and combine the correlated particles, designated “blobs”. The presence of a blob indicates the appearance of a moving object in the video, which might be one of the targets. But the system only selects moving objects for the next step – object recognition – which are larger than a pre-defined threshold. The threshold was defined given the minimum size (in terms of pixels) of a truck that could be detected by the object recognition algorithm. The object detection algorithm uses a sliding window approach with a minimum size of 128x80 pixels to detect trucks, therefore it would be useless to accept a moving particle with smaller size than 128x80 pixels as it simply cannot be picked by the object recognition. As a result, the width and height of the bounding box of a blob to be qualified for the next step should be larger than 128 and 80 pixels, respectively.

3.2 Object Detection

The Histogram of Oriented Gradients (HOG) (Dalal and Triggs 2005) algorithm was used in this research, because this popular object recognition method has provided promising results in detection of construction equipment (Memarzadeh et al. 2013; Rezazadeh Azar and McCabe 2012a; Rezazadeh Azar and McCabe 2012b). Details of the background effort for the object detection module of this framework to recognize dump trucks is described in Rezazadeh Azar and McCabe (2012a). Implementation of this
algorithm using parallel computing on a Graphics Processing Unit (GPU) could dramatically improve the computation runtime (Rezazadeh Azar et al. 2013). The next step in identifying individual trucks is to recognize attached markers, therefore, object recognition searches only for the views in which the marker could possibly be visible. The markers were attached to the sides of dump trucks in this research, thus the object recognition engine searches for the side viewpoints.

The HOG algorithm generally employs a binary classifier, SVMlight (Joachims 1999), in which the classifier uses a threshold to classify candidates. Therefore, the detection threshold of the classifier was lowered in this system to avoid the risk of false negatives (i.e., failing to select views in which a dump truck was visible), although it could also result in more false positives (i.e., selecting windows in which the machine does not exist). This is not a major concern as the next module of this cascade system – marker recognition – is designed to reject the possible false positives.

3.3 Fiducial Marker Recognition

Fiducial marker identification is a well-investigated topic in the field of computer science and several methods have been developed to address this issue. Marker recognition algorithms were initially developed for superimposing virtual objects in augmented reality, but they have been gradually adopted in other field, namely pose estimation in robotics. Fiducial markers are artificial tags designed with a set of black and white features to create simple geometric shapes, such as straight lines, and sharp angles and edges, to be robustly detected in low resolution, rotated, unevenly lit conditions, or in the corner of an occluded image. The fiducial marker recognition methods essentially differ from general 2D barcode detection techniques, such as QR code (Figure 3.a), because they also have to provide the camera position and orientation relative to the detected marker. ARToolkit (Kato and Billinghurst 1999), ARTag (Fiala 2005), and AprilTag (Olson 2011) are among the most popular marker recognition methods. Figure 3 illustrates instances of ARToolkit (Figure 3.b), ARTag (Figure 3.c), and AprilTag (Figure 3.d) markers. AprilTag algorithm outperformed other methods (including ARToolkit and ARTag) in detection rate and localization accuracy under various visual conditions, including distance and the angle between the camera’s optical axis and the tag’s normal (Olson 2011). Therefore, this algorithm was selected as the last step of the identification process.

AprilTag is a sequential algorithm which firstly computes the gradient at every pixel, including magnitudes and direction. Then, the pixels with similar gradient magnitude and direction are clustered using a graph-based algorithm. Afterwards, it fits multiple line segments to form the boundary of each cluster and finally, existing quadrilaterals are detected and decoded to identify a candidate tag ID.

![QR code, ARToolkit, ARTag, AprilTag](image)

Figure 3: Samples of a) QR code, b) ARToolkit, c) ARTag, d) AprilTag

3.4 Zoom control

As mentioned above, detected trucks have low resolutions in the wide angle frames, which are not sufficient for the marker recognition, therefore the system needs to zoom on the potential candidates for marker recognition. The size of the markers (in pixels) is the key factor to robustly detect them, which depends on both the distance and orientation of the marker (Olson 2011). Application of optical zooming could overcome these limitations. A set of experiments was carried to determine the size (in pixels) of an
AprilTag marker to be reliably recognized (>98%). The results are presented in Figure 4, in which an AprilTag marker should be at least 18x18 pixels to achieve more than 98% detection rate. It should be mentioned that no false positive was observed in these tests.

Based on this result, an automated zoom control module is necessary to zoom on the targets to achieve a reliable marker resolution. This module changes the focal length of a motorized lens to provide a resolution sufficient for the marker identification.

![Figure 4: Detection rate of various resolutions of AprilTag markers](image)

First, a set of tests was done to determine a linear relationship between the focal length and the magnification factor of the camera lens. For this purpose, the length of a specific target (in pixels) was measured in the frames captured from the same viewpoint but with altered focal lengths. Second, the module should calculate the magnification factor required to achieve sufficient resolution based on the size of the detected dump truck (in pixels). Then, it finds the corresponding focal length and therefore, sets the focal length of the lens. Magnification factor is determined using the ratio of actual length of the marker to the actual length of the machine (e.g. 0.6m: 8m) and the minimum detectable marker size (18x18 pixels). For example, if the size of a detected dump truck is 200x125 pixels, the expected size of the marker would be 15x15 (200x(0.6/8) = 15), which is not sufficient for robust marker recognition. Therefore, the magnification factor should be 18/15 = 1.2. Moreover, the calculated magnification factor is increased by 20% to compensate the effects of variations in the size of the detected bounding box, and variations in size of different models of dump trucks. Thus, the scale factor of the example would be adjusted to 1.2x1.2 = 1.44.

This module should also examine whether the detected target will remain in the frame after magnification. For example, an object might be detected in the corner of the frame, but it might not remain after zooming, which makes the zoom useless. A scale affine transformation is used to calculate the coordinates of the object in the zoomed frame, and analyze whether it will appear within the zoomed view. This process is illustrated in Figure 5. First, the origin of the coordinate system is moved to the center of the frame as most computer vision applications use the frame’s top-left corner as the origin (see Figure 5.b). This change is due to the fact that the lens zooms toward the center of the view. The coordinates of the detected dump truck (see Figure 5.c) are multiplied by the calculated magnification factor (see Figure 5.d) to examine if the target will appear in the view after zooming.

The magnified frames are usually blurred from the change of the focal length, thus an autofocus process (a function provided by the camera manufacturer) is employed to enhance the contrast of view. Then, the AprilTag algorithm searches the frame for a marker.
3.5 Tracking

The system passes identified dump trucks to the tracking module for monitoring purpose. A hybrid tracking algorithm was developed that provided promising performance in tracking slow-moving objects in construction videos, such as dump trucks (Rezazadeh Azar et al. 2013). This hybrid tracking method uses a combination of the HOG object recognition and KLT feature tracking (Tomasi and Kanade 1991). The hybrid structure of this tracking algorithm allows handling orientation and scale changes of a slow-moving target. The tracking module has two main applications in this system: first, it continually locates the dump after identification until it exists the frame, therefore it can prevent double identification of a dump truck. The system examines the location of the candidates with the location of tracked machines and will ignore the candidates which have more than 50% overlapping area with a tracked machine. Second, it confirms a hauling trip for an individual dump truck when it exits the scene.

4 EXPERIMENTAL RESULTS

This framework was developed in Visual Studio Express 2010 using three open source libraries: 1) IC Imaging Control C++ Class Library for frame acquisition and camera control (The Imaging Source 2014), 2) OpenCV 2.4.4 library for background subtraction and the HOG object recognition (OpenCV 2013), 3) cv2cg library for AprilTag marker recognition (Feng 2013).

This system can only process real-time videos as it must change the focal length of the camera based on the real-time information provided by other modules. Therefore, all the experiments had to be carried out on-site, which limited the testing opportunities. The experiments were done in two stages: First the performance of the system was evaluated using videos of scale model equipment to validate the concept,
and then it was tested using real-world cases. Altogether, eight videos with the total length of 25 minutes and seven videos with the total length of 43 minutes were processed for scale model and actual dump trucks, respectively. Three unique AprilTag markers were attached on three dump trucks in actual test cases. The camera was positioned in overlooking locations to obtain a clear sightline of the hauling operations. Four criteria, including runtime efficiency, precision, recall, and identified trips rate, were used to evaluate the performance of the system.

4.1 Runtime efficiency

This system should be able to operate on a regular computer in real-time. Therefore, all the experiments were carried out using an ordinary laptop with a 2.2 GHz Intel Core i7 CPU, 8 GB RAM, and an NVIDIA GeForce GT 525M GPU. This system has a pipeline structure, which includes a chain of processing elements and the output of each element is the input of the next. Table 1 presents the process times of the compute-intensive elements of this chain. The rest of the elements —such as frame grabbing and zoom control— are simple processes and immediate. It was aimed to achieve five frames per second (5Hz) runtime efficiency, which is sufficient for a real-time monitoring of hauling operations.

<table>
<thead>
<tr>
<th>Operation</th>
<th>Frame size (pixels)</th>
<th>Average process time (millisecond)</th>
<th>Average frame per second (Hz)</th>
</tr>
</thead>

<td>3.3</td>
</tr>
<tr>
<td>AprilTag identification</td>
<td>1280 x 960</td>
<td>400</td>
<td>2.5</td>
</tr>
</tbody>
</table>

The background subtraction and component segmentation are quick processes and meet the requirement, but the HOG object detection and AprilTag identification processes are quite slow. These runtimes, however, did not delay the average five frames per second performance of the entire system as they are occasionally used in this pipeline system. For instance, the object recognition is only triggered when a large moving object is detected and subsequently, AprilTag is merely used when the HOG object detector locates a candidate in a possible zooming region. Moreover, an interval constraint (four seconds) was set to avoid pointless searches. For example, the background subtraction detects a moving entity but the HOG algorithm could not identify a dump truck (e.g. the moving object was a grader), so the HOG will not search the subsequent frame; rather, it waits for interval constraint and then searches for candidates, if there is any. This way, the system could maintain the average five frames per second throughout all the real-time experiments of this research project.

4.2 Identification performance

The experiments were carried out in two stages: scale model machines and actual equipment. The size of the AprilTag labels installed to the real machines was 60 cm x 60 cm, and the same ratio was used for 1:32 scale models which resulted in 1.9 cm x 1.9 cm markers. Table 2 provides the overall performance of the system, which contains three evaluation parameters:

- Recall: True positives / (True positives + False Negatives)
- Precision: True positives / (True positives + False positives)
- Identified trips: Number of identified hauling trips made by individual machines/ total number of hauling trips

Recall and identified trips are two different evaluation criteria as the identified trips only considers detection of dump trucks’ trips whereas the recall also considers unsuccessful identification attempts (i.e., false negatives).
Table 2: Performance of the system in test videos

<table>
<thead>

<td>24</td>
<td>20</td>
<td>28</td>
<td>100%</td>
<td>71.4%</td>
<td>83.3%</td>
</tr>
</tbody>
</table>

A noticeable outcome of these experiments is the precision rate, which was 100% in all test cases. This indicates that the results did not include any false positives, which was mainly due to the robust performance of the marker recognition module in rejection of all false positives. The rates of identified trips were higher than the recall rates in both cases, because the system had several failed marker recognition attempts, in which the marker recognition could not detect the marker in the zoomed frames. In particular, the system was unable to identify a few fast moving trucks, because the system could not zoom and focus on targets on time. This system requires about 1.6 seconds (0.045 sec for background subtraction + 0.3 sec for HOG recognition + 0.25 sec changing focal length + 1 sec autofocus) to grab a zoomed frame for marker recognition, which demonstrated to be too long to identify a marker attached on the fast moving dump trucks. In addition, the system was not able to identify the dump trucks with obscured markers, e.g. by other equipment. This is an inherent disadvantage of any vision-based method compared to radio-based devices, which do not require clear sightline.

5 CONCLUSION

Vision-based systems showed promising performance in detection and tracking of key resources, such as heavy equipment, in construction jobsites. These systems, however, were not able to identify individual machines, which prevent them from providing detailed performance data of each machine. A hybrid vision-based system has been developed which uses a pipeline combination of a background subtraction, an object detection method, and a marker recognition algorithm to identify tagged dump trucks, and then passes them to a tracking module. This system includes a smart zooming feature to zoom on the potential targets for marker recognition. This framework could identify 83.3% of the hauling trips made by dump trucks in construction jobsite. In addition, application of a robust marker recognition algorithm – AprilTag – proved to be effective in rejecting all false positives. Despite the promising performance, some shortcomings, such as limited coverage area and inability to detect fast moving targets, exist with this system. Thus, future research effort aims in addressing these issues by adding smart panning and tilting features to the system, and also tracking of other equipment-intensive operations will be investigated.

Abstract: The key objective of the present article is to use artificial neural network and genetic algorithm optimization techniques along with environmental Life-Cycle Assessment (LCA) methodology to find the optimum building envelope design in an office building for minimization of life-cycle impacts on the environment. Insulation material type, glazing type, window frame material, wall R-value, and window-to-wall ratio (WWR) are the design characteristics of interest. Global warming potential (GWP), acidification potential (AP), eutrophication potential (EP), smog formation potential (SFP), and ozone depletion potential (ODP) are the environmental impact categories of interest. We use eQuest 3.65 and Athena Impact Estimator to simulate the energy and environmental performance of 89 combinations of building envelope design. The results are then used in a hybrid neural network and genetic algorithm approach to find the combination with the least environmental impacts.

Because of significant impacts of buildings on the environment – e.g., about 40% contribution of buildings to fossil-fuel energy use and CO\textsubscript{2} emissions - , the results could raise design teams’ awareness about the impact of their decisions on natural environment.

Keywords: environmental LCA, optimization, building envelope, energy use

1 INTRODUCTION

Life-Cycle Assessment is widely applied to assess the environmental impacts associated with products, projects, processes, and programs (Heijungs and Suh 2002). The quantitative technique uses a four-step methodology (ISO 14040, 2006): goal and scope definition, inventory modeling, impact assessment, and interpretation of results.

Numerous studies have attempted to apply the technique in construction and compare different building materials, systems, and components. Dodoo et al (2014), for instance, uses the consequential-based LCA at the scale of building systems to compare three versions of timber structures; i.e., cross-laminated timber, beam-and-column and modular structures. In a research at the scale of building materials, Tingley et al (2015) applies LCA to compare three different insulation materials when applied in a typical dwelling. As another example, Azari and Kim (2012) use process-based LCA to examine the effect of change in curtain wall mullion materials on life-cycle environmental impact of buildings. Azari (2014) is another
example of LCA studies in which a parametric LCA analysis is conducted by applying an integrated energy and environmental LCA analysis to examine a limited number of combinations of building envelope design characteristics with regard to their impacts on the environment. A limitation of this study, however, is the few combinations that are investigated. This limitation would naturally impair a comprehensive conclusion on the optimum combination of design parameters.

To consider all possible combinations of design parameters, an optimization problem needs to be defined. An optimization problem formulation starts with the identification of design variables and proceeds with identification of risks and constraints, finding the objective function, setting the minimum and maximum thresholds on design variables, choosing an optimization algorithm, and eventually obtaining the results; i.e., the optimum solution (Deb 2012).

The target audience is therefore architects, professional community and researchers in the field of built environment. The main goal of the current study is the establishment of an intelligent LCA optimization algorithm capable of precisely predicting appropriate input parameters, consisting of building envelope design characteristics (insulation material, window frame material, wall R-value, glazing type, south WWR, and North WWR), that would result in desired outputs, i.e. the simultaneous minimization of the main indicators of environmental impacts (GWP, AP, EP, ODP, and SFP). Table 1 shows the input and output parameters of interest.

2 METHODS

In the first step of the present research, we identified 89 combinations of input parameters, out of all possible combinations, as a representative sample of population. We then used a hypothetical two-storey open-concept office building in Seattle (3600-sf floor area; 60-year service life) as the base-case and conducted energy performance modeling, using eQuest 3.65, and life-cycle environmental assessment, using Athena IE, on all 89 combinations of input parameters; i.e. building envelope design characteristics. Seattle was selected because of availability of its inventory data in Athena IE with the assumption that it could be first in a study considering various geographical locations.

To select optimum values of input parameters, a two-step optimization algorithm was developed. In the first phase, each output, such as GWP, was separately modeled with an artificial neural network. To do this, a five-layer ANN was defined with 5-3-4-2-1 neurons in hidden and output layers, respectively. The number of neurons in the input layer equals the number of input variables, i.e. 6 neurons.

To train the defined ANNs and precisely compute their weights and biases, an evolutionary optimization algorithm is used. A well-organized computer program was developed capable of handling a predefined ANN and stochastically computing and readjusting its weights and biases applying genetic algorithm.
evolutionary method. We then used the results of energy and environmental life-cycle assessment for training the above-mentioned ANNs. The data set was randomly divided in training and test subsets in the proportion of 70% and 30%, respectively. All input and output experimental data were normalized in the range of -1 to +1. Moreover, a hyperbolic tangent sigmoid is utilized as an activation function for the hidden and output layers that produces outputs in the range of -1 to +1. The performance of the neural networks was evaluated applying mean squared error (MSE) as the difference between the target output and the network output. The optimization of ANNs was set to stop as soon as its training and test errors reach 1% and 2%, respectively. Figure 1, shows the training error versus epochs for ozone depletion potential output, for instance. It is obvious that the neural network parameters (weights and biases) are continually readjusted and modified by the applied evolutionary algorithm and the error decreases to a predefined minimum at 1%. To illustrate the performance and precision of obtained neural network, the difference between ANN predictions and target values of ozone depletion potential for all data set including training and test subsets is depicted in Figure 2, which demonstrates the compliance between the targets and the ANN outputs.

In the second phase of optimization effort, another computer code was developed to stochastically find the optimal input variables results in minimum environmental impacts applying genetic algorithm optimization method. To do this, six input variables including insulation material, window frame material, wall R-value, glazing type, and south and north WWRs are codified into a chromosome. The number of initial population and mutation percent were set to be 50 and 5%, respectively. Having implemented the trained ANNs into the code, the computer program was capable of precisely predicting and calculating the fitness of each chromosome (randomly generated scenarios for an office building envelope). It is noteworthy to mention that the fitness of each chromosome was defined as the sum of the calculated values of five above-mentioned indicators of environmental impacts. Figure 3 represents the optimization trend.

3 DISCUSSION OF RESULTS AND CONCLUSION

The results of the optimization effort, as shown in table 3, revealed the values of the genes for the fittest chromosome, i.e. the optimal input variables for the office building envelope design. According to the results, an office building envelope in Seattle which consists of walls with the R-value of 21, and about 10.476% north WWR and 59.812% of south WWR, and double-glazed Fiberglass/Vinyl-framed windows would yield the optimum, i.e. the minimum, overall life-cycle environmental impacts.

Figures 4-9 show the impact of changes in north and south WWR on environmental impacts of the building envelope of interest in this study with respect to operational energy, operational energy (OE), Global Warming Potential (GWP), Acidification Potential (AP), Ozone Depletion Potential (ODP), Eutrophication Potential (EP), and Smog Formation Potential (SFP). As figure 4 shows, highest operational energy consumption in double-glazed windows occur at higher percentages of north WWR. In triple-glazed windows, higher north WWR should be concerning only at lowest south WWR.

Acidification Potential generally increases with the increase of windows from both types on north façade. The same pattern is evident in ozone depletion potential in double glazing windows when increase of north WWR elevates the contribution to ozone depletion. Highest ODP in triple glazing windows occur at highest WWR in both north and south facades. Eutrophication Potential also gets to its peak in line with WWR.
Figure 4: Association between operational energy and WWR(%) in double- and triple-glazing.

Figure 5: Association between global warming potential and WWR(%) in double- and triple-glazing.

Figure 6: Association between acidification potential and WWR(%) in double- and triple-glazing.
Figure 7: Association between ozone depletion potential and WWR(%) in double- and triple-glazing.

Figure 8: Association between eutrophication potential and WWR(%) in double- and triple-glazing.

Figure 9: Association between smog formation potential and WWR(%) in double- and triple-glazing.
The optimum south WWR of about 59.8% is in general agreement with the literature and indicates that heating, cooling and lighting loads at this WWR are balanced to yield optimum environmental impacts as well as energy use. R-value of 21 was the highest R-value studied. Achieving R-21 as the optimum R-value did not surprise us as high R-values, and therefore low U-factors, help further limit the heat transfer through the building envelope and would contribute to lower energy use and lower environmental impact. Interestingly, the results supported double-glazed window over triple-glazed window. While triple-glazed windows are considered to be a better alternative in reducing energy use, their greater use of glass increases the overall life-cycle environmental burden associated the building envelope.

4 LIMITATIONS

The present research is subject to several limitations. First, due to limitations of the inventory database of Athena IE and input entry possibilities in eQuest 3.65, limited design variables and limited values for those variables could be examined. The optimization in this research was based on 89 combinations of design inputs. Future research can increase the number of modeled combinations in order to generate a more representative sample of population. Future research can also examine a parametric study that incorporate various building types, geographic locations, climate, building envelope materials, etc.

PUBLIC-PRIVATE PARTNERSHIPS – ANALYSIS OF GOVERNMENT IMPLEMENTATION UNITS

Ahmed M. Abdel Aziz¹,², and Amr Elmahdy¹
¹ Construction Management, University of Washington, USA
² amaziz@u.washington.edu

Abstract: In the international Public-private partnerships (PPP) market, there is a common use of PPP units for the initiation and management of PPPs. The common examples include Partnerships BC, Partnerships UK, and Partnerships Victoria. A PPP unit could be a policy unit, implementation unit, or both. In the United States PPPs have been implemented through the same offices that manage the conventional design-bid-build projects. Content analysis and a case study approach have been used in this research to examine the use of PPP units in the United States. The analysis shows that PPP transportation projects are delivered in the PPP-enabled states through the internal resources of the departments of transportation without centralized government office. Around fourteen states have internal PPP offices that provide partial/full policy formulation/guidance, coordination, and promotion. Only five states have expanded the functions to the real PPP procurement management work, and that those states are also the leading states in PPP implementation. Having a unit that carries only policy guidance might not be as effective as a unit that does both PPP policy and procurement management. Without centralized units, the implementation of PPP would not be effectively streamlined and implemented in government. The analysis also shows that Florida and Texas are expanding their PPP toward more public facilities and infrastructure; this signifies that the more a state became familiar with PPP, the more it used it for the delivery of projects. The research provides insights to public agencies on the use of PPP units.

1 INTRODUCTION

1.1 Background

Public-private partnership (PPP) units are entities established to support the use of PPP in infrastructure development. Their use has been on the rise and the Organization for Economic Co-Operation and Development reported that over half of its member countries have PPP units (17 of 29) (OECD 2010). A PPP unit can take several roles including policy guidance and development, transaction advice, evaluation, and ongoing oversight or contract management throughout the life of a contract. However, PPIAF (2007) mentioned that the idea behind PPP units was not fully grasped in the PPP global market. A review of literature reveals that a PPP unit may have several definitions, structures, features, and roles:

- A PPP unit is “any organization set up with full or partial aid of the government to ensure that necessary capacity to create, support and evaluate multiple public-private partnership agreements is made available and clustered together within government” (OECD 2010).
- “A PPP unit is any organization designed to promote or improve PPPs … have a lasting mandate to manage multiple PPP transactions, often in multiple sectors.” (PPIAF 2007)
A PPP Unit is an entity designed to fulfill functions such as quality control, policy formulation and coordination, technical advice, standardization and dissemination, and/or promotion of PPPs... it is not the procuring agency" (B-R 2011).

“A PPP unit is established as a point of coordination, quality control, accountability, and information related to PPPs either within a single sector or across a range of sectors. These units are created as a new agency or within a ministry such as the finance ministry.” (ADB 2008)

The United States has been expanding the use of PPPs at the state level. Recent statistics from the Federal Highway Administration shows that there are thirty-three states, District of Columbia, and Puerto Rico to have authorization to use PPPs (FHWA 2014). The objective of this research is to investigate and examine the use of PPP units in the United States in terms of their structure, location within government, and the type of functions they do. The first section of the work reviews the general need for PPP units, the organizational structure, and the functions performed by such units. In section two, three international successful PPP units are investigated for their structure, functions, and projects. Section three investigates the PPP-enabled states through content analysis and a case study approach.

1.2 Need for PPP Units

The need for establishing PPP has emerged over time. Initially, governments used PPPs as an approach to attract private finance into public infrastructure delivery that suffers from a shortage of public funding. However, the need evolved into achieving better value for the money (VfM) spent on public infrastructure, and for optimal, rather than maximum, risk transfer that also achieve VfM (PPIAF 2007).

Governments have established PPP units to provide certain capacities that were not available under the traditional public sector methods. Some of these capacities include: designing projects that balance the risks and rewards in a way to attract more of the private sector companies, calculating the cost to taxpayers of such new PPP transactions, establishing managerial and contract management skills to supervise private operations over the long term of such contracts, establishing guidance materials for the different levels of governments, and designing educational/promotional programs about PPPs (WB 2006).

From another perspective, specialized PPP units are created to fix deficiencies that occurred due to different governmental and institutional failures in the PPP management and procurement. (PPIAF 2007).

1.3 Organizational Structure/Type of PPP Units

The most common forms of PPP units are independent units and centralized units (B-R 2011). Another arrangement is where the unit would be established as a central unit or office arranged by sector or division. In an independent model, a PPP unit act as an agency or joint venture fully or partially owned by the government. Examples include Partnership BC, a corporation owned by the BC government, and Partnerships Germany, a mixed corporation (60 percent owned by the government and 40 percent by a holding company). PPP agencies enjoy more freedom from the political effects, and more flexibility in attracting experienced personnel. These agencies would still be regulated by a central government. The independent joint model carries concerns of conflict of interest between the private sector objectives in profit generation and the public agencies accountability and guaranteeing value for money. Joint PPP agencies might be seen as promoting PPP in order to justify their existence as an entity. However, OECD (2010) argued that such concerns could be minimized or prevented by establishing for transparency in all aspects of work, and issuing work rules and conduct.

In a centralized PPP model, a PPP unit would be established in the Ministry of Finance or Treasury, which is the common model among the OECD countries (OECD 2010). While close to where decisions are made and to in-house expertise, this model may suffer from political impacts on how the unit will function or accept projects. Examples of this model are Infrastructure UK and Partnership Victoria.

1.4 Functions of PPP Units

There are several functions that can be performed by a PPP unit, including (ADB 2008, OECD 2010): policy formulation and guidance, procurement management and technical support, promotion and
capacity building (including training), quality assurance/control, and review of proposals, projects, and programs against PPP statutes/regulations.

Some PPP units would be classified as policy units while others classified as PPP implementation units (Abdel Aziz 2007). PPP policy units emphasize on policy formulation, guidance document development, and PPP training. The guidance would include guidelines for PPP options analysis, feasibility, procurement documents (drafting RFQ, RFP, and agreements), negotiations, and post-award contract monitoring. Examples of such policy units include Partnerships Victoria, the Scottish Private Finance Unit, and HMT Private Finance Unit (OECD 2010). On the other hand, PPP implementation units carry out procurement management and technical support functions. The functions would include an assessment of value-for-money, establishing discount rates, allocation of risk between public and private sectors, assistance in the procurement stages (RFQ, RFP, negotiation). An example includes Partnerships BC, which perform procurement management and financial advisory functions. However, a PPP unit can be a multi-function unit, with policy guidance and technical support for the main functions. B-R (2011) raised a concern over conflict of interest for those PPP units that perform both quality control and technical assistance as they would be working by the same rules that they established themselves.

2 PPP UNITS INTERNATIONAL EXAMPLES

2.1 Partnerships BC, Canada

Founded in May 2002 by the British Columbia Treasury Board, Partnerships BC (PBC) performs a comprehensive financial and procurement management in delivering performance-based infrastructure. PBC has completed several projects in healthcare, water treatment, transportation, sports, and education.

2.1.1 Organizational Structure

Partnerships BC (PBC) is an independent corporation wholly owned by the province of British Columbia. PBC is governed by a five-member Board of Directors that reports to its sole shareholder, the Minister of Finance (PBC 2011). The Board of Directors includes members from both public and private sectors that have a substantial experience in developing and managing PPPs, as well as joint-venture projects. The Board's major function is to guarantee that the company's operations and actions reflect the interests of the shareholder. Moreover, two committees support the Board; these committees are Audit and Risk Management Committee, and Human Resources and Governance Committee. The company is managed and operated by a seven-member management team, and is structured into three major strategic service units Projects, Finance and Administration, and Partnerships Services.

2.1.2 Functions and Projects of Partnerships BC

PBC provides three major service categories: business planning support (e.g. project screening, concept plans, procurement options and business case), procurement management (e.g. competitive selection, evaluation, and contract negotiation), and advisory services during the design, construction and operations phases. PBC's mission is to plan and structure partnership delivery solutions for public infrastructure that are expected to accomplish value for money, implement these delivery solutions effectively and maintain a self-sustaining organization through a strong base of clients (PBC 2011). PBC, however, does not have the approval right on projects as it belongs to The Ministry of Finance.

Partnerships status report of February 2015 shows 43 projects of which 23 are operational, 14 under construction, and 6 in procurement. The projects include the following facilities: 16 healthcare, 10 transportation and transit, 4 educational, 4 accommodations, 2 for each of correctional, bio-energy, power, water/wastewater plants, and 1 sports facility.

2.2 Partnerships UK and Infrastructure UK

Following to UK’s Private Finance Initiative (PFI) in 1997, a Treasury Task Force (TTF) was established. TTF had a policy formulation/guidance office and a projects’ office with the main objective to initiate,
standardize, and train on PPPs. By 2000, the projects section was made into Partnerships UK. In 2010, the government reviewed PFI and introduced PF2. PF2 provided more support for PPP in local governments, increasing transparency, adding more scrutiny and testing value for money, and updating guidance relating to financing. Further, Infrastructure UK was introduced replacing Partnerships UK.

2.2.1 Organizational Structure

Unlike Partnerships BC, PUK was a joint-venture with 51 percent private sector and 49 percent public sector represented by HM Treasury. PUK worked closely with the Treasury supporting the different levels of government while maintain the business freedom as in the private sector. PUK operated on a fee-for-service basis, in addition to other funds that came from governments who paid PUK in return for providing assistance for their PPP projects (Farrugia et al. 2008). PUK's structure included more than 70 specialists in procurement, project management, law, finance, accounting and other fields (Farquharson 2009).

Following to the recession of 2008/2009 and the difficulty in obtaining funds, HM Treasury created the Infrastructure Finance Unit (TIFU) to lend PPP/PFI projects using similar terms to commercial lenders. In 2010, HM Treasury developed Infrastructure UK from the government three existing offices - TIFU, the program and project delivery team of Partnerships UK, and the Treasury PPP Policy Unit (Farquharson and Encinas 2010). Infrastructure UK is a unit within the Treasury and governed by the Infrastructure Advisory Council, which is made of fifteen government and private sector members.

2.2.2 Functions and Projects of Partnerships UK

PUK worked as a PPP policy support and project implementation technical support entity. This technical support for project review included value-for-money review, affordability review, project management, stakeholders’ support and risk allocation. It also closely monitored any departures from the standard PPP contracts for all projects before signature. PUK had no decision-making power, its recommendations were enforced through the relevant approval bodies (Farrugia et al. 2008). PUK provided other services such as marketing and promotion of PPPs, policy formulation, and quality control (PPIAF 2007).

The new IUK had several functions mainly, coordinating planning and prioritization of investments in UK infrastructure, securing private sector investments, and achieving higher infrastructure value for money.

Following PFI and by March 2012, the number of PFI projects reached 717 projects (at £54.7 billion) including various project types such as healthcare facilities, transportation, housing, and education. In the 2012/2013 financial year, a total of 15 projects were signed, and 22 projects were in procurement.

2.3 Partnerships Victoria, Australia

In Australia, Victoria has one of the largest PPP programs followed by New South Wales. Established in 2000, Partnerships Victoria (PV) is a unit of the Department of Treasury and Finance (DTF). DTF has established PPP guidelines, requirements, and framework to be followed by each new PPP project; an example is the Investment Lifecycle and High-Value High-Risk Prove and Procure Guidelines. Victoria PPP guidelines promote government objectives including maximizing the efficiency, social and economic returns from government expenditure, promoting growth and sustainability and ensuring value for money.

By 2008, Infrastructure Australia (IA) was established as the federal entity promoting for PPPs and setting PPP policies and guidelines. In consultation with the Council of Australian Governments (COAG), IA introduced the National PPP Policy and Guidelines which superseded all other guidelines that were in use by all other states. Both the national and PV guidelines principally focus on seeking value for money, innovation, market competition and good project governance. PPP projects in Victoria have to follow both the National PPP Guidelines and the specifics of Victoria’s PPP guidelines.

2.3.1 Organizational Structure

Partnerships Victoria (PV) is an office representing one of the seven subgroups under the Infrastructure Advice and Delivery group, which is one of the eighteen groups under Victoria’s Department of Finance
and Treasurer. PV has two teams, policy, and projects. OECD (2010) mentioned PV has 12 full-time employees including the Director of the group. The Government funds PV through its budget. It is worth mentioning that other government departments may have their own PPP experts.

2.3.2 Functions and Projects of PV

Two entities share responsibilities for PPPs in Victoria: 1) the Procuring Agencies of the relevant Portfolio Minister, and 2) the Department of Treasury and Finance and its PV office. In terms of functions, Procuring Agencies establish a procurement team and governance framework, develop a Public Sector Comparator and performance specifications, secure government approvals, manage key stakeholders, and deliver the project based on the National PPP Guidelines and the Victorian PPP requirements.

On the other side, DTF and its Partnerships Victoria arm are not responsible for the direct project delivery or procurement management; their roles are for review, advice, and quality assurance. DTF monitors project risks through the High Value High Risk Assurance Committee, sets as a member of the PPP Project Steering Committee, and is consulted on key appointments (e.g. for project directors, managers, and advisors). DTF/PV must do a review within the PV PPP framework, which include six gateways; review at gate 1 (Strategic Assessment) for preliminary business case, and review at gate 2 (full business case, procurement options analysis, preliminary public sector comparator, public interest test). Approvals for each of the framework gates are to be done by the government through the Portfolio Minister. It is fair to say that PV is more of a policy and oversight PPP unit rather than an implementation unit.

Based on the National PPP Guidelines, infrastructure projects over $50 million are required to be evaluated against a PPP procurement option. Options analysis follows the new National PPP Guidelines Procurement Options Analysis, Victorian guidelines. By February 2015, Partnerships Victoria website reported 24 projects contracted, worth around $12.4 billion in capital investment. These projects included Healthcare, education, correctional center, transportation and others.

3 PPP UNITS IN THE UNITED STATES

The number of jurisdictions authorizing the use of PPP reached 33 U.S. States, District of Columbia, and one US territory. However, the actual number may vary since some states allow its PPP authorization to expire without renewal. This research surveyed those states using state documentation, organizational structures, and online material. With content analysis, Table 1 shows a summary of the findings. A preliminary review shows that a suitable listing of the functions include the following: G - Guidance for policy formulation, and guidelines and best practice development, C - Coordination among the relevant departments and/or with upper authorities or stakeholders, P – Promotion, outreach and training, PM Procurement Management and technical support, and Q – Quality assurance/control.

As shown in Table 1, fourteen states have PPP offices that mainly do a combination of guidance, coordination, and promotion with partial or full capacity. Of those states, five do engage in procurement management in partial or full capacity; those include Colorado, Florida, Puerto Rico, Texas, and Virginia. The rest of the other 34 states has no dedicated P3 office, rely on the resources of the Department of Transportation, and would be supported by external consultants. A more detailed review is as follows.

3.1 California - Public Infrastructure Advisory Commission (PIAC)

California DOT (Caltrans) is one of the leading states for transportation PPPs since enacting Assembly Bill 680 in 1989, AB 521 and AB 1467 in 2006, and finally to Senate Bill Second Extraordinary Session 4 (SBX2 4) in 2009 which is set to expire by 2017. PPP is managed internally by the Caltrans through a PPP Program. The program has five members including members from the Office of Innovative Finance, and the Planning and Modals Office, along with a program manager, analyst, and attorney. The PPP program is supported by the Office of Innovative Finance, which mainly focuses on utilizing innovative public and private financing along with traditional financing. Caltrans PPP Program can be considered as a PPP Coordination office that implements PPP with the help of the finance and planning offices.
In 2009 and following the SBX2 4 Senate Bill, California created a dedicated PPP advisory office, the Public Infrastructure Advisory Commission (PIAC), under the Business, Transportation, and Housing state agency (BTH). In 2013, BTH was superseded by California State Transportation Agency. PIAC has 20 commissioners from diverse backgrounds; academia, industry, and government. The BTH agency funds PIAC. PIAC can only advise Caltrans and the regional transportation authorities (RTAs) on PPP issues. PIAC has several PPP roles and functions including promotion and training, technical support and screening, and policy guidance. However, since PIAC is an advisory group, it still has to build capacity and hire experts to do such functions as procurement management. As concluded by the California Legislative Analysis Office, PIAC has not yet published any best practices, outsources P3 reports, lacks members with state finance, procurement, and labor issues (CLAO 2012). The power to proceed with a PPP project is still with the relevant transportation agency. Also, SBX2 4 statute requires the California Transportation Commission to establish the evaluation criteria for each PPP project, a function that should have been delegated to PIAC! Finally, PIAC should have been created as an independent public agency for all infrastructure types in CA.

By 2013, California was among the top four states that have more than 10 PPP projects; it had 16 projects at a value of $9.5 billion. The PPP Program previously managed SR91 and SR125, and currently working on the Presidio Parkway and has seven projects in the pipeline. The Presidio Parkway was the first project to be reviewed and recommended by the new advisory commission PIAC.

3.2 Colorado – Office of Major Project Development (OMPD)

OMPD was established as an integrated effort between HPTE (Higher Performance Transportation Enterprise) and Colorado DOT. HPTE was created based on the Colorado PPP act in order to seek out opportunities for innovative and efficient means of financing and delivery of important infrastructure. OMPD/HPTE has certain roles including policy formulation and coordination, develop best practices, assessing the feasibility of projects, manage project development and provide technical assistance. By 2013, Colorado had 9 PPP projects worth $5.7 billion, and currently has multiple PPP project.

3.3 Florida – Office of Construction and Project Finance Office

Florida is one of the major states in using PPPs in transportation. PPP is one of the alternative contracting systems administered jointly by the Office of Construction and the Project Finance Office of the State DOT. The Office of Construction had a number of template documents for PPPs such as RFP. The Project Finance Office is one of the four offices under the Office of Comptroller of the State DOT; it...
provides support, coordination, and oversight in the PPP areas of build-finance, DBF, and DBFOM. It is fair to say that there is no dedicated PPP unit. The availability of a dedicated Project Finance Office has contributed to the advances and implementation of PPPs.

As of 2013, Florida had 17 projects worth of $6 billion, and there are other 7 projects under construction as of early 2015; of these projects is the I-4 Ultimate Improvements in Orange & Seminole Counties (a $2.3 billion DBFOM road project), and the Palmetto Section 5 – SR 826/836 Interchange (a $566 million DBF project). It is worth noting that Florida was one of the few states that started the use of availability payment in three of its PPPs, the Port of Miami Tunnel (DBFOM), the I-454 Improvements (DBFOM), and the I-4 Ultimate Improvements (DBFOM). This signifies that the experience in Florida has advanced to start using other forms of contractor’s compensation, a one that is mainly based on performance.

Florida has gone beyond transportation by enacting a new legislation, House Bill in 2013, which opened the door to local governments, counties and cities to use PPPs in social infrastructures and any facilities used for public purposes. A requirement of the Act was to establish a task force that would recommend a uniform process for establishing PPP. This effort was the first cited in the United States and a great step for streamlining PPP as a delivery system for public facilities and infrastructure. However, it lacked introducing a government unit(s) that would consolidate the experience in PPPs.

3.4 Georgia - PPP Program,

In 2009, the state of Georgia passed a renewed P3 legislation to create a P3 program team. This team is located within the Georgia Department of Transportation and is supported by external advisors. It is responsible for developing a policy framework and guidelines to promote P3s as well as identifying potential P3 projects. The office can be considered as a PPP Guidance, Coordination, and Promotion office. PPP procurement management and technical assistance will still be done by the DOT internal resources, e.g. planning, finance, construction, and procurement offices. The team has also started the procurement process for several transportation projects such as I-285 & SR 400 improvements, Northwest Corridor, and Multimodal passenger terminal. Georgia’s P3 framework can accelerate project delivery and encourage life cycle cost efficiencies. However, it solely focuses on transportation projects.

3.5 Illinois – Office of Innovative Project Delivery (OIPD)

Illinois has the OIPD as the small office leading the effort into PPPs. The office objective is to assist in determining the best project delivery method, research, develop policy, develop legislation as needed, deliver, and oversee the procurement of PPP projects. The office can be considered as a PPP Guidance, Coordination, and Promotion office. PPP procurement management and technical assistance will still be done by the DOT internal resources, e.g. planning, finance, construction, and procurement offices. By 2013, Illinois DOT is known for the 2005 Chicago Skyway (99-year long term lease, $1.83 billion) and investigating other PPPs, e.g. the Iliana Corridor project and the South Suburban Airport.

3.6 Massachusetts – Public-Private Partnership Oversight Commission

Following to the Transportation Reform in 2009, the MA legislature created the PPP Oversight Commission. The Commission has a panel of six executives and seven members appointed by the Governor, Senate President and House Speaker, and State Treasurer. The mission was to facilitate the formation of transportation PPPs, to develop, facilitate and promote the use of innovative financing, design-build, and other PPP tools, and to encourage the acceptance of the use of PPPs. The Commission can be considered a PPP promotion and quality assurance unit supported by the DOT resources. MA DOT in 2000 delivered a one DBF project at $385 million; it is the Rout 3 North.

3.7 Minnesota – Joint Program Office (JPO) for Economic Development and Alt. Finance

Following the passage of the 2013 Omnibus Transportation Finance Law (HF 1444), a new office, JPO, was added to MnDOT. The JPO office can be considered as a PPP Guidance, Coordination, and Promotion office. PPP procurement management and technical assistance will still be done by the DOT internal resources, e.g. planning, finance, construction, and procurement offices. While the office has yet
to identify projects, by 2013 MnDOT had 5 DB projects at a total cost of $1.2 billion, including Hiawatha Light Rail, TH 212, St Anthony Falls Bridge, US 52 reconstruction, and I-494 reconstruction.

3.8 Ohio – Division of Innovative Delivery
Following the passage of HB 114, Ohio DOT created the Division of Innovative Delivery to manage its PPP projects. The office has five members. The Division office can be considered as a PPP Guidance, Coordination, and Promotion office. PPP procurement management and technical assistance will still be done by the DOT internal resources, e.g. planning, finance, construction, and procurement offices. By 2013, there were 2 DB projects at a total cost of $487 million, the I-90 Innerbelt Bridge, and the I7/670 Interchange. The office is currently working on the Brent Spence Bridge (DBFOM).

3.9 Oregon – Office of Innovative Partnerships and Alternative Funding (OIPAF)
In 2003, Oregon Legislative Assembly passed Senate Bill 772 to establish the Innovative Partnerships Program (OIPP) within the Oregon Department of Transportation. OIPAF was created as a PPP implementation unit supported by the internal DOT resources, e.g. planning, finance, construction, and procurement offices in order to run the OIPP and evaluate the PPP proposals. Due to limited capacity, ODOT has contracted consultants to assist in procurement, evaluation of proposals, negotiation of agreements, and management of public-private initiatives. The Oregon Transportation Commission has the ultimate authority to approve the projects that go forward and the terms of each agreement.

3.10 Pennsylvania – PennDOT Public-Private Partnerships Office
Pennsylvania is a new to the PPP market with its PPP Act 88 of 2012 which created the PennDot P3 office. The office has an executive board of six members from public and private officials. The office is gearing up as a PPP Guidance, Coordination, and Promotion office. PPP procurement management and technical assistance will still be done by the DOT internal resources. It has a new PPP project, the Rapid Bridge Replacement project (replacement of more than 4000 structurally deficient bridges).

3.11 Puerto Rico - The PPP Authority (P3A)
Following to the Public-Private Partnership Act of 2009, the Public-Private Partnerships Authority (P3A) was established as a centralized dedicated PPP unit for managing PPPs in public infrastructure, schools, rail, social infrastructure, airport, roads, and water. The P3A Authority is responsible for promoting PPP policy and has developed regulations/procedures for PPPs. The P3A Authority is involved in all aspects of PPP including identifying projects, requesting proposals, selecting the proponent, negotiating the contract and monitoring contract compliance. It is fair to say that the P3A carries all functions of a PPP unit in policy guidance, promotion, and procurement management. The P3A has developed a list of candidate/priority PPP projects in schools, rails, roads, social infrastructure, airport, and water facilities. By 2013, there were two projects with total value of $3.7 billion, the PR Highways (long-term lease, $1.44 billion) and the Tren Urbano Rail (DB, $2.25 billion).

3.12 Texas – Strategic Projects Division
Texas is one of the top four states using PPP; as of 2013, it had 13 projects at a value of $12.9 billion. Some of the projects developed include: LBJ Managed Lanes (DBFOM, $2.6 billion), North Tarrant Express (DBFOM, $2.04 billion), SH130 Segment 5-6 (DBFOM, $1.36 billion), Grand Parkway (DBFOM, $1.04 billion), and North Tarrant 3A/3B (DBFOM, $1.4 billion).

Texas DOT established the Strategic Projects Division to oversee procurement policies, right-of-way acquisition and to support activities for public-private partnership agreements known as Comprehensive Development Agreements (CDAs). It is fair to say that the Division is a PPP Guidance, Coordination, Promotion, and technical assistance (procurement management) office. PPP procurement management will still be done by the DOT internal resources, e.g. planning, finance, construction, and procurement.

Moving beyond transportation, in 2011 Texas enacted the Public and Private Facilities and Infrastructure Act (S.B. 1048) which provided for using PPP in nearly all public facilities (e.g. transit, power generation,
water/waste water facility, or other similar facility needed for public use). This will be managed by the Texas Facilities Commission, which is the real estate representative of the State of Texas in the purchase of buildings, grounds and property. However, still no dedicated PPP unit.

3.13 Virginia - Office of Transportation PPP (Virginia P3)

In 2010, Virginia Office of Transportation Public-Private Partnerships (Virginia P3) was created following a review of Virginia’s Public-Private Transportation Act (PPTA) of 1995. Virginia P3 is a dedicated public PPP unit, responsible for developing and implementing a statewide program for transportation PPPs. Virginia P3 is located within the Virginia Department of Transportation (VDOT) and reports to and works with the Secretary of Transportation. Virginia P3 has ten members and augmented by consultants in two groups: business management services and financial services. The Secretary of Transportation funds it.

Virginia P3 works through the PPTA Implementation Manual and Guidelines. At the program level, it is responsible for overseeing the P3 program including outreach and stakeholders coordination. At the project level, Virginia P3 works collaboratively with other state transportation and aviation agencies using a four-stage PPP project, namely project identification, screening, development, and procurement. For example, during project screening, Virginia P3 conduct detailed screening and makes recommendation to the procuring agency to make a final decision; if approved, they both submit a recommendation to the PPTA Steering Committee to make a final recommendation on whether a project should advance or not. During project development, it works with Agency in assessing a procurement strategy, conducting initial value-for-money analysis, and developing procurement documents. Along with working with the procuring agency administrators, Virginia P3 works with the PPTA Steering Committee and the Oversight Boards. With the support of Virginia P3 on the issues/terms of PPPs, the agency administrators have several decision points during the process as they represent the final authority for a project.

By 2013, Virginia is another one of the top four states that have more than 10 PPP projects; it had 12 projects at a value of $11.6 billion. A number of recent projects include 595 Express Lanes ($1.9 billion), 95 Express Lanes ($925 million), and the Midtown Tunnel ($2.1 billion). Virginia P3 is a successful step toward streamlining PPPs in Virginia; it does the common functions of PPP units while the responsibility for the PPP projects is still with the procuring agencies. The unit is for the transportation infrastructure; the state has yet to investigate if it would have other units for the different types of infrastructure.

3.14 Washington State – Transportation Partnerships Office (TPO)

WSDOT has an authority to engage in agreement of PPPs. The agency’s office to do that is the TPO. In addition to WSDOT, however, the 2005 PPP law authorized a process called Transportation Innovative Partnership (TIP) program to evaluate the potential transportation PPPs but restricted the use of private finance. The Washington State Transportation Commission (WSTC) has an oversight role over the TIP program and a final approval authority of such PPPs. WSTC provided WSDOT’s TPO to carry out the TIP program’s functions and responsibilities. In summary, TPO has activities that include consultation and advisory services, analysis and assessment, project development, and liaison and representation. TPO, however, has a limited budget (less than $350,000/yr) that funds the office’s three members and all other activities. Since the 2005 law, there were no significant transportation PPPs reported by the state. It is fair to say that TPO is a PPP Guidance and Coordination office supported by internal WSDOT resources.

4 CONCLUSION AND RECOMMENDATION

PPP units are becoming an important vehicle to implement PPPs. A unit can have one or more functions including, policy formulation and guidance, procurement management and technical support, promotion and capacity building (including training), and quality assurance/control against PPP statutes/regulations.

PPP units can be established as a centralized unit under a finance or treasury department where it can work with all other government departments. It can be an independent public agency that report to a treasure or a higher level council. With these two locations, the unit can work at a full or partial scale performing all the functions including procurement management. At the minimum, a PPP unit can be just an office under a department of transportation or another relevant department. In this case, the unit/office
would have limited functionality and a necessity to rely on internal resources (another government office such as construction, finance, and procurement) for PPP procurement management.

Among the international units reviewed in this research, Partnerships BC stands as an excellent example of a unit that performs most of the functions of a PPP unit, particularly procurement management and technical support. Its location as an independent agency gives PBC flexibility in managing its own portfolio without being under political pressures, while still being a public agency owned by the BC Treasurer, and can be self-sustained without a government budget line. In UK, the several years of experience under PFI/ PF2, guidance documents, and hundreds of PPP projects, sufficient PPP knowledge base has been established at the different levels of government. This has provided for Partnerships UK to be another good example of a PPP unit, however, with mixed private and public ownership. Infrastructure UK came to merge the roles of Partnerships UK, and other finance and policy units. With the maturity of PPP in UK, it is expected that Infrastructure UK will emphasize more on the roles of policy formulation, quality assurance, and technical assistance rather than procurement management. Partnerships Victoria was another good example of a unit that has roles in policy guidance and review/quality assurance while leaving procurement management to the procuring agencies.

The survey of PPP units/offices in the United States revealed that most of the PPP-enabled states rely on the internal resources of the departments of transportation. Fourteen states have PPP offices/units. All of such PPP offices provides, partial or full, policy guidance, coordination, and promotion roles, and only five of them have real PPP procurement management and technical support roles.

It is no surprise that the best states using PPPs are those that also have PPP units that do partial/full procurement management along with the regular guidance, coordination, and promotion duties. These states include Florida, California, Texas, Virginia, and Colorado. California and Florida had dedicated offices for innovative project financing, and this should have added significant capacity in financing to pursue more PPP than other states.

It is also found that nearly all the PPP-enabled states have their PPP offices in the Department of Transportation and that they do not have the authority to approve projects that are given to the upper administration. A significant finding was that Florida, Puerto Rico, and Texas are expanding their PPP implementation (new acts made) beyond transportation to include schools, hospitals, water facilities, and other facilities and public projects. This also signifies that the more a state becomes familiar with PPPs, the more it is likely to expand it beyond transportation facilities.

Abstract: Safety hazards are one of the major challenges facing construction industry across the globe. Despite a growing literature on assessment of construction safety, the majority of the existing studies are descriptive in nature, do not capture the specific conditions of construction operations and provide one-size-fits-all strategies for enhancing the safety of construction projects. On the other hand, productivity improvement is also a main concern in construction projects. However, the research effort addressing both safety and productivity improvement concerns is still missed in the construction industry. Among different tools used for construction project planning and productivity improvement, discrete event simulation is a well-known tool which has been widely used for analyzing and improving complex construction operations. In this research, for the first time, we are proposing a simulation based framework which concurrently follows safety and productivity improvement in construction projects.

1 INTRODUCTION

Job safety and productivity improvement are main interests in many construction projects. There is a growing literature in construction industry for enhancing safety in projects (e.g., Jannadi and Almishari 2003, Seo and Choi 2008, Zhou et al. 2011, Hinze et al. 2013, Votano and Sunindijo 2014). Improving productivity of construction projects has also been a big concern for many scholars (e.g., Maloney 1983, Arditi 1985, Roseefeld et al. 1992, Han et al. 2008, Zhai et al. 2009, Gouett et al. 2011, Borg and Song 2014). Despite the large number of research efforts done for enhancing safety and productivity in construction projects, construction industry is still missing the research efforts addressing simultaneous improvement of the both aspects. The need for this type of research efforts is more felt when we see mutual impacts that safety and productivity can have on each other in construction jobsites. For example the chance of job hazard is increased when improvement in work productivity amplifies jobsite congestion. Cumbersome safety systems, on the other hand, restrain work productivity and increase the costs of construction jobs. As a matter of fact, there is a big resistance from many construction managers to acquiesce to the safety regulation and enforce safety codes in the construction sites as they see it a non-productive and expensive part of the job and assume it a break on the work progress; this is especially the case in developing countries where construction jobsites are not frequently inspected by safety officers. Increased number of hazards and decreased productivity in construction jobsites are outcomes of this single-dimensional view to the work safety and productivity.
Among the different tools used for improving construction projects productivity, as a result of its capabilities to capture operation details, discrete event simulation (DES) has been widely used in the construction industry. DES capability for modeling complex construction operations has been proven by applying it in a variety of construction operations such as earthmoving (e.g., Farid and Koning 1994), lifting (e.g., Nam et al. 2002), piling (e.g., Zayed and Halpin 2004), pipeline construction (e.g., Lou and Najafi 2007), excavation (e.g., Marzouk et al. 2010) and road construction operations (e.g., Mostafavi et al. 2012). In this research we have introduced a new framework which uses capabilities of DES for modeling construction operations and has exploited it to concurrently model and evaluates safety and productivity levels of different operation scenarios. The framework enables construction project managers to select a scenario which fulfills safety and productivity concerns in the best way. Proposed framework has been tested by modeling a fabricated example of roof tile installation operation; safety and productivity levels of six different operation scenarios have been evaluated and compared in this example and the most suitable scenario has been identified.

2 SAFETY EVALUATION OF CONSTRUCTION OPERATIONS

Safety enhancement is not possible without obtaining a robust safety evaluation method which points the improvable parts of the job. Though, depending on the time and the scope of evaluation, safety evaluation itself can be done in different directions. After a review of safety evaluation research efforts done for construction projects, we identified four main directions for them.

1. Safety performance evaluation: These research efforts are focused on defining safety performance indicators using different project safety outcomes such as the number of accidents, the number of first aids and medical aids, the number of injuries and the time lost. Project safety improvement in this type of research efforts is sought by trending and analyzing values of safety performance indicators.

2. Safety system evaluation: This type of safety evaluation follows a holistic view to the safety, similar approach safety standards such as OHSAS18001, ILO-OSH 2001 and Z1000 pursue. Safety system evaluations or audits in this point of view to safety evolution, is done by direct inspection of different parts of the company to check the compliance of different parts of the organization to the safety procedures, codes and regulations. (e.g., Griffith 2011, Alvanchi and Kanerva 2012).

3. Safety evaluation of job site condition: In these research efforts the safety condition of the job site and its relation to specific job hazards are evaluated. (e.g. Huang and Hinze 2003. Sacks et al. 2012)

4. Project safety risk assessment: Project safety risk assessment is a widely used safety planning method in construction projects. In this method likelihood and severity of possible hazards (or hazard potentials) are estimated based on the project condition. Proper responses are suggested to prevent, control, or transfer risk of hazards during the course of the project. (e.g., Jannadi and Almishari 2003, Mitropoulos and Namboodiri 2010, Lee et al. 2012)

Among these four directions, in the first two directions researchers have based their evaluation methods on the implementation or construction phase of the project and use implementation records for safety evaluation; these approaches pursue a passive perspective to the safety improvement, i.e., improve wherever deficiency has occurred. In the third direction researchers follow a general view to the jobsite safety condition rather than evaluating and improving a specific safety project. Direction four refers to the safety evaluation methods done for a project during the planning phase. Therefore, in terms of safety evaluation method, our ex-ante approach to the safety hazards follows this direction of safety evaluation.

Accuracy in estimation of hazard potentials is a major concern in the research efforts done for safety planning. For example, Jannadi and Almishari in 2003 developed a computerized safety assessment program which bases its estimation on the historical data collected for injuries occurred in different construction activities. This research, however, disregards dynamic nature of construction jobsites, i.e., result of historical data collected from different construction sites, with their specific work conditions, are not necessarily applied to another construction project with its unique work condition; the safety level estimated in this research contains a level of bias depending on the variation of the work condition. In
Identify hazardous operations

Operation assessment

Simulation model of operation

Evaluation of safety and productivity of scenarios

Figure 1. Different parts of the framework

4.1 Identify hazardous operations

Although in recent years simulation software packages have been improved a lot and development of simulation models has become much more easier for model developers, but still development of simulation models requires more efforts compared to traditional planning tools such as CPM or EVM; we need to make sure that we are going to do the simulation modeling for the operations that are in our priorities for safety improvement. In fact, there might be operations which are not considered as hazardous operations, based on the organization past experiences. So, the first part of the framework is to identify most hazardous operations within the project. This can be done by a team of project manager, HSE team members, project planners and any other key project participant at the project manager’s discretion (namely project team) via review of past records, jobsite condition and the project’s priorities.

4.2 Operation assessment

Every operation which is going to be simulated needs to be analyzed in two main aspects including 1) alternative scenarios and 2) possible hazards and influential factors.
4.2.1 Alternative operation scenarios

Alternative operation scenarios are formed by deviations in activities and/or resources. These deviations can cause change in the operation’s safety and productivity levels for different scenarios. In fact, in many cases (e.g., Lamptey 2010, Namboodiri 2010, Dikmen, 2012, Liu, 2005) one of the main concerns construction managers are dealing with during the planning phase is to find scenarios with the most suitable combination of safety and productivity levels. So, simulation of construction operations, which is the main approach for evaluating safety and productivity levels of hazardous operations in this research, is basically the case if there is more than one alternative scenario for an operation. To be able to develop simulation models of construction operation scenarios, orders and durations of activities done in an operation as well as the number and types of resources required should be estimated. These estimations are usually based on past records and project expert judgement.

4.2.2 Possible hazards and influential factors assessment

Possible operation hazards as well as influential factors affecting those hazards should be recognized and quantified to be able to incorporate them in the simulation model. First, we need to assign relative weights to different hazards; this relative should be assigned by project team considering past hazard experiences. Then, we need to measure the impact of changes in values of influential factors on hazard potential. The quantification process itself can be a challenging process; moving from one company to the other or even from one project to the other within a company can change the extent of influential factor impact on hazards. It should be considered that organizational and environmental factors, such as workers skill, climate condition, geographical condition, safety equipment used and past experiences, play significant roles in hazards and influential factors quantification (Mitropoulos et al. 2009). For example working in a windy region might cause more concern for the height falling hazard during steel installation operation while working in a hot region might create more concern for workers dewatering threat during the job. In fact, many safety quantification data collected for a project operation are only valid for that specific project; a mechanism through which safety measurement data is collected and validated for a project is required.

At the first step of influential factor assessment it is suggested that a list of possible influential factors be prepared. As proposed by Mitropoulos et al. (2009), to be able to better recognize a variety of influential factors better, we divide influential factors into three main categories including: task factors, environmental factors and work behavior factors. Activity factors are influential factors affecting activity condition and can increase/decrease hazard potentials during activity. Activity height, distance to the edge, equipment specifications, and material movement distance are some examples for activity influential factors. Environment factors return to the environmental condition in which work is done such as wind, light, temperature, humidity and topography. Operation factors refer to the work congestion and concurrency of different operations. Shared workspace, shared equipment and equipment speed in an adjacent operation are some examples for operation factors. It is recommended for every operation a table, presenting different hazards and related influential factors, is drawn as the output of the first step. The table is going to be completed in next two steps.

The Second step of influential factor assessment is to set thresholds and range of values of influential factors. For example working within 1.8 meter distance to the edge can create a more hazardous condition than beyond 1.8 meter. Safety codes and standards, past hazard reports and team members’ past experiences are the main assets for this step. The output table at step one is more completed by writing down different ranges next to each influential factor. At the third step, the extent of the impacts of different values of influential factors on hazard potential is determined by the project team. The use of a three level rating method proposed by Mitropoulos and Namboodiri (2010) in TDA method, as discussed in section 2, is recommended here. At this step team members evaluate impact of every value range of each influential factor by assigning 1 (low impact), 3 (moderate impact) or 9 (high impact) ratings. Team members are encouraged to use output table from the second step to assign proper rates to the value ranges of influential factors. Table 1 presents a sample output from implementation of three steps of hazard and influential factor assessment.

4.3 Simulation model of operation

Productivity evaluation of construction operations is a common output from DES models (Martinez 2010). But, the use of DES models for evaluation of safety level is a new approach we are proposing in this research. To be able to evaluate safety levels of different operation scenarios we need to make sure the model can trace changes in hazard influential factors, especially when they pass their thresholds. For calculating safety level of an operation scenario, Mitropoulos and Namboodiri (2010) were videotaping the operation and manually changing ratings of influential factors when their values cross thresholds. In our approach, however, DES model traces change in value of influential factors over time and automatically calculates the level of each hazard at a given time by multiplying rates of its different influential factors. Total safety level of an operation is then calculated by considering relative weights of different hazards. In addition, work productivity level of an operation is calculated simultaneously by calculating cost of workers and the equipment (and material, if it is a source of deviation in scenarios) used in the operation. In our simulation based approach when the model of a base scenario is developed, development of other scenarios (usually) requires minimal efforts by simply deviating DES model elements from the base model. So, capacity of the proposed framework to easily evaluate outcomes of different work scenarios is an advantage of the framework compared to the TDA method proposed by Mitropoulos and Namboodiri (2010). For detailed explanation on DES model development and simulation processes please refer to Banks et al. (2005).

4.4 Evaluation of safety and productivity of scenarios

Dimensionless values of safety levels and dollar values of productivity levels measured are main outputs of an operation simulation model. In cases where a scenario scores the minimum cost and hazard potential, simply this scenario is considered the best scenario. However, it will not happen in most cases. So, to be able to compare results achieved in different scenarios properly and select the most suitable scenario we need a comparison method which works for all situations. Our suggestion is a normalization method in which safety and productivity values are transferred to the range of 0 to 100. More explanation for the proposed normalization method follows.

4.4.1 Normalization of safety

The safety results calculated for scenarios represent hazard potentials of scenarios, i.e., lower values are more favourable. The normalization method is in a way that can address our two main concerns. First, we aimed to be able to distinguish major and trivial safety value differences in different scenarios; it is very important to avoid giving extra credits to trivial safety improvements and degrading substantial safety improvements. Second, we were interested in setting higher values as higher priorities, as a prevalent approach used in grading. Our proposal for addressing the first point, again, is to refer to the project team and ask them to set a desirable value of safety or hazard potential improvement (namely SDV); it is going to be set in percent. For example, while 3% safety improvement, as a result of organizational culture and past experiences, can be assumed a desirable improvement for a project team, another project team might consider 10% safety improvement as a desirable improvement. It is important that improvements close to the desirable value can be easily seen by comparing different scenarios. We also do not expect to receive much higher improvements than desirable improvement, during comparing safety results.
Furthermore, as improvements get more distance from the desirable value (i.e., are reduced) their level of significance decreases and we need to see this reduction in improvement level.

In our normalization method, we assume 0 to 100 represents a range equal to twice of the desirable safety improvement value (DSV). Suppose SSb represents the scenario with the best (or minimum) hazard potential score, SSw is the scenario with the worst (or maximum) hazard potential score. We set the middle value (SSm) as formula below:

\[ SS_m = \frac{(SS_w + SS_b)}{2} \]

In the normalization method SSm or middle value reflects value of 50 (at the range of 0 to 100). But depending on the improvement achieved SSw is normalized to a point between 0 and 50 (namely SNw) and SSb is normalized to a point between 50 and 100 (namely SNb). However, their transferred points are symmetric about 50. If SSi represents hazard potential score of its scenario, its normalized value or SNi is calculated as formula below:

\[ SN_i = 50 - \left(\frac{SS_i - SS_m}{SS_w / DSV}\right) \times 50 \]

To calculate normalized values for the best and the worst scenarios, simply replace SSi with them. For example if hazard potential values for an operation with 3 scenarios have been calculated as 25, 27 and 31 with desirable safety improvement of 10% set by the project team, normalization calculations, using formulas 1 and 2 are:

SSm = (31 + 25) / 2 = 28

SN1 = SNb = 50 – (25 – 28) / 31 / 10% * 50 = 98.4
SN2 = 50 – (27 – 28) / 31 / 10% * 50 = 66.1
SN3 = SNw = 50 – (31 – 28) / 31 / 10% * 50 = 1.6

**4.4.2 Normalization of Productivity**

The Similar approach followed for normalization of safety is followed for productivity too. The only difference here is that the values scored for each scenario here have monetary unit. With similar approach and different notation for the desirable productivity improvement value of DPV, scenario with the best productivity value of PSb, scenario with the worst productivity value of PSw, middle value of PSm, productivity value for its scenario of Psi and its normalized value of PNi, related formulas are:

\[ P_S_m = \frac{(PS_w + PS_b)}{2} \]

\[ P_N_i = 50 - \left(\frac{PS_i - P_S_m}{PS_w / DPV}\right) \times 50 \]

**4.4.3 Scenario comparison**

Combining normalized safety and productivity values achieved, for example, by assigning priority or weight to them, is possible but it is a challenging issue. At its simplest way, we can ask project team to set weights for safety and productivity and simply calculate final values of different scenarios to be able to select the best scenario. However, at this stage we propose a colour coded two dimensional X-Y diagram, with productivity values represented on the X axis and safety values represented on the Y axis (Figure 2). The diagram has been divided into four areas by intersection of middle values (i.e., 50):

- Area 1 or green area: Holds scenarios with high safety and productivity levels
- Area 2 or yellow area: Scenarios with high safety and low productivity levels fall into this area
- Area 3 or orange area: Scenarios with high productivity and low safety are seen in this area
- Area 4 or red area: Holds scenarios with low safety and productivity levels
In general, scenarios within area 1 are more desirable. However, depending on the project team’s priority, scenarios within area 2 (with project team priority on safety) and area 3 (with project priority on productivity, might be selected as well. Distance to the middle values is also another effective factor. It is likely that a project team rejects scenarios within area 1, but very close to middle point and accept a scenario within area 2 with high standing in safety and minor distance to the middle value of productivity.

5 FRAEMWORK IMPLEMENTATION

To test different features of the proposed framework, different steps of the framework have been applied to a fabricated roof tile installation operation. Since this is a fabricated operation rather than an actual project, in this test we skip step one to “identify hazardous operations”. Furthermore, a group of authors have played the role of project team with inputs from literature.

5.1 Operation description

In this operation there is one worker on the ground that loads and hoists roof tiles to the top. Another worker works on the roof top that, first, depots tiles on the roof and, then, installs them. Main specifications of the roof are:

- Roof pitch is 1 to 3
- Roof area is 9 m long and 4 m wide
- Roof has a fall protection guard on the width but is not protected on the length
- Tiles have dimension of 25 cm to 35 cm; with tiles overlapping the effective dimension is 20 cm to 30 cm

5.2 Operation scenarios

Six different scenarios are evaluated and compared in this example. Different scenarios are created as a result of using different depot arrangements and different types of hoists with different capacities and working speeds. Figure 3 illustrates the roof specifications and two main depot arrangements types on the roof used in different scenarios. Table 2 presents main characteristics of different work scenarios.
5.3 Influential factors assessment

Falling hazard is the hazard identified for this operation. Three influential factors are identified for this hazard including: the roof pitch, the distance to the not-protected edge and the workers movement. Table 3 presents influential factor assessment for the roof tile installation operation.
Table 3: Influential factor assessment for roof tile installation

* There is no change on the roof pitch during the operation and its value is considered constant.

5.4 Simulation model assessment

Simulation models are developed in Anylogic simulation program. For productivity calculations based on Iran’s construction market, equivalent hourly rate of 2.5 US$ is considered for the hoist operator and equivalent hourly rate of 5 US$ is considered for the tile installer. In addition hourly rate of hoist rental for bucket sizes of 10, 15 and 20 tiles are respectively considered as 2 US$, 2.5 US$ and 3 US$. Table 4 presents raw and normalized results achieved for productivity and safety level of each scenario. Desirable improvement for both productivity and safety levels is set as 10%. A comparison between results is also illustrated in colour coded diagram in Figure 4.

* This price is related to the cost of hoist rent and Labors.

Figure 4. Colour coded diagram presenting normalized result achieved for scenarios
Among different scenarios, scenario 3 has scored the lowest hazard potential value and has the best safety level with normalized value of 84. In regard to the productivity scenario 4 has the lowest cost and highest productivity level with normalized value of 81. At a fast glance to the colour coded diagram, scenario 2 in area 1, with a relatively high safety and productivity levels, is the first scenario to be selected. However, final scenario selection can be changed due to the project team priority.

6 CONCLUSION

Safety and productivity improvement is a day after day concern of construction project managers. Although many research efforts have been done to improve safety and productivity of construction projects, the research efforts addressing these two aspects of construction projects are still missed. In this research we proposed a new simulation based framework to concurrently evaluate safety and productivity levels of construction operations. The framework helps construction project managers to select most suitable alternative operation scenarios, especially for hazardous operations within a project. It involves project team members in different steps; it uses their related past experiences and incorporates their concerns during the decision making process. In this perspective the framework tries to model and evaluate the work condition as realistic as possible. To assess different features of the framework we applied the framework to a fabricated example of a roof tile installation operation. However, more validation efforts for applying the framework to real construction projects are still in progress.

ASSESSMENT OF NETWORK-LEVEL ENVIRONMENTAL SUSTAINABILITY IN INFRASTRUCTURE SYSTEMS USING SERVICE AND PERFORMANCE ADJUSTED LIFE CYCLE ANALYSIS

Mostafa Batouli¹,³, Ali Mostafavi²
¹ PhD Candidate, Department of Civil and Environmental Engineering, Florida International University, USA
² Assistant Professor, OHL School of Construction, Florida International University, USA
³ corresponding_author_sbatouli@fiu.edu

Abstract: Managing environmental impacts of civil infrastructure systems is critical for fostering sustainable development. However, despite the growing body of literature, an integrated methodology that captures the specific traits of infrastructure systems for a network-level environmental impact assessment is still missing. The objective of this paper is to propose a novel methodology [called Service and Performance Adjusted Life Cycle Assessment (SPA-LCA)] for addressing the limitations of the traditional LCA in environmental assessment of infrastructure networks. The SPA-LCA methodology adopts a service-based accounting approach to enable aggregation of the impacts pertaining to assets with different functions and service life expectancies at the network level. In the proposed SPA-LCA methodology, first, through conducting traditional asset-level LCA, life cycle inventories for the assets are determined. Second, the life cycle inventories are disaggregated to performance-sensitive and non-sensitive impacts. Then, using a hybrid mathematical/agent-based simulation model, the levels of service and performance are simulated for different assets in the network across the analysis horizon. Finally, the environmental impacts are determined for each year based on the levels of service and performance. The application of the proposed SPA-LCA method is demonstrated in environmental assessment of a road network. The results highlight the capabilities of SPA-LCA in providing better insight regarding environmental performance of infrastructure networks.

1 INTRODUCTION

With the growing awareness of environmental protection, decision makers are increasingly interested in careful assessment of the environmental impacts associated with civil infrastructure networks. However, the majority of the existing environmental assessment studies are based on asset-level models, which cannot fully capture the environmental impacts at the network level. There are fundamental differences between asset-level and network-level environmental assessment of infrastructure (Öberg et al. 2012):

1. Asset-level impacts mostly depend on technical solutions (Vanier 2001). For instance, the environmental performance of a single road depends on a technical plan that determines the design specifications and identifies the timing and type of future maintenance/rehabilitation activities. However, at the network level, non-technical considerations (such as financial plans corresponding to allocation of resources among several assets with competing maintenance needs) also affect environmental performance (Zhang et al. 2012).
2. Environmental impacts of an asset are assessed within the service life of the asset (i.e. from construction to demolition and reconstruction of the asset). However, infrastructure networks do not have a definite life cycle. Instead, at the network level, the objective of network management determines the analysis horizon. Objectives may be related to short-term operational, mid-term tactical, and long-term strategic planning horizons (Vanier 2001).

3. Management of a single asset is mainly consisted of decisions made at the time of asset design. However, the management of infrastructure networks is an ongoing process involving multiple stakeholders whose adaptive decision-making processes and behaviors affect the environmental impacts of these networks over time (Osman and Nikbakht 2014; du Plessis and Cole 2011).

4. Asset-level infrastructure management is solely focused on “objects” (i.e. projects or facilities). However, at the network level, the focus is on objects and their interdependencies (functional, budgetary, and resource) (Öberg et al. 2012; Vanier 2001).

Life Cycle Assessment (LCA) is a widely used environmental impact assessment method which was initially developed for assessment of manufactured products (ISO 14040 2006). Due to its unique capability in compilation and evaluation of the potential environmental impacts, LCA has now become a dominant method for assessment of environmental performance in infrastructure. However, LCA has certain methodological limitations that affect its reliability for network-level environmental assessment. First, LCA provides a lump sum assessment of environmental performance by compiling the potential environmental impacts of a product throughout its expected service life (ISO 14040 2006). Such analysis assumes that the performance of the product is uniform throughout the analysis horizon which is contradictory with the varying nature of service and performance in infrastructure networks. The lump sum outcomes of LCA are most useful for manufactured products for which decision making is usually a single task done during the design or procurement of the product. However, in infrastructure networks, decision making is an ongoing process, which has significant implications particularly in use/operation phase when decisions about timing and type of maintenance and rehabilitation of infrastructure are made. Second, LCA is a static method in which the dynamic changes in the level of service and performance are not considered. The level of service and performance in infrastructure networks is affected by the decision-making processes and behaviors of stakeholders. LCA is not capable of capturing these dynamic behaviors affecting the performance and level of service in infrastructure networks. Finally, LCA has been developed based on the premise that a sustainable approach is the one that minimizes the environmental impacts per functional unit for a product. This approach is valid when the life cycle is definite and functional unit is unique. However, infrastructure networks have a continuous service life and serve multiple performance functions. Hence, for infrastructure networks, a sustainable approach is the one that provides the longest service life and greatest performance with the lowest environmental impacts. Hence, an appropriate methodology for assessment of environmental impacts in infrastructure networks should consider the following: (i) Continuous service life of networks; (ii) Dynamic changes in the level of service and performance of networks affecting the environmental impacts; and (iii) The decision making processes of stakeholders affecting the level of service and performance in infrastructure networks.

An integrated methodology that captures the requirements of network-level environmental assessment in infrastructure is missing in the existing literature. The objective of this research is to address this gap in the body of knowledge by creating a network-level environmental assessment methodology that considers the specific traits of infrastructure networks.

2 BACKGROUND

The majority of the existing environmental assessment methodologies are based on an environmental accounting principle in which the environmental events are recognized at the time when emission occurs or natural resources are depleted. This accounting principle is prone to shifting burdens from one location to another (Hoekstra and Janssen 2006), or from one stage of life cycle to another stage (ISO 14040 2006) [e.g., by postponing the required maintenance of a road and creating a need for earlier reconstruction]. Life cycle assessment has successfully solved this problem for asset/product-level environmental assessment by taking all the impacts related to the entire service life of the asset/product.
into consideration (ISO 14040 2006; ISO 14044 2006). However, when it comes to network-level environmental assessment, individual assets have different start/finish dates of life cycles. Hence, when LCA is used for a network-level environmental impact assessment, it only captures the emissions during the analysis horizon and does not capture the emissions related to activities (such as maintenance and rehabilitation activities) prior and after the analysis horizon. Therefore, using LCA for a network-level assessment leads to the same burden shifting problem of emission-based environmental accounting.

We propose that changing the accounting principle for environmental assessment from emission-basis to service-basis accounting can both prevent burden shifting and provide flexibility regarding the length of analysis. To this end, we make an analogy between the environmental accounting and financial accounting. In business and finance literature, two distinctive types of financial accounting are used: i) cash-based accounting in which revenues and expenses are recorded when the cash is transferred. The existing emission-based environmental accounting is similar to cash-based financial accounting in which the release of pollutants or consumption of resources play the role of cash flows; and ii) accrual accounting in which economic events are recognized at the time of transaction rather than when a payment is made (or received). Accrual accounting has shown to be more reflective of the impacts of managerial decisions and the financial conditions of a company because it takes both current and expected future cash flows into consideration (Kwon 1990). Using an analogy to accrual accounting approach (Figure 1), we propose a service-based environmental accounting principle in which the impacts are recognized when the service is provided rather than when emission is made. For example, the huge impacts created during the construction of a new road, are not recognized at the time of construction. Instead, these impacts are attributed to each year of the service life based on proportion of total expected service offered in that year. The service basis principle enables consideration of both current and future impacts of a network on a yearly basis, thus providing a measure for evaluation of the environmental performance of the network during any desired analysis horizon.

3  SERVICE AND PERFORMANCE ADJUSTED LIFE CYCLE ASSESSMENT (SPA-LCA)

The proposed service-based accounting for environmental assessment of infrastructure networks requires determination of levels of service and performance in a network during the analysis horizon. Hence, a simulation-based approach is needed for dynamic modeling of the service and performance. To this end, the proposed SPA-LCA methodology consists of two modules to capture the specific requirements of network-level environmental assessment in infrastructure systems (Figure 2). The module of network performance simulation is comprised of a hybrid mathematical/agent-based simulation framework to model the complex dynamic interactions between the conditions of assets, the demand pattern, and the managerial decisions regarding preservation of the network. The outcomes of the simulation model include the level of service and performance of each asset. Given an inventory of relevant energy and material inputs and environmental releases, the simulated service and performance of the assets are then used in network environmental assessment module to calculate network-level. The network performance simulation module is based on the methodology proposed by Batouli and Mostafavi (2014) for dynamic modeling of agency-asset-user interactions in infrastructure systems. The level of
service and performance in infrastructure networks is an emergent property as a result of the interactions between the conditions of assets, the extent of demand, and the decision making processes in administrating agency (Batouli and Mostafavi 2014). The decision making processes are modeled in the asset management component of the proposed framework. The asset management component uses agent-based modeling to abstract and simulate the decisions regarding the timing and type of maintenance and rehabilitation (M&R) activities considering the current condition of the assets as well as the underlying policies and availability of funding (Mostafavi et al. 2013). The service model simulates the level of demand on each asset based on the historical information and the conditions of assets. The conditions of assets are in turn identified in asset performance model using dynamic mathematical simulation. The performance of an asset is a function of the level of service it provides and the preservation (i.e., maintenance or rehabilitation) it receives. Detailed information related to the components of network performance simulation module can be found in Batouli and Mostafavi (2014).

The service and performance of all assets are used as inputs to the network environmental assessment module to calculate the network-level environmental impacts. An inventory of relevant energy and material input/output flows is created similar to the traditional LCA (ISO 14040 2006; ISO 14044 2006). However, in the asset-level life cycle inventories (LCI) of the SPA-LCA methodology, the inventory items are divided into two categories based on the sensitivity of the inventory item to the performance of the asset. Disaggregation of LCI to performance sensitive and non-sensitive items is required for translating the lump-sum environmental impacts in traditional LCA into a dynamic environmental profile in SPA-LCA methodology.

The items whose quantities vary based on the performance of the asset fall into the performance sensitive category. The flows that impose a fixed amount of impact regardless of the performance of the asset are attributed to performance non-sensitive category. For example, in analyzing the environmental impacts of a pavement network, items related to the use phase of the pavements belong to the performance sensitive category. That is because fuel consumption and pollutant emissions of vehicles depend on the roughness of the pavement as well as the travel time (Yu and Lu 2012). However, the impacts related to the construction of the pavement are independent from the pavement performance and hence they fall into the non-sensitive impact category. In the SPCA-LCA model, a Performance Adjustment Factor (PAF) is defined to modify the quantities of performance-sensitive items based on the simulated levels of performance. The PAF is defined based on historical information regarding the correlation between environmental impacts and performance of infrastructure assets.

The impact values of performance adjusted inventory items are then summed up with the values of non-sensitive items to form an adjusted life cycle inventory. Finally, the adjusted life cycle impacts of each asset are attributed to different years of the asset’s expected service life based on the level of service at each year (obtained from the network performance simulation model). Attributing the impacts based on the level of service is consistent with the service-based accounting principle explained in previous section. Application of the proposed framework is elaborated in next section using a case study pertaining to a road network.
4 NUMERICAL EXAMPLE

Global warming potential (GWP) associated with the service life of pavements pertaining to twelve sections of a road network are analysed over a 40 year analysis horizon to demonstrate the application of the SPA-LCA methodology. The information related to the network characteristics are obtained from The ICMPA7 Investment Analysis and Communication Challenge for Road Assets (Haas 2008) and are summarized in Table 1. The network includes roads with flexible (F), rigid (shown as CP (Concrete Pavement) in Table 1), and Composite (C) pavements. Roads are either rural (R) or interstate (I) highways. The initial traffic on each road is represented by Equivalent Single Axle Load (ESAL) in Table 1.

4.1 Module of network performance simulation

This module includes three components: asset management model, performance model and service model. The interaction between these three components determines the level of service and performance of assets during the analysis horizon.

The performance model uses dynamic mathematical simulation to model the deterioration of the pavements given the initial conditions of the roads, traffic demand, environmental conditions, and the timing and type of M&R treatments. Present Serviceability Rating (PSR) is used as a metric for measuring pavement performance and is quantified using an empirical equation proposed by Lee et al. (1993) as shown in Equation 1:

\[ PSR = PSR_i - A \cdot F \cdot a \cdot STR^b \cdot Age^c \cdot CESAL^d + MR \]
In Equation 1, \( PSR_i \) denotes the initial value of PSR for a given link right after construction. This value is 4.5 according to Chootinan et al. (2006) and Lee et al. (1993). Cumulative Equivalent Single Axle Loads per day (CESAL) and STR (existing structure of pavement) capture the impact of traffic load and structural design of the pavement, respectively. CESAL is mathematically calculated in the service model based on the historic traffic data and projections of future traffic growth. An adjustment factor (A.F.) is used for considering the effect of climate conditions. Finally, \( a, b, c \) and \( d \) are empirically-based coefficients whose values depend on the type of pavement (Lee et al. 1993).

The improvements in pavement condition due to maintenance/rehabilitation activities are incorporated in Equation 1 with the denotation \( MR \). The value of \( MR \) is calculated in asset management model. The asset management model uses agent based modeling to simulate the decision making behavior of the administrative agency regarding the timing and type of M&R activities. Four types of M&R activities are considered in this case study: routine maintenance, surface treatment, overlay, and rehabilitation. Each of these activities leads to a certain level of improvement in performance depending on the age of the pavement (Chootinan et al. 2006). For preservation of the network, the administrative agency follows a “worst-first” strategy in which the roads with lowest performance are prioritized for allocation of M&R funding. A maintenance and rehabilitation (M&R) activity is implemented only if it can restore the pavement to an excellent condition; otherwise, if an adequate funding is not available for the required M&R, repair activities are deferred to the next period. Details related to the agent-based modeling of the agency decision processes can be found in Batouli and Mostafavi (2014) and Batouli et al. (2014).

The outcomes of the network performance simulation model include the level of service and performance of pavement assets, the expected service life of each asset, and the type and timing of M&R activities. The expected service lives of individual pavement assets are determined based on the threshold values of PSR to determine the need for reconstruction. These threshold values are considered to be 2.2 and 2 for urban and rural roads, respectively (Elkins et al. 2013). Once a road reaches this threshold PSR value, it is considered to be irremediable by maintenance activities, and hence, it should be reconstructed. The outcomes of simulation model are used in the module of SPA-LCA to calculate the global warming potential of the network at each year of service.

4.2 Module of network environmental assessment

The cradle-to-grave life cycle inventories related to different types of pavements, based on average conditions in the United States, are obtained from Loijos et al. (2013). The data includes greenhouse gas emissions created during all stages of pavement life cycle from materials production to construction, use, M&R, and end of life. However, the LCI inventory provided in Loijos et al. (2013) is developed using traditional LCA methodology. This inventory information needs to be adjusted to be used in the SPA-LCA model. To this end, the life cycle inventory was divided into three categories of inventory items:

The impacts associated with the materials production, construction and end of life are not sensitive to the level of service and performance. The inventory items related to this category are kept unchanged in the adjusted LCI of SPA-LCA model.

The impacts related to M&R activities directly depend on the type and frequency of M&R treatments. For example, a typical preservation plan during the service life of a pavement asset may include 3 routine maintenances, one surface treatment, and one rehabilitation. However, in reality, budget constraints and agency priorities may result in deferring or changing the planned maintenance. Similarly, accelerated deterioration of the pavement may lead to the need for an additional overlay treatment. Hence, the impacts related to M&R activities are determined based on the outcomes of the simulation model, which determines the timing and type of M&R activities. The unit emission for each of these M&R activities is extracted from the LCI inventory and is multiplied by the simulated number of each type of treatment during service life of an asset.

The quantity of GWP generated during use phase of a pavement highly depends on the rate of fuel consumption of vehicles traveling on the pavement. On the other hand, the fuel efficiency of the vehicles is a function of pavement performance. To incorporate the impact of the pavement roughness on the
overall GHG emissions related to the use phase, the adjustment factors suggested by (Barnes and Langworthy 2003) are used in this study. According to Barnes and Langworthy (2003), when PSR value of a road is between 3 and 3.5 the fuel consumption is 5% greater than fuel consumption on pavements with excellent condition. For PSR values in the range of 2.5-3.0, fuel consumption increases 15%.

The first two categories of inventory items are independent from the level of performance of pavement assets, while the last one is performance sensitive. Calculations of impacts for performance sensitive and non-sensitive impacts are explained below.

1. Calculation of performance non-sensitive impacts

The performance adjusted inventory impacts are used in the service basis accounting model to distribute the life cycle impacts of a pavement asset over its service life. For performance non-sensitive items, the impact at each year is calculated using Equation 2:

\[
X_{ij} = NS_{ij} \cdot \frac{ESAL_{ij}}{ESAL_{av}}
\]

Where:
- \(X_{ij}\): The GWP related to performance non-sensitive impacts of road \(j\) in year \(i\) (in Mg Co2 equivalent)
- \(NS_{ij}\): Total GWP related to performance non-sensitive impacts of road \(j\) during the life cycle that contains year \(i\) (in Mg Co2 equivalent)
- \(ESAL_{ij}\): Total equivalent single axle traffic load on road \(j\) in year \(i\)
- \(ESAL_{av}\): Total equivalent single axle traffic load on road \(j\) during its service life

In Equation 2, the fraction \(\frac{ESAL_{ij}}{ESAL_{av}}\) is a service adjustment factor that determines what proportion of the total service of road \(j\) is provided in year \(i\).

The outcomes of the network performance simulation model is used to determine the level of service, performance condition, number and timing of M&R activities, and service life of individual assets in the network. This information is used in calculating the performance non-sensitive impacts in Equation 2. For example, the simulation model shows that road A reaches its end of life at year 7 of the analysis horizon, and hence, it is reconstructed at year 8. Year 8 is the beginning of a service life for road A. This service life lasts for 41 years. During this service life, based on the simulated conditions and the worst-first preservation strategy, road A will receive two surface treatments, three overlays, and one rehabilitation. Each surface treatment, overlay and rehabilitation of road A creates a total of 24, 71 and 141 Mg of CO2 eq. GWP, respectively. Therefore, during this service life (from year 8 to year 49) a total of 402 Mg CO2 eq. (2×24+3×71+1×141=402 Mg CO2 eq.) impact will be created due to M&R activities. In addition, the materials production, construction and end of life of road A create 6508, 123 and 1175 Mg CO2 eq. global warming potential, respectively. Thus, a total of 8208 Mg CO2 eq. GWP of performance non-sensitive impacts is created during the service life of road A.

For distributing the impacts to each year, total impacts are multiplied by the service adjustment factor. For example, the simulation model shows that the traffic on road A in year 10 is 0.1442 ESAL. The total traffic load of Road A during this life cycle (i.e., year 8 to 49) is 10.70157 ESAL. Therefore 1.3% of the total service is provided in year 10. Based on the service basis accounting principle, 1.3% of the total life cycle impacts of road A (approximately 110.6 Mg CO2 eq. GWP) is due to the service in year 10.
2. Calculation of performance sensitive impacts

In order to consider the impacts of pavement performance on the fuel consumption of the vehicles, the impacts of use phase are adjusted based on the simulated pavement roughness (measured using in PSR) using Equation 3.

\[ Y_{ij} = TS_j \frac{ESAL_{ij}}{ESAL_{av}} \times PAF \]

Where:
- \( Y_{ij} \): The GWP related to performance sensitive impacts of road \( j \) in year \( i \) (in Mg Co2 equivalent)
- \( TS_j \): GWP related to use phase impacts of road \( j \) considering excellent road conditions
- \( PAF \): Performance Adjustment Factor
- \( ESAL_{ij} \): Total equivalent single axle traffic load on road \( j \) in year \( i \)
- \( ESAL_{av} \): Total equivalent single axle traffic load on road \( j \) during its service life

For example, under excellent roughness condition, 2150 Mg CO2 eq. GWP is created due to use of road A during this life cycle (i.e., years 8-49). However, the performance of road A is not excellent in year 10 (PSR=3.36), and hence, impacts will be worse. To account for the additional impacts, the use impact of road A is multiplied by a PAF of 1.05 (associated with PSR of road A in year 10). Thus, the use impact in year 10 is calculated as follows: 2150×1.3%×1.05= 29.35 Mg CO2 eq. GWP. Accordingly, the total environmental impacts of road A in year 10 can be calculated by adding the performance sensitive and non-sensitive impacts. A similar process is conducted for all assets in the network for the 40 year analysis horizon. The results are shown in Figure 3. In Figure 3, the decreases in GWP values are related to reduction of the service due to partial or complete road closures for applying M&R treatments.

![Figure 3: Asset-level SPA-LCA GWP impacts.](image)

Another advantage of SPA-LCA for the network-level environmental assessment is that it facilitates aggregation of asset-level impacts into network-level environmental performance. The results of traditional LCA are based on the aggregation of the life cycle of individual assets. However, the aggregated lump-sum impacts of individual assets could be misleading. For example, a planning strategy might lead to lower aggregated lump-sum impacts at the network level; however, it might reduce the service life of the network and raise the need for major reconstruction projects after the analysis horizon. However, in the SPA-LCA method, the impacts are not presented as a lump sum value for the total life cycle of an asset. Instead they are calculated for each year, and thus, the impacts at network-level are obtained by aggregating the asset-level impacts in each year during the analysis horizon. Hence, using this approach, the need for defining a definite service life for the network is eliminated, and the analysis could be performed for any desired analysis horizons. Figure 4 depicts the network-level impacts for the case study network. As shown in the figure, the network-level impacts increase with time. This is due to
two reasons. First, the traffic growth rate is positive in this network which basically means there will be accelerated deterioration and increased fuel consumption in future. Second, with the current preservation strategy on this network, the average PSR of the network decreases over time from an initial value of 4.1 to a final value of 3.55. This results in increased fuel consumption at the later stages of the life cycle of these assets, which leads to greater GWP impacts. This implies that, for networks with expected demand growth, a sustainable approach is to adopt more durable materials and pavement types to slow down the rate of deterioration and eliminate the need for frequent M&R treatment.

![Figure 4: Network-level SPA-LCA GWP impacts.](image)

4. CONCLUSION

This study proposed a new methodology for assessment of environmental impacts of infrastructure systems at the network level. From a theoretical aspect, the underlying premise of the proposed methodology introduces a new paradigm for assessment of environmental sustainability in infrastructure networks. While the traditional LCA fails to recognize the level of service and performance in conceptualizing sustainability in networks, the proposed method defines a sustainable approach to be the one that provides the longest service life and greatest performance with the lowest environmental impacts. From a methodological perspective, the proposed methodology addresses the limitations of the traditional LCA methods for network-level assessment of infrastructure systems by: (i) capturing the complex interactions affecting the level of service, performance, and environmental performance of infrastructure networks; (ii) eliminating burden shifting through recognizing environmental impacts at the time of service; and (iii) considering the continuous service life of networks by determining the environmental impacts for each year, and thus, eliminating the need for defining a global life cycle for the network. From a practical aspect, the proposed method enables evaluation of environmental impacts associated with various operational (e.g., prioritizing M&R activities for funding allocation) and strategic (e.g., corridor planning) decisions.

NEW MULTIMEDIA SAFETY EDUCATION PROGRAM: IMPACTS ON EMOTIONS, RISK PERCEPTIONS, AND LEARNING

Siddharth Bhandari¹, ², Matthew Hallowell¹
¹ University of Colorado Boulder, United States of America
² siddharth.bhandari@colorado.edu

Abstract: Safety training is a vital component of any construction organization’s safety program. Training offers an opportunity for the transfer of explicit and tacit knowledge of safe work practices. Often, safety training focuses on core issues faced by the specific organization and links to desired worker behaviour. Unfortunately, the typical delivery modes involve PowerPoint presentations, written safety protocols, and classroom-style settings. Such teaching modes do not facilitate active, inductive, context-based learning that is essential for effective andragogy (i.e., adult learning) and, therefore, often fail to achieve their desired objectives. This study tests the hypotheses that a new method of risk-free safety training, Live Safety Demos, increases engagement through emotional response to training activities. The technique involves demonstrating the cause and effect of actual injuries to human hands, which are the most commonly injured body part in construction. The delivery of the demos include the following key components: (1) biologically-realistic replicas of human hands that include flesh, bones, and blood networks; (2) in-person demonstrations of common injuries to worker’s hands (e.g., pinch-points between sections of pipe); (3) videos showing injuries to the replicas recorded at over 2100 frames per second to show detail; and (4) worker-led activities to design work practices that would prevent each injury type. The research was achieved with a team that included one faculty member, three students, a senior manager from the owner organization, four safety managers, and an English-to-Spanish translator. To test the aforementioned hypothesis, the research team used field-validated methods from experimental psychology to measure emotional response to the training program. Using a longitudinal A+B experiment, the demos were tested over the course of a one-week period with approximately 1,200 workers who belonged to approximately 100 crews. The results indicate a very strong emotional response to the Live Safety Demos with statistically significant changes in almost every emotion category. There was a significant increase in negative emotions, which is known to increase risk perception and decrease risk tolerance. Increase in induced activating emotions lead to a more engaged learning commitment during safety training, which increases the ability of workers to recognize more hazards. Thus, this research shows that live safety demos, although resource-intensive, has the potential to transform safety training in the construction industry. Future research is suggested to broaden the sample population and to test additional elements such as retention levels, duration of these induced emotions, communication networks, and ability to respond ad hoc to new safety environments.
1 INTRODUCTION

Carter and Smith (2006) and the Center for Disease Control and Prevention (CDC 2012) suggest that construction workers lack the necessary skill set to correctly identify potential hazards at the job-site. This is a valid claim because, despite constantly improving industry standards and years of extensive research to reduce injuries, there were 4,405 fatal work-related injuries during 2013 (Bureau of Labor Statistics 2013). Furthermore, although there was a modest decline in injury rates between 2011 and 2013, there was an overall increase in fatality rates and a dramatic 7% increase in injuries and fatalities to Hispanic workers (Bureau of Labor Statistics 2013). These trends imply that the industry could benefit from more engaging safety-training that heightens awareness of potential hazards and addresses andragogical principles of learning (Wilkins 2011).

There has been extensive research conducted to understand how people learn in occupational contexts. For example, Baddeley (1992) suggested that the working memory uses both verbal and visuals channels to process and retain information. Hence, in contrast to generic presentation-based training programs, multimedia styles of learning are theoretically more effective as they engage both visual and verbal channels. Moreover, adults seek engaging learning approaches with significance to everyday life as a motivation for learning (Lindeman 1956). This study involved the development and empirical testing of Live Safety Demos, an experiential learning program built upon the principles of Generative Theory of Multimedia Learning (Mayer 1997). As Mayer (1997, p.4) suggests, "multimedia instruction affects the degree to which learners engage in the cognitive processes required for meaningful learning within the visual and verbal information processing systems." The Live Safety Demos were designed within this theoretical context.

The Live Safety Demos included realistic simulations of commonly occurring injuries and a concurrent explanation of the cause and effect of those injuries. To enhance andragogy, the demos involved biologically accurate replications of human hands, realistic simulation of injuries on the artificial hands, a high-speed video of the injury to illustrate detail, and in-depth conversations with the workforce. To test the effectiveness of this new form of safety training, the research team aimed to measure the extent to which the participant’s emotions change as a result of the training program. There has been substantial research that suggests that emotions play a major role in a person’s decision-making process and, thus, affect an individual’s risk perception and tolerance (Clore et. al. 1994; Keller et. al. 2006). This is the first investigation to measure emotional response to an experiential safety program despite the empirical connections between emotional response, learning, and safe work behaviour.

2 LIVE SAFETY DEMONSTRATION CREATION AND DELIVERY

Researchers have found that the only major factor that affects an individual’s risk tolerance is previous personal injury history (Hallowell 2010). That is, a past injury or witnessing a severe injury to a close co-worker is the only factor that has been shown to decrease risk tolerance. Unfortunately, the implication of this finding is that someone must be injured in order for risk tolerances to change. A major objective of this research was to create a hyper-realistic demonstration of an injury that gives participants the experience of an injury without the negative consequences. In this study, we gauge change in emotional response to measure the change in the risk perception/tolerance. Drevets and Raichle (1998) showed that blood supply to brain decreased near the risk-based decision-making sections during acute induced emotional moments and Loewenstein et. al.’s (2001) research found that specific emotions sway human response in adverse situations. Previous studies have shown that people with positive emotional state have more affinity for risk (Isen and Patrick 1983). This implies that if the demonstrations induce a negative emotional state, it should lower the participant’s affinity towards risk.

An important component of the Live Safety Demos was the creation of a hyper-realistic demonstration of an injury. To achieve the goals artificial hands were created that look, feel, and respond like actual human hands (Figure 1). The hands were built using life-casting techniques primarily found in dentistry and prosthetics and include flesh with the exact properties of a human hand, an internal blood bladder and
blood network, and bones. To illustrate the level of realism achieved in the creation of the hands, Table 1 provides a complete comparison between the fabricated hand and the average adult human hand according to the Oxford Handbook of Clinical Medicine (Longmore et al. 2014). As one can see from Table 1 and Figure 1, the hands were sufficiently accurate to serve as a realistic proxy for a worker in dangerous situations.

To accompany the fabricated hand in a training demonstration, a video was created where the hand was injured in two modes: a falling concrete chisel and a pinch point between two sections of three inch steel pipe. A brief description of the two demonstrations is provided below.

**Falling Concrete Chisel:** This demonstration aimed to replicate an actual disabling injury where a carpenter dropped a one-kilogram concrete chisel when stripping concrete formwork. The falling chisel struck another worker who was working below the formwork and punctured his hand. Ultimately, there were three broken phalanges and nerve damage, which resulted in limited use of the hand. The first part of the demonstration involved educating the workers of the speed that the chisel was falling at time of impact (approximately 43 kilometers per hour), the impact area of the chisel (0.30 cm²), and the overall pressure on the hand (48 MPa). To achieve a memorable mnemonic, a discussion related to speed, sharpness, and weight was held among the workers as prompted by the instructors. Following this discussion, the resilience of the human hand was described. Specifically, the human hand can withstand approximately 1 MPa without significant damage. Given the load on and resistance of the hand, the
workers were asked to predict what would happen to a gloved and ungloved hand. Once this discussion was complete, a high-speed video was shown with both a gloved and ungloved hand, illustrating dramatic differences in outcome. The first demonstration session concluded with a discussion of the safe work practices for the type of work demonstrated.

**Pinch Points between Two 3-Inch Steel Pipes:** The second demonstration focused on an injury where a worker was in the process of connecting a 3-inch steel pipe to a pipe couple when the pipe sling shifted and the worker’s hand was pinched between the pipe and the couple. The result of the injury was a deep flesh wound and nerve damage. Similar to the falling chisel demo, the first step of the demonstration was to present the physics behind the injury. This included the momentum of the moving pipe, the contact area of the pipe, and the overall pressure on the hand. Once the resistance of the hand to pressure (1 MPa), the workers predicted the outcome for a gloved and ungloved hand and the associated videos were shown that depicted both scenarios. Also, a discussion was held regarding the potential outcomes of a heavier, sharper, or faster moving pipe. The session also concluded with a discussion of safe work practices for installing steel pipe.

### 3 RESEARCH METHODS

As previously indicated, our research goal for this study was to measure emotional response to the active, experience-based demonstrations that incorporated theory of andragogy. In order to achieve this goal, we delivered the demos to 1,200 construction workers in a one-week period in Kenedy, Texas through sixteen different sessions (average of 75 workers per session). The same delivery technique and the same instructors were used in each session to ensure consistency. Additionally, a set script was followed to enhance reliability and replicability of the study and all instructors followed a set script.

In order to measure emotional response, we implemented a before and after (AB) experimental design where Rottenberg et al.’s (2007) emotional polarity questionnaire was used to survey workers before and after the Live Demos. On this questionnaire, the participants were asked to rate their emotions on 8-point scale. In addition to Rottenberg et al.’s (2007) questionnaire, we considered various alternative methods to gauge the emotional response such as the Balloon Analogue Risk Task (BART), which is a laboratory based computerized self-reporting risk assessment tool (Lejuez, C. W., et al. 2002). We decided to pursue the paper form of the Rottenberg et al. (2007) questionnaire because of our sample size and time and resource constraints in the field. The emotion questionnaire was quantitative with one optional qualitative question, which requested comments or other emotions.
Out of the 1200 workers, 489 (40%) participated in the surveys as participation was voluntary and uncompensated. The surveys were administered in paper form and all the participants were provided sufficient time and resources to complete the surveys both times. Surveys were provided to the participants immediately before and immediately after the Live Demonstrations and no more than a 3-minute time lag was allowed as suggested by Verduyn et. al. (2009 & 2011).

The following protocol was implemented when delivering the live safety demos and collecting data:
1. Introduction to the topic and welcome
2. Emotions survey with demographics
3. Delivery of dropped object demo or pinch point demo
4. Delivery of the second demo (one not delivered in step 3)
5. Emotions survey and open-ended qualitative question
6. Closing remarks

As previously indicated, all demos were delivered to workers in Kenedy, Texas. Subjects involved had no knowledge of the demos prior to the session. Some work crews in this region were Spanish-only-speaking while others were English-only-speaking. We delivered the demonstrations in both English and Spanish, as members of the research team were bilingual. The participants were allowed to choose between the English or Spanish session. Seventy-five percent of the participants attended English sessions and 25% attended Spanish sessions.

To ensure anonymity, the participants were not required to enter their names or any direct identification. Instead, workers used a personal password that was not linked to their name, trade, or employer. For demographic questions, we also offered participants the opportunity to decline to answer a question if they felt uncomfortable providing the information. In our sample, 69% were married, 50% had witnessed a severe injury first-hand, 23% had been injured (recordable injury), 6% have a bachelor’s degree or more, 32% have some college education, 57% completed high school, 4% have no education, 70% were Hispanic, and 30% were Caucasian. The average age of the participants was 38 years and, interestingly, less than 5% of the workers were female. Figure 3 illustrates the overall research process including development, data collection, statistical comparisons, and conclusions.

4 RESULTS

In order to study the emotional responses, the data were analyzed using paired t-tests. Paired t-tests were used because we have two nominal variables and one measurement variable (McDonald, J.H. 2014). One nominal variable represents the participant and other is the “pre” and “post” emotional state recorded via their responses. Table 2 shows the results of the emotional change for the entire sample. We considered the change to be significant at 95% confidence (p <0.05). Based on the results shown in Table 2, there was a large and statistically significant change in the following emotions: confusion, disgust, guilt, fear, happiness, joy, love, pride, sadness, surprise, and unhappiness. The greatest change occurred in fear and surprise. We can also say here that the ‘negative’ emotions or those associated with being serious, sombre, and vulnerable increased significantly.

Table 3 shows the emotional response of Caucasians and Hispanic workers separately. It also shows that Caucasians showed a significant change in confusion, fear, happiness, joy, love, pride, sadness, shame, and surprise whereas Hispanic workers had a significant change in anger, confusion, fear, guilt, happiness, joy, love, pride, sadness, surprise, and unhappiness. This is further discussed in the next section in the context of this paper.

</tbody>
</table>
Key takeaways from the data are that emotions such as anger, anxiety, confusion, disgust, embarrassment, fear, guilt, happiness, joy, pride, sadness, love, surprise, and unhappiness showed a fluctuation in the same direction. Both Hispanic and Caucasian workers registered an aggregate decrease in their positive emotions such as happiness (-29%), joy (-25%), love (-29%), and pride (-23%) and an increase in negative emotions unhappiness (18%), fear (47%), surprise (47%), and sadness (43%). When viewed separately, Caucasian surveys showed statistically significant change in 'fear' and Hispanic surveys showed statistically significant change in 'anger' and 'fear' (activating).

The implications of the observed emotional changes on learning are significant. Pekrun (2006) explains that negative emotions increase extrinsic motivation to learn and avoid failure. Specifically, Pekrun et. al. (2002, p.97) claims that "Emotions may trigger, sustain, or reduce academic motivation and related volitional processes." They also suggest that changes in positive emotions (happiness, joy) and negative emotions (anxiety, anger) can be activating and may facilitate learning. Bless et. al. (1996) further proposed that negative emotions lead to more detail-oriented and cautious approach towards solving problems, which could be preferable to construction safety. Thus, it can be concluded that Live Safety Demos is an improvement over the current training style for the construction crews because workers will be more detail-oriented and cautious as they troubleshoot safety problems and plan for safe work.

In addition to enhanced learning, the changes in emotions are linked to decreased risk taking. As mentioned in the introduction, it is overwhelmingly accepted that negative emotions lead to a less affinity towards taking risk (Öhman and Mineka 2001; Clore et. al. 1994; Keller et. al. 2006). Taylor and Brown (1988) claimed that “false optimism” leads to a fake sense of security towards any situation thus, making them less cautious and oblivious to hidden risks. Additionally, it should be noted that negative emotional states are strongly associated with an increase in risk perception (i.e., workers perceive greater risk in their environment) and reductions in risk-taking behaviour (Gruber et. al. 2011). Results in Tables 3 and 4 also show that there is a significant decrease in joy and interest emotions, which leads a decrease in safety valuations of situations (Izard 1977). Based on these established theories, we believe that the Live Safety Demos makes construction workers perceive more risk, which should decrease sense of false optimism and risk taking behavior.

There were some interesting differences in the emotional reactions between Hispanic and Caucasian workers. Firstly, Caucasian workers experienced greater increases in anxiety, fear, surprise, shame, and disgust than their Hispanic counterparts. Hispanic workers, on the other hand, experienced greater relative changes (increase) in amusement unhappiness, and guilt. Hispanic workers were less angry and less happy while Caucasian workers were much more fearful and surprised. Matsumoto et. al. 1988 showed that there are cultural differences in self-reporting of any emotional experience, which include intensity, control, and duration of emotion. However, these induced emotions though varying in intensity, need to correlate positively with cognition among these workers. Since the changes in emotions are all in the same direction, there is no indication that the differences in emotional response would have any serious implications for risk taking or safety learning. Figure 4 outlines some of the major changes due to Live Safety Demos on the participants and the implications of those changes.
Figure 4: Major Implications of the Results from Live Safety Demos

The findings mentioned above come with limitations. As discussed briefly in the research methods section, the survey responses are never quite accurate for various reasons. First, there was an inherent discomfort observed among the participants even if surveys are anonymous that they could be traced back to them. Second, there was also some conversations among the participants as they filled the surveys out which might have also affected their answers. Third, and most importantly, it has been documented that people are sometimes incapable of understanding our own emotions. Finally, there is a clear male bias in the sample.

Other studies can further these results by analyze how long did the induced emotions last among the participants after the demos and what is the level of emotional intelligence among construction workers. It will be interesting to also research if ethnicity impacts. More importantly, emotional intelligence examination might allow us to judge whether self-reporting questionnaire form is a good choice or not among construction workers. In conclusion, this paper shows that current safety training programs are inefficient and monotonous. Live Safety Demos is an effective multi-media safety-training program, which embraces the andragogical principles and increases risk perception by inducing a sombre and cautious emotional response among construction workers. These demos will by-pass the need to introduce new and more stringent rules by improving participants’ hazard recognition and the risks associated with it.

Acknowledgements

The authors would like to thank Conocophillips for the opportunity to conduct this research on their site in Kenedy, TX. In particular we would like to thank David Wulf, Dwayne Beadle, Pedro Oronia, Bobby Bourque, and the many workers who participated in the Live Demos. We would also like to thank Sofia Hafdan for her assistance with statistical analyses

Abstract: Due to a lack of common financial benchmarking for various BIM functions, decisions regarding adopting BIM functions are usually made based on market pressure or a manager’s intuition. While larger firms can afford such a trial and error process, the cost burden on small- to medium-sized firms is significant. Therefore, there is a need to assemble the tacit knowledge of BIM users into a simple algorithm that can aid new users in understanding the advantages and disadvantages of implementing BIM functions in a project. This study aims to develop a decision-making algorithm that helps practitioners choose BIM functions for their project to maximize success. Some of the independent variables that were considered are project category, project size, delivery method, and time of involvement of different parties. A questionnaire was developed to measure the importance of these variables on using different BIM functions. The survey was sent out to 3,017 owner representatives, architects, and project managers. In total, 119 individuals responded to the survey of which 81 were BIM users. The analysis of the data resulted in a decision matrix and an algorithm that provides guidance for decision makers regarding adopting different BIM functions. Most of the respondents worked in the building and commercial construction sector, which likely influenced the respondents. The findings of the study have contributions to both academia and practice. The results can be used by researchers as a benchmark for future studies and practitioners can use the decision-making algorithm to select an appropriate BIM function for their projects.

1 INTRODUCTION

The potential of building information modeling (BIM) to unify the traditionally fragmented AEC industry has contributed to BIM gaining wide acceptance in the North American market (Bynum et al., 2013). BIM has fostered closer collaboration by enabling interaction and aiding collective understandings of projects (Grilo and Jardim, 2010; Hanna et al., 2013). In doing so, BIM has been simultaneously expanding and advancing in its applications. The Smart Market series (McGraw-Hill, 2008; 2009; 2012) provides a comprehensive understanding of the adoption pattern of BIM among various construction sectors and disciplines in the AEC industry. Per the McGraw-Hill report (2012), the industry adoption rate of BIM in North America has shown a noteworthy increase, from 28% in 2007 to 71% in 2012. The report also indicates that there has been a steady increase in BIM adoption within various disciplines, especially among mechanical, electrical, plumbing, and structural engineers. However, despite BIM enabling the construction industry to merge via a virtual process (Azhar, 2011), limitations and challenges to the expansion of this approach still exist.
The ongoing challenges to BIM mainly exist in the realms of technical, contractual, and personal relationships among construction professionals (Hamdi and Leite, 2014). BIM-enabled projects continue to be organizationally divided (Dossick and Neffe, 2009), and on average 25% of construction industry professionals refuse to use BIM for various reasons. Some reasons contributing to lower usage of information and communication technologies (ICT’s) like BIM are identified in literature review as technical and financial problems, attachment to conventional ways of conducting business (Doherty, 1997; Samuelson, 2002), and the lack of an effective tool for the entire construction market (Egbu and Botterill, 2002). Another challenge encountered by BIM is the low adoption rate among small and medium enterprises (SME’s). Studies indicate that despite ICT’s being a means for instant knowledge transfer, few SME’s can use such innovations to their full capacity (Acar et al., 2005) and most SMEs fail to adopt and implement them (Blackley and Shepard, 1996; Acar et al., 2005). These findings are reflected in the fact that the adoption rate of BIM is only 49% among small firms as compared to 91% in large firms (McGraw-Hill Report, 2012).

Very few studies—McGraw-Hill series reports (2008; 2009; 2012) and Krieder et al., (2010)—have attempted to evaluate the value and the frequency of use of various BIM functions across disciplines and project phases. Due to a lack of common financial benchmarking for various BIM functions (Becerik-Gerber and Rice, 2010), decisions regarding adopting BIM functions are usually made based on market pressure or a manager’s intuition. While larger firms can afford such a trial and error process, the cost burden on small- to medium-sized firms is significant. Therefore, there is a need to assemble the tacit knowledge of BIM users into a simple algorithm that can aid new users in understanding the advantages and disadvantages of implementing BIM functions in a project. To address this need, this study aims to develop a decision-making algorithm that helps practitioners choose BIM functions for their project to maximize their success.

This study begins by conducting a literature review to identify relevant BIM functions and independent variables that can be used in the decision-making process when selecting which of these functions to use in early stages of a project. An online survey is conducted to gather the tacit knowledge of existing BIM users. Descriptive statistics are then used to present the findings. An easy-to-use algorithm is developed based on the independent variables. The results of this study project a novel tool that can be further enhanced for accuracy. This study will benefit future researchers seeking to understand the factors contributing to the implementation of BIM functions. It will also aid construction professionals in the decision-making process while they select the appropriate BIM functions.

2 LITERATURE REVIEW

The wide acceptance of BIM could be partly accredited to the growing number of applications that appeal to various disciplines in the construction industry. Therefore, an extensive list of BIM functions can be found in literature. Since inception, collaboration has been one of the key characteristics of BIM (Eastman et al., 2011). 3D visualization and clash detection are two major functions of BIM that aid effective communication and interdisciplinary understanding among multiple disciplines (Eastman et al., 2011). Apart from these two functions, BIM has shown high potential for use in several other construction processes and has rapidly advanced in its number of applications in the past decade. Currently, BIM encompasses the most integral processes in construction, namely scheduling, constructability analysis, structural analysis, the shop drawing process, cost estimation and quantity takeoff, facility space planning and logistics, material-tracking delivery and management, stakeholder engagement, project turnover and closeout, code validation, energy analysis, and facility management.

Prior to use of BIM, studies (e.g., Chau et al., 2004) presented a 4D visualization model by linking 3D geometric model with scheduling data. Chau et al. (2004) presented the potential benefits of 4D visualization as a means of facilitating site planning and management, predicting the occurrence of any potential site problems, and streamlining site management practices. Even though 4D visualization models presented several advantages over the traditional 2D CAD process, the process remained tedious and lacked the significant feature—change management—that BIM later introduced. Tulke et al.
(2008) suggested integrating construction scheduling in a collaborative, BIM-based design process by establishing quantity takeoff as a model-based central approach prior to scheduling and cost estimation. However, even though benefits of BIM were well-documented for construction-management work—like scheduling—the application’s use was reported as infrequent (Goedert and Meadati, 2008).

Another important process in construction benefited by BIM is constructability analysis. Constructability analysis is a preconstruction process that identifies potential obstacles during construction and thus helps prevent delays and cost overruns (Pulaski and Horman, 2005). Sulankivi et al. (2014) discusses six promising ways of using BIM to improve constructability: visual examination of BIM, clash detection using a combined model, BIM-based construction planning, visualization in 3D or 4D, BIM as a tool for cooperation, and BIM-based checking, analysis, appraisal, and measurement of safety or constructability. Despite the benefits named in literature, very few studies have investigated the use of BIM for constructability.

In contrast to the inadequate research regarding several BIM functions, in the past few years, two BIM functions have been extensively discussed namely facility management and energy analysis. Facility management has evolved from being a practice to a profession. As defined by IFMA (2004), facility management is a multidisciplinary profession that integrates people, places, processes, and technology during the operations and maintenance (O&M) phase to assure the smooth functioning of the built environment. The O&M phase demands extensive information from multiple disciplines (Caldas et al., 2005). This information is provided by contractors to the facility managers in the form of a pile of project documents in various formats (William East et al., 2013), all of which need to be manually fed into the maintenance management software. BIM has the capability to eradicate this cumbersome process. Becerik-Gerber et al. (2012) identified ten potential application areas for BIM in facility management: locating building components, facilitating real-time data access, visualization and marketing, checking maintainability, creating digital assets, space management, planning and feasibility studies for non-capital construction, emergency management, controlling and monitoring energy, and personnel training and development. However, along with the numerous potential application areas, implementation of BIM for facility management also faces numerous challenges. Seven barriers to implementing BIM in facility management—as identified by Becerik-Gerber et al. (2012)—are: unclear and invalidated benefits of BIM, increase in the amount of work, lack of interoperability, lack of demand by owner community, lack of clarity about responsibility in contracts, lack of standardization in facility management tools, and lack of experience in using BIM. Even though there has been a lot of research related to BIM and facility management, to-date, the adoption of BIM in facility management is slow (Brooks and Lucas, 2014).

Energy analysis is another application discussed extensively in the literature, likely due to the increasing importance of sustainable construction. Considering buildings' huge share in energy consumption, having an efficient energy analysis tool that is easy to run and easy to understand could empower designers to make more energy-conscious decisions during the early design phase (Kim and Anderson, 2013). BIM has been found to have the potential to aid energy analysis to ensure optimized, sustainable building designs (Krygiel and Nies, 2008; Azhar et al., 2011; Kim and Anderson, 2013; Bynum et al., 2013). However, upon investigating the perceptions of designers and constructors on using BIM for sustainability, Bynum et al. (2013) found that most of their survey respondents believed that sustainability was not a primary application of BIM; they also found that problems with interoperability continue to persist among the various BIM applications in the industry.

Our literature review concludes that although several studies have investigated the role of BIM functions individually and have offered unique objectives as part of their investigations, very few studies have attempted to evaluate the advantages and disadvantages of implementing BIM functions in a project.

3 METHOD OVERVIEW

To achieve the objective of the study, first the study attempted to explore factors impacting the decisions of using BIM functions within the construction industry. An in-depth literature review was conducted to identify fourteen relevant BIM functions shortlisted after expert opinion. The identified BIM functions
formed the basis of inquiry for each of the independent variables investigated. A comprehensive questionnaire was developed and distributed to 3017 construction professionals via an e-mail that contained the project description and a link to the survey. The e-mail addresses of contacted individuals were extracted from the publically accessible member lists of Associated General Contractors (AGC) and Associated Builders and Contractors (ABC) organizations from eleven states of North America (Iowa, Illinois, Hawaii, New Mexico, Nebraska, Washington, Florida, Arkansas, Arizona, New York and Maine); though the limited public access added a geographical limitation to the findings of the study. In an attempt to reach maximum audience, the participants of the 2012 Design-Build Institute of America (DBIA) conference were also approached. The questionnaire link was also posted on the LinkedIn page for the American Society of Civil Engineers. Participation in the survey was voluntary.

The objective of the questionnaire was to understand whether BIM is required for all projects and whether project-delivery method and team selection impacts the decision to use BIM in projects. For those projects in which BIM is required, this questionnaire also examined which functions should be used based on the project’s size (Refer Table 1) and objectives (i.e., cost, time, quality, and owner satisfaction). The questionnaire contained two sections. First, a personal experience and information section that sought to identify the participant’s professional background; to increase participation and encourage open expression of opinion, this section did not require any contact information (e.g., name, e-mail addresses). The first section ended with a key question regarding whether or not the participant had used building information modeling for their projects. In the second section—the BIM users’ section—participants were provided with a description of every BIM function. The Likert scale ranging 1 (low) to 6 (High) was used to inquire about frequency, difficulty, and perceived value for each BIM function. The scale also provided an option called ‘I don’t know’ for respondents unfamiliar with a certain function or unknowledgeable about a question. The survey was conducted for a period of one month, during which time two reminders were sent to each of the recipients. This study uses descriptive statistics to present the findings. Based on these findings, the study develops a decision matrix and an algorithm that provides guidance for decision makers regarding adopting different BIM functions. Based upon the independent variables, this study uses descriptive statistics to present the findings and develops an easy-to-use algorithm to translate the findings into a tool for new BIM users.

4 RESULTS

Of the 158 responses received, all partial responses were excluded from the analysis to maintain consistency in results. This yielded a response rate of 3.9% with 81 responses from BIM users and 37 from BIM non-users.

4.1 Participant Background

The analysis indicated participation of all targeted divisions of construction professionals in the survey. In total, 69% of respondents were BIM users and 31% were BIM non-users. Majority of respondents held a managerial position (87%) with the average work experience of participants as 26 years. Among BIM users, majority of the participants indicated their project categories as medium and large; and employed design-bid-build and design build as the project delivery method for most projects on average. Among BIM non-users, majority of the participants indicated their project categories as small and medium; and employed design-bid-build as the project delivery method for most projects on average. Most of respondents among BIM users (30%) stated to be multi role organizations with half the respondents identifying as DB+CM/GC, while majority of respondents among BIM non-users (39%) stated to be owners. The findings indicate that a total of 72.5% of respondents think that BIM is not required for all the
projects which highlights the importance of developing decision making algorithm for selecting right BIM function for a project.

4.2 Descriptive Statistics

The project delivery methods used in construction projects determine the organizational relationships and have been found to influence project outcomes and processes (Beard et al. 2001). To investigate the role of project delivery methods in facilitating successful adoption of BIM, the questionnaire asked respondents to provide a rank order for each. The Design Build (DB) delivery method was found to play the most significant role in facilitating successful adoption of BIM followed by Integrated Project Delivery (IPD) method. Design Bid Build (DBB) was ranked at the bottom. For project procurement methods, 2-Stage RFP was ranked at the top in facilitating successful adoption of BIM, followed by Pre-Qualified Bid, Sole Source, 1-Stage RFP and Low Bid (Refer Table 6). Upon inquiring about prefabrication, respondents indicated that on average a minimum of 24% of prefabrication is required in a project to benefit from BIM.

The questionnaire inquired about the minimum project size required for implementation of each of the listed BIM functions. The findings indicate that a total of 72.5% of respondents think that project size impacts the decision of using BIM functions. As shown in Table 2, more than 75% of participants believe that the minimum project size for employing 3D visualization, clash detection, constructability analysis, structural analysis, cost estimation and quantity take off and; stakeholder engagement is 1 million to 10 million (Medium size project). While more than 50% participants believe that minimum of medium size project is required for employing any of the fourteen BIM functions listed.

| Table 2: Minimum project size required to have a significant impact on project success |
|---------------------------------|---------|------|-----|-----|------|--------|
|                                 | VS      | S    | M   | L   | VL   | Number of users |
| 3D Visualization                | 21%     | 52%  | 86% | 100%| 100% | 80      |
| Clash Detection                 | 9%      | 30%  | 80% | 98% | 100% | 75      |
| Facility Space Planning and Logistics | 15%   | 23%  | 67% | 94% | 100% | 47      |
| Code Validation                 | 14%     | 21%  | 67% | 93% | 100% | 17      |
| Constructability Analysis       | 12%     | 32%  | 80% | 96% | 100% | 56      |
| Structural Analysis             | 10%     | 27%  | 75% | 98% | 100% | 35      |
| Cost Estimation & Quantity Take-off | 8%   | 30%  | 76% | 98% | 100% | 50      |
| Scheduling (4D Animation)       | 4%      | 10%  | 50% | 96% | 100% | 45      |
| Energy Analysis                 | 7%      | 20%  | 74% | 98% | 100% | 27      |
| Shop-drawing Process            | 9%      | 28%  | 72% | 87% | 100% | 55      |
| Material Tracking, Delivery and Mgt. | 4%   | 13%  | 48% | 85% | 100% | 17      |
| Stakeholder Engagement          | 20%     | 35%  | 84% | 98% | 100% | 50      |
| Project Turnover & Closeout     | 6%      | 19%  | 66% | 94% | 100% | 39      |
| Facility Management             | 9%      | 13%  | 67% | 98% | 100% | 21      |

More than half (59.26%) of the respondents indicated that project objective impacts the decision of using BIM functions. Four project objectives were investigated in this study - reducing project cost, reducing project time, improving quality and; improving owner’s satisfaction (Table 3). Findings indicated that clash detection was the only BIM function among the fourteen BIM functions investigated that had a high impact on all four project objectives.

5 ALGORITHM FOR SELECTING BIM FUNCTIONS

Using the results of the study, an algorithm is developed to aid practitioners choose BIM functions for their project to maximize success. The algorithm is limited to the fourteen BIM functions discussed in this
study and is based on the following assumptions: (1) decision to use/not use BIM in a project is a function of the project delivery method and team selection; (2) selecting different BIM functions depends on the project size and project objectives; (3) the project objectives that determine applicability of a BIM function are cost, schedule, quality, and owner’s satisfaction. Based on these assumptions, the research team developed a decision making algorithm that consists of four major steps. These steps are explained in more details below.

### Table 3: Impact on reducing project cost and time and; improving quality and owner’s satisfaction*

### Step 1: Project delivery and procurement method

Studies have found project procurement and project delivery methods to have varying impact on success of BIM (Becerik-Gerber and Rice, 2010). Integrated project delivery (IPD) (Becerik-Gerber and Rice, 2010; Azhar, 2011) and Design-Build (DB) are cited as the most effective project delivery methods in facilitating the use of BIM (Bynum et al., 2013). Also, procurement methods are found to be crucial in identifying the key issues while developing a BIM contract (Chunduri et al., 2013). Thus, in the first step of the algorithm we identify combinations of project procurement and project delivery methods eligible for achieving BIM benefits. The research team suggests that for the following combinations of the project delivery method and team selections, BIM provides the most benefits for project stakeholders: DB and 2-Stage RFP; DB and Pre-Qualified Bid; DB and Sole Source; CMR and 2-Stage RFP; CMR and Pre-Qualified Bid; IPD and 2-Stage RFP; IPD and Pre-Qualified Bid; and IPD and Sole Source. In the first step, the decision maker checks whether the project has any of the above mentioned delivery and team selection combinations. If the combination is right, using BIM would be beneficial for the final project success.

### Step 2: Project size

While selecting a BIM function, the most frequent question raised by a novice BIM user is about the project size (Won et al., 2013). Upon investigating whether or not the project size impacted the decision of BIM implementation, 72.5% respondents complied. The findings also indicated that the ratings for BIM functions differed as per project size. Thus, in the second step, the algorithm classifies the use of BIM function as per project size. The results of the survey indicated that BIM functions are not required for very small projects. On the other hand, BIM functions can be beneficial for large and very large projects. Therefore, the size of a project can be differentiator when one is comparing a small ($100,000 to $1Million) and medium ($1Million to $10Million) size project. In the algorithm proposed in this study, the ratings provided by experts for project size will be used as modification factor for the contribution of a BIM
function \( M_j \). For example, 3D Visualization potential contribution into a small size project should be multiplied with 52% while in a medium size project it should be multiplied with 86% (Table 4).

Step 3: Project objectives
Another factor that plays a significant role in determining the applicable BIM function for a project is the relative weight of project objectives \( W_k \). These weights will be used later to be multiplied with the contribution of a BIM function to achieve the objective \( S_{kj} \) obtained from the survey and summarized in Table 3. The ratings scale from Table 3 is converted to percentage for uniformity (Table 4).

</tbody>
</table>

Step 4: Prioritizing BIM functions
After identifying the weight of project objectives, one can calculate the potential contribution that each function can provide for the project using the following equation:

\[
C_j = \sum_{k}^{\text{objectives}} (W_k \times S_{kj}) \times M_j
\]

In which \( C_j \) is the contribution of a BIM function \( j \) to the overall success of the project; \( W_k \) is the relative weight of objective \( k \) for the project; \( S_{kj} \) is the contribution of a BIM function to the objective \( k \) (Table 4; columns 1 to 4); \( M_j \) is the modification factor related to project size (i.e. medium and small) for BIM function \( j \) (Table 4; columns 5 and 6). By calculating the potential contribution of each BIM function, one can select most beneficial BIM functions for a project. Flowchart of the proposed process is shown in Figure 1.

To demonstrate practicality of the process, one can consider a project with the following characteristics: assume that the a medium size DB project is procured using 2-Stage RFP and cost and quality are the main project objectives with relative weights of 0.80 and 0.20 respectively. The potential contribution of BIM functions are presented in Table 5 and sample calculations for the contribution of clash detection is provided below:
As one can see in Table 5, clash detection (contribution score = 80%), stakeholder engagement (contribution score = 70%), constructability analysis (contribution score = 67%), structural analysis (contribution score = 63%), and 3D Visualization (contribution score = 62%) have the highest priority to be implemented in the project.

As one can see in Table 5, clash detection (contribution score = 80%), stakeholder engagement (contribution score = 70%), constructability analysis (contribution score = 67%), structural analysis (contribution score = 63%), and 3D Visualization (contribution score = 62%) have the highest priority to be implemented in the project.

6 CONCLUSION

The benefits provided by Building information modeling are frequently documented in literature (Becerik-Gerber and Rice, 2010; Meadati et al., 2011; Azhar, 2011; Bryde et al., 2013). However, small- to medium-sized firms fail to adopt and implement BIM as there is no common financial benchmark for making decisions regarding adoption of BIM functions. As an attempt to solve this problem, we conducted a survey to gather the tacit knowledge of BIM users. It was found that 72.5 % respondents believed that...
BIM is not required for all the projects. As far as project delivery and procurement methods are concerned, Design-Build (DB) and 2-Stage RFP procurement method were ranked at top for facilitating successful BIM adoption. In addition, most BIM users (72.5%) believed that project size impacts the decision in using BIM and more than half (59.26%) of the respondents indicated that project objective impacts the decision of using BIM functions.

Using these findings, a decision making algorithm was developed that can aid new users in understanding the advantages and disadvantages of implementing BIM functions in a project. The project provides significant contribution to the body of knowledge; however, there are some limitations that need to be mentioned. First, to develop the algorithm we assumed that the decision to use or not to use BIM in a project depends on project delivery method and team selection. Future studies should be conducted to identify other influential variables on making decision to use BIM in a project. Second, we assumed that selecting different BIM functions can be determined mainly based on project size and objectives. However, other variables can also be critical in using BIM functions such as availability of skillful personnel in a company. Third, large number of respondents were from design-build firms; this can explain why structural analysis and energy analysis were adopted more than expectations among respondents. Finally, the developed algorithm needs to be validated by conducting real cases studies.

² Department of Psychology, University of Nebraska–Lincoln, USA
³ besmaeili2@unl.edu

Abstract: Although there are several studies that have highlighted the importance of attention in reducing the number of injuries in the construction industry, few studies have attempted to empirically measure the attention of construction workers. One of the techniques that can be used to measure workers’ attention is eye-tracking. Eye-tracking is widely accepted as the most direct and continuous measure of attention given that where one looks is highly correlated with where a person is focusing his/her attention. Thus, with the fundamental objective of investigating hazard identification abilities and the visual attention of construction workers, this study pioneers the application of eye-tracking technology to the realm of construction-safety practices. The study conducts a pilot test to examine the pattern of participants’ eye movement and attention distribution when shown a hazardous situation in a construction site. To achieve this objective, thirty-five pictures that include multiple areas of interest were shown to ten participants, and their eye movements were recorded using a head mounted EyeLink-II system (SR Research). Then, the absolute duration heat maps were generated and the fixation/gaze-related and saccade-related metrics were calculated for each area of interest. The results of the analysis revealed that some people failed to fixate on hidden hazards or even a danger sign. The findings of the study exhibit the immense potential of using eye-tracking technology for improving construction site safety.

1 INTRODUCTION

The U.S Bureau of Labor Statistics reported 845 fatalities within the construction industry in 2013 (U.S Bureau of Labor Statistics 2015). Even though the number of injuries have decreased significantly in the past couple of decades (Esmaeili and Hallowell 2012), accidents continue to take place. One of the main causes of accidents is the lack of attention and the failure of workers to identify hazards. If workers are distracted, they cannot identify and properly respond to a hazard. Therefore, it is rewarding to study attention and to identify ways for improving it. Although there are several studies that have highlighted the importance of attention in reducing the number of injuries in the construction industry, few studies have attempted to empirically measure the attention of construction workers.

One of the scientific ways for studying attention is to use eye-tracking technology. Eye-tracking is widely accepted as the most direct and continuous measure of attention given that where one looks is highly correlated with where a person is focusing his or her attention (Hoffman and Subramaniam 1995). In the past decade, use of eye-tracking has been flourishing in studies related to human computer interaction (Jacob and Karn 2003, Jaimes and Sebe 2007), usability research (Poole and Ball 2006), advertisement
To address this knowledge gap, the present study employs eye-tracking technology to investigate the visual attention of workers. The objective of the study is to identify the hazard identification patterns that participants demonstrate while performing a task-based search. To achieve this objective, a pilot test was conducted wherein eye movements were recorded using a head mounted Eye Link-II system (SR Research) and eye movement patterns were generated using the EyeLink® Data Viewer tool. The paper is organized into four sections. In the first part, the study presents the relationship between eye movement and attention, followed by a brief history of eye-tracking research, its application areas, and eye-tracking metrics. The second part explains the research method employed to conduct the pilot test. The third section includes findings of the study that are presented using absolute-duration heat maps and various eye-tracking metrics. Finally, the study concludes by providing a list of suggestions for using eye-tracking technology in future research.

2 LITERATURE REVIEW

2.1 Eye movement and attention

Humans eyes have finite capabilities and cannot attend to everything in their surroundings at once (Nilsson 1989). To be able to focus our vision on an area of interest, we have to move our eyes continuously, inspecting the field of view using brief fixations. Very often, our attention is directed toward the point we are looking at. This inextricable link between perception and attention was found by Yarbus in 1967. In a series of experiments that provided evidence for the relationship between human eyes and cognitive goals, Yarbus demonstrated that human eyes fixate longer on elements that project more information of interest to the observer. The experiments also implied that the analysis pattern (or eye movement path) of the scene under observation differs depending on the purpose of the observer (Yarbus 1967). The relationship between eye movement and attention mechanisms led to the vast use of eye-tracking research in the fields of neuroscience, psychology, ergonomics, advertising, and design (Richardson and Spivey 2004). By observing eye movements and the proportion of time spent looking at areas of interest, researchers attempt to infer which portions of a scene capture the participant’s visual attention and which portions are ignored.

2.2 History of Eye-Tracking Research

Historically, eye-tracking research was conducted to reveal what individuals look at, where they are look, or how they investigate an object of interest. Throughout the past century, several other concepts have emerged regarding the evolution of the eye-tracking technology, all of which have led to a wider scope for application areas (Duchowski 2007). Richardson and Spivey (2004) presented a commendable chronological account of various eye-tracking methods developed in the past century. They traced the history of eye-tracking back to the study of Louis Emile Javal in 1879. Javal (1879) used mirrors to observe the reader’s eye movements and was the first to observe that eye movements were not smooth. Later, to gain more insights about eye movements, Delabare (1898) simultaneously succeeded in inventing the first eye-trackers. Although the first eye-trackers provided valuable information for conducting reading studies, these tools were criticized for being invasive. To provide a non-invasive approach, Dodge and Cline (1901) invented a device that used photography for recording eye movements. With advancements in technology, researchers such as Buswell (1922) were able to use the reflection of light for recording eye movements on a film that enabled the production of some of the first two-dimensional scan paths.

The early 1970’s marked the onset of digital technology and image processing, which enabled Young (1970) to suggest scanning the image of the eye for the limbus. Due to the difficulty faced in scanning the limbus and vertical eye movements with Young’s technique, an alternative approach of scanning for the lack of reflectance from the pupil (“dark-pupil” tracking) was proposed. The limitation to dark pupil tracking was the low contrast between the black circle and brown irises. Therefore, Merchant et al. (1974)
suggested the bright-pupil tracking technique, wherein the pupil is lit directly from the front so that the light bounces off the back of the retina and appears very bright and is easily detected while scanning. The same technique was used to find the smaller, brighter corneal reflection that is seen in the contemporary systems. Over years, eye-tracking devices have been improved to achieve higher-precision records of observers’ points of regard, which allow for natural head and body movements (Richardson and Spivey 2004). Currently, eye-tracking technology exhibits a robust capability to aid in visual attention studies related to construction safety and can provide invaluable insights for further improvement.

2.3 Application Areas of Eye-Tracking

Although early eye-tracking research mainly focused on investigating the process of reading, the relationship between cognitive goals and eye movements opened gates for the use of eye-tracking in neuroscience, psychology, and behavioral research (Richardson and Spivey 2004). The application areas of eye-tracking research include diagnostic as well as interactive purposes. Considering the research objective of this study to be diagnostic in nature, we will limit the discussion of related eye-tracking research to diagnostic purposes only.

In the past decade, the use of eye-tracking has been flourishing in studies related to human-computer interactions and usability research (Jacob and Karn 2003, Poole and Ball 2006) and it has also been applied to transportation (Suh et al. 2006, Yao et al. 2011), driving (Recarte et al. 2008, Palinko et al. 2010), aviation (Sarter et al. 2007), marketing (Pieters 2008), nuclear power control rooms (Ha and Seong 2009), medicine (Zheng et al. 2011) and petrochemical control rooms (Ikuma et al., 2014). The use of eye-tracking in the above listed fields has been mostly related to estimating cognitive loads, analyzing user behavior, revealing differences in aptitude and expertise, and diagnosing neurological disorders. Even though eye-tracking is being applied in an increasing number of fields, it remains unexplored in the field of construction safety.

2.4 Heat Maps

A heat map is one of the most frequently used techniques for the visualization of data in eye-tracking studies. Heat maps can be described as graphical representations of eye movements over a scene. Major advantages of using heat maps include that they are easy to create and interpret because they graphically represent data using a color scale that relates to temperature, they provide a quick view of existing patterns, and they reveal a huge amount of data that would otherwise require more mental effort if presented in numerical formats (Bojko 2009). Therefore, heat maps are found to be widely used in web usability studies (Cutrell and Guan 2007, Buscher et al. 2009). Heat maps are limited in their representation of data—i.e. they only show density-based representation and heat maps lack information about the sequential order of eye movements. Thus, understanding the different types of heat maps, their limitations, and their purpose of use is necessary prior to their implementation (Bojko 2009).

2.5 Eye-Tracking Metrics

A large number of eye-tracking metrics have been used in previous studies to analyze human cognitive processes. The most common measurements used in eye-tracking research are “fixations” (relatively stationary eye positions over minimum duration) and “saccades” (quick eye movements). In order to explore the determinants of ocular behavior, a multitude of derived metrics that stem from these basic measures are incorporated into eye-tracking studies as dependent variables. Fixation-related and saccade-related metrics identified from literature are described in Table 1.

3 POINT OF DEPARTURE

Eye-tracking research has been flourishing widely in various fields of study. Even though the key characteristic of eye-tracking research—namely, that eye-tracking is the only direct measure of attention—provides immense potential for investigating, understanding, and improving construction workers' attention, eye-tracking remains unexplored in the field of construction safety. This study addresses this gap in knowledge and pioneers the application of a widely developed technology to the realm of construction-safety practices.
4 METHODOLOGY

A pilot test was mandatory for this research since no study had previously investigated using eye-tracking technology to explore the hazard identification abilities of construction workers. The pilot test was designed to examine participants’ viewing behaviors and attention distribution when shown a hazardous situation in a construction site. The experiment tested participants’ search-efficiency skills when required to use cognitive processing to determine whether or not a hazard is present in a given situation.

Eight male and four female graduate students at the University of Nebraska–Lincoln participated in the experiment as paid volunteers. All of them had normal or corrected-to-normal vision and had been prohibited from drinking coffee on the day of the experiment. Participants were invited to the study by responding to an invitation flyer. Eye movements were recorded using a head mounted Eye Link-II system (SR Research) with a sampling rate of 500 Hz and an instrument spatial resolution of 0.01°. The construction site images were displayed on a square 19’ computer screen. Participants used a video-game remote control to complete the task. The EyeLink® Data Viewer tool was used to generate eye movement patterns and variables.
Following the guidelines provided by Pernice and Nielson (2009), the experiment was performed in a lab setting. The lab was well lit and equipped with a dual screen setup, with the eye-tracking monitor placed behind the participant to avoid distracting him or her from the assigned task. The study strictly followed a well-drafted research protocol based on literature and expert advice. The experiment consisted of a single task wherein each participant was shown thirty-five construction site images ordered randomly on a computer screen while wearing the eye-tracker and was told to identify whether or not the situation in the image presented a hazard. Each image was displayed for a maximum of 20 seconds. The research assistant observed the participants’ eye movements on the eye-tracking monitor. The participants had to answer whether or not they found any hazards with the use “A”—Yes—or “B”—No—buttons on a video-game remote control. No specific information was provided regarding the type of hazard to look for.

After conducting the experiment and collecting the data, the first step for analyzing the relationships between eye movement parameters and dependent measures was to define areas of interest (AOI) in each picture. AOI(s) are visual environments of interest defined by the research team (Jacob and Karn 2003). For example, in marketing-related studies, specialists might be interested to know about the total time each observer views the desired target (brand area) on home page (Goldberg et al. 2002). In this study, because we aim to find out how participants scan a picture to identify hazards, we defined AOI(s) as visual environments of interest in pictures that include a hazard. The research team specified areas in each picture, and two examples are shown in Figure 2.

![Figure 2: Picture I and II’s Areas of Interests](image)

After conducting the experiment, to graphically represent the data, an absolute fixation duration heat map was generated for each picture. The results were also analyzed using different eye movement metrics such as time to the first fixation on target, average gaze percent (time) on each AOI, average number of fixations per AOI, average run count, saccade/fixation ratio, and average saccade amplitude.

5 RESULTS

The experiment was conducted on twelve participants and data were collected according to the established protocol. The data of two participants were omitted from the analysis because acceptable levels of calibration on the eye-tracker could not be achieved. Then, the EyeLink® Data Viewer was used to extract data and perform the analysis. To compare visual representations of participants’ eye movements with their hazard identification abilities, heat maps were created and compared with the number of hazards identified by each participant. Then eye movement metrics were analyzed to determine which areas of interest (areas that contain a hazard or a hint to identify a hazard) were identified fastest, which areas of interest were perceived more important, and how the participants searched and scanned pictures.

5.1 Hazard Identification and Heat Maps

The results of the pilot test conducted on ten students at the University of Nebraska-Lincoln confirmed that most of the hazards in a construction site can be easily missed or not considered to be a hazard by
individuals. Although all of the thirty-five images shown to the participants had multiple hazards varying in safety risk, the number of hazards identified by participants for all pictures ranged from 11 to 29 with a median of 22.5. The results can be alarming because working in an environment with latent hazards drastically increases the risk of an incident (Laurence 2005, Sneddon et al. 2004).

The absolute duration heat maps were generated by combining data from all ten participants to provide a quick view of average existing viewing patterns. To demonstrate the potential application of eye-tracking technology for measuring construction workers’ attention, a heat map for one of the images is shown in Figure 3. By looking at heat maps, one can visually understand which objects captured participants’ attention in a scene. While the absolute duration heat maps generated by combining data from all ten participants illustrates existing viewing patterns on average, the heat maps developed per participant for each image shed light on another aspect of the individual’s visual attention. In one of the pictures, five out of ten participants did not fixate on a person standing at a height without any fall-arrest protection systems. In another example, participants missed a danger sign, raising doubts as to the effectiveness of the signboards in catching peoples’ attention.

### 5.2 Eye-Tracking Metrics

The metrics provided in Table 1 are calculated by analyzing the two-dimensional eye movement patterns of participants. The two-dimensional eye movement analysis starts by measuring the visual angle of pairs (or more) of data points in a time series—i.e., \( (x_i, y_i) \)—and also, the distance between successive data points—i.e., \( (x_{i+1}, y_{i+1}) \) (Duchowski et al. 2002). Using this concept, the following eye-tracking metrics were calculated for all AOI(s) in each image: the time to the first fixation on an AOI; the average proportion of gaze duration on each AOI based on time; the average number of fixations per AOI; and the average run count. The results for two pictures (out of 35 pictures) are shown in Table 2. Using these metrics, one can answer the following questions: How long does it take for a participant to see an AOI for the first time? On average, how long does a participant fixate on an AOI? In a given time, how many times does a participant fixate on an AOI? How many times does a participant come back to an AOI?

</tbody>
</table>
In picture I, the time of the first fixation in three areas of interests shows that the lack of guardrails placing around walking/working surface (AOI 1) captured people’s attention quicker than other areas of interest. This is an important finding, as previous studies related to graphical user interfaces showed that a lower first-fixation time indicates that the target better captured one’s attention (Byrne et al. 1999). In addition, the results of the analysis illustrate that participants spent more time on the AOI 3 (larger gaze proportion, number of fixations, and run count). In the AOI 3, a person is looking down a third floor of a building without any fall protection. This is against OSHA regulations as an employer has to provide some type of fall protection for workers who are working more than six feet above the lower surface. The highest run-count and proportion of gaze duration looking at the AOI 3 indicate the importance of this hazardous situation for participants.

In picture II, the AOI 1 was a danger sign that received only 5.84% of the proportion of gaze duration. This means that, on average, participants paid little attention to this part. Further analysis revealed that seven out of 10 participants did not even look at the sign. On the other hand, the AOI 2, which included a human figure, grabbed more attention (37.16% of proportion of gaze duration). This was expected as previous studies found that participants mostly tend to fixate preferentially and rapidly on human figures (Wilkinson and Light 2011, Thiessen et al. 2014). In the construction safety domain, it can be concluded that participants can identify areas with an imminent danger to a person faster than those areas that include a dormant hazard. The AOI 3 was also important because it showed that the worker standing on an elevated lift did not use the personal fall-arrest system properly: while he was wearing the body harness with attached lanyard, he anchored himself to the elevated lift in way that created a swing-fall hazard. According to the OSHA regulations, the anchorage point must support the force of a person falling and the worker should be tied off to an anchor in such a way that if he fell, he would not swing into an obstruction. The AOI 3 was the second most important area viewed by participants.

In addition to metrics per image, one can calculate mean value of eye-movement variables per participants to further investigate each person’s search strategy. These values are summarized in Table 3. Larger saccade/fixation ratios reflect that a person was more careful to scan pictures and search for hazards. Also, larger average saccade amplitudes indicate that a person could find the hazards more rapidly according to his/her experience. These values can help a researcher divide participants into multiple groups based on certain characteristics (e.g., age, gender, hazard-identification ability, risk perception, previous training, etc.) and test related hypotheses to compare their visual attention. Due to the low number of participants in this pilot test, the results of this analysis are not shown here.

5.3 Scanpath

Scanpath is a compelling visualization of eye movements that shows the sequence of saccade-fixate-saccade. Figure 4 depicts a scanpath obtained from one of the participants for Picture II. An optimal scanpath is a straight line eye movement to desired targets and a short fixation on targets (Jacob and Karn 2003, Pole and Ball 2005). Different quantitative measures and statistical analyses are used to analyze scanpaths—these analyses are outside of the scope of this study. Previous studies investigated scanpath variability between multiple webpage designs and found that visual complexity contributes to eye movement behavior. Similar studies can be conducted in the construction industry to measure the impact of crowded jobsites in distracting workers.

6 CONCLUSION

One of the root causes of accidents is human error (Abdelhamid and Everett 2000), i.e., the lack of attention and failure of workers to identify hazards. Given that hazard identification plays a crucial role in construction safety (Holt and Lampl 2006), the use of eye-tracking technology to investigate hazard identification abilities can aid in reducing construction worksite injuries. This paper presents a novel approach to improving construction-site safety by employing the eye-tracking technology that has been widely accepted as the most direct and continuous measure of attention. As a first step towards exploring the use of eye-tracking technology for construction safety, this study conducted a pilot test aimed at investigating patterns of participants’ eye movements when performing a task-based search. To analyze
the results, heat maps were created for data visualization, and gaze/fixation-related and saccade-related metrics were calculated.

The findings of this study provide a proof-of-concept and indicate the immense potential for using eye-tracking technology to improve construction-site safety and to attempt to facilitate more detailed
investigations in future research. As implied above, eye-tracking can be utilized for innumerable purposes inclined towards achieving safer working conditions, such as identifying hidden hazards, measuring situational awareness of workers, and improving the effectiveness of safety-training programs. With advancements in technology, eye-tracking equipment is available at lower costs, allowing for higher flexibility in use and providing a higher precision record for observer’s eye movements. There is no doubt that investments in eye-tracking technology will prove beneficial in academic as well as professional fields, thereby unveiling invaluable findings for improving construction-site safety.

CLOSING THE CONTRACTUAL CIRCLE: INVESTIGATING EMERGENT SUBCONTRACTING APPROACHES

Salvatore Antonio Biancardo¹, Natasha Osmanbhoy², Jeffrey L. Ottesen², Giovanni C. Migliaccio² and Caroline Clevenger³
¹ University of Naples Federico II, Italy
² University of Washington, Seattle
³ University of Colorado Denver

Abstract: The Architecture-Engineering-Construction (AEC) industry is shifting away from the traditional paradigm, one that places users, planners, designers, and contractors in different silos during professional practice. Other contractual schemes, which rely on contractual integration at lower contractual tiers, are emerging. These schemes close the contractual framework at lower tiers by having multiple upper-tier contractors subcontracting work to the same lower-tier entity. In these instances, subcontractors have contractual relationships with more than one other upper-tier party in the same project. A previous study on Building Information Modeling (BIM)-enabled projects revealed the emergence of these types of contractual relationships. To date, however, little is known on these emergent approaches, their diffusion, criteria for adoption, or expected utilities. This research proposes a methodology to analyze the benefits of these emergent models, then applies this methodology to recent projects to quantify outcomes, and finally develops a holistic framework of integrated contracting to assess its impacts on project efficiency. The specific objective of this research is to identify and delineate new lower-tier organizational relationships in today's construction practice. Preliminary results are included in the paper. Use of these emergent models for building contractors was assessed using a survey instrument. Data collection involved contractors in Washington State. After initial screening, several contractors were selected and interviewed regarding the nature of the adopted emergent subcontracting practices, the purpose for using them, and their perceived outcomes. This research contributes to a greater understanding of the occurrence, reasons, and advantages and disadvantages of these emergent contractual schemes. A discussion of their impact on overall project performance is included.

1 INTRODUCTION

Engaging subcontractors is an essential part of any construction project. While the Integrated Project Delivery (IPD) method aligns all the team members through a multiparty contract, other contractual schemes, which rely on contractual integration at different contractual tiers, are also emerging. Although procurement practices of subcontractors come in many forms and may be custom to various organizations, to date the literature lacks studies on the practices of lower-tier subcontracting.

According to Ndekugri (1988), on many individual projects, the level of subcontracting can be up to 80-90%. While general contractors hold the direct relationship with the client, they are usually not the only party involved to ensure successful completion of the works. Subcontractors are often engaged to assist
general contractors address difficulties due to the necessity to secure special expertise, resources and finances to the project (Elazouni and Metwally 2000). According to Shimizu and Cardoso (2002), subcontractors are specialist agents in carrying out a specific job, supplying manpower, besides materials, equipment, tools or design. Subcontractors act as representatives of the production system of the contractor company and are responsible only for the executed part of the workmanship.

The concept of supply chains is progressively becoming more significant to improve performance in the construction industry (London and Kenley 2001). Construction supply chain management (CSCM) refers to the coordination of distinct quantities of material delivered to specific construction projects.

Obrien et al. (2009), understanding the implications of supply chain management, to improve the effectiveness in the construction project execution. In particular they recognizes the importance of considering arrangements between the different firms involved in designing, procuring, and assembling construction, and reviews various perspectives to understanding and improving organizational issues in the supply chain. Also, they provide an overview of a range of information technologies that can contribute to supply chain performance, as well as examples of effective use.

Cox (2004) highlights the importance project managers develop different sourcing relationships depending on the different situation they are involved.

Additional impacts of subcontracting often include the spread of project risk and financing burdens across contractual parties. For example, to allow subcontractors to overcome project complexity, economical and efficiency problems, they frequently sublet a portion of their contract to other specialized firms. These specialized firms are commonly known as lower-tier subcontractors or sub-subcontractors. Engaging these specialized contractors enable them to perform their work at a quicker pace and lesser cost due to the availability of the resources as compared to general contractors. However, subletting parts of a subcontract to a lower tier subcontractor also provides an added complexity. When there are multiple levels of contractors involved in a project, the communication links between the parties - particularly the client and subcontractors - are weakened. The clients do not communicate directly with some of the firms that actually perform the work as they often do not know the identity of the lower-tier subcontractors (Choudhry et al. 2012; Arditi and Chotibhongs 2005). There are many forms of relationships between general contractor and subcontractors. Partnering is a common relationship between contractual parties at large, but partnering with subcontractors has different connotations from traditional owner-contractor forms of partnering. Hsieh (1998), affirms that more than 80% of general contractors prefers to create a durable working relationship with a particular subcontractor and material seller, also known as strategic partnership (Li et al 2000). Anyway, general contractors have a preference with a financial autonomy more willingly than any type of joint ownership. Most of the general contractors preserve a durable working relationship with an average of three subcontractors and two material vendors for any specified trade. Considering the prevalence of durable working relationship, a small number of general contractors engage new subcontractors except when forced by public procurement laws. If there is a new engagement, general contractors are influenced by the recommendations of other firms basing most of the weight of their decision on subcontractor’s references and track record. Differently to ordinary conviction, financial capability and equipment ownership are not much take into account for selecting subcontractors.

Partnering has also been considered as an avoidance technique in the form of alternative dispute resolution. A variety of reasons have been brought forward as consideration prior to the decision for partnering. According to Kumaraswamy and Matthews (2000), prime contractors and subcontractors believe that there are benefits in developing partnering arrangements between prime contractors and key subcontractors.

According to Tommelein and Ballard (1997), the coordination of the specialty contractor management by the general contractors affects the quality of production management on projects. Only knowing the appropriateness of the power regime perspective on sourcing and relationship management, the coordination can be appropriate.
According to Burr and Jones (2010) and Kelly (2014), project and system complexity, coupled with piece-meal design specialization has resulted in the need for greater collaboration among project participants in order to avoid cost overruns and other negative project outcomes. A widespread lack of trust, respect and honesty in the American, Australian and European construction industries has been credited as one of the main drivers toward the adoption of partnering concepts (Kumaraswamy and Matthews, 2000).

In the last years several forms of relational contracts, contracts in recognition to the commercial “relationship” between the parties to the contract, have been implemented in the architectural, engineering, and construction (AEC) industries to improve project performance by reducing schedule duration and increasing participants collaboration (Colledge, 2005).

Building upon transaction cost economic theory, Winch (2001) propose a conceptual framework for governing processes in the construction industry. While studying the impact of BIM-enabled design on project delivery, Clevenger and Khan (2014) highlighted that there are several organizational similarities and differences with regard to the contractual relationships between the relevant parties of the projects. Similar to Integrated Project Delivery (IPD) where the main parties of a construction project are contractually linked (at minimum the Client, Consultants and the General Contractor, but often also subcontractors and vendors), there are also circumstances where the lower tier subcontractor closes the contractual circle.

This research analyzes the preliminary results of emergent subcontracting approaches in the US improving the knowledge of the occurrence, reasons, and advantages and disadvantages of these emergent contractual schemes. The outcomes develop a holistic framework of integrated contracting to assess its impacts on project efficiency.

2 RESEARCH METHODOLOGY

This research was conducted in two steps: a) an online survey was performed to provide a current overview of emergent contracting practices among building contractors in Washington. The survey was mainly used to identify and screen potential candidates for follow-up interviews; b) on-site interviews were conducted to discuss reasons and results of these emerging contracting practices. The survey was completed in fall 2014 while the interviews were completed in winter 2015.

2.1 Online survey

The online survey was created using a web-based service (questionpro.com). The target audience included contractors and subcontractors in Washington State. Prior to conducting the survey, a pilot survey was carried out with students and faculty of the construction management department in University of Washington (UW) with experience in subcontracting practices. The questionnaire was modified to incorporate feedback from the pilot survey, to adapt it for the construction industry. The questionnaire was sent to registered firms with the Associated General Contractors of America of Washington (AGC-WA) and The UW Construction Industry Advisory Council (CIAC).

The survey consisted of three parts. The first part focused on the individual's background and personal experience in the construction industry, referring to the contractor's current position in the company and the value of the largest construction contract over the last 3 years. The second part addressed information on the individual's company, such as the general size of the company, the estimated average annual revenue (in US dollars) during the last 3 years and the company's main role, either as a General Contractor or as a Specialty Contractor. This was used to provide a better understanding of the size of the company and size of the projects they deal with. In addition, the participants were asked their level of involvement in the administration of subcontracts. The last part of the survey was used to collect data regarding the delivery methods commonly used in the projects, the factors that can influence the selection of subcontractors, and, in particular, if any subcontractors have signed contracts with other any project team members.
2.2 On-site interviews

The authors decided to select as first interviewee, an individual with significant knowledge of industry practices who also serves as instructor for short-courses on contracting practices for industry organizations in Washington State. This interview was used to “calibrate” our interview guide, including our tentative list of subcontracting models. The following list includes all the subcontracting models that resulted from this first interview. They were shown and explained to all the later interviewees.

- **Traditional Subcontracting (TS):** Figure 1a reflects the traditional contracting approach where the Owner (O) engages the General Contractor (C) and the Designer (D). The Designer refers to the lead consultant, and may be the Architect or the Engineer depending on the project type; D will then engage their own sub-designers (SD), C will engage their own subcontractors (SC). There are no mandated functional relationships between SD and SC.

- **Traditional Subcontracting with Design Assist (TS-DA):** Figure 1b is similar to the traditional approach except for the presence of a mandated “Design Assist” functional relationship between SD and SC.

- **Design-Build Subcontracting (DBS):** Figure 1c refers to O engaging D and C at an early stage known an Early Contractor Involvement (ECI) and only C engages SC in a Design Build contract for the design and construction phases.

- **Integrated Design-Construction Subcontracting (IDCS):** Figure 1d refers to O engaging D and C who then engages the same SC; D engages SC for design work while C engages SC for construction work. Therefore, SC holds a contractual relationship with both D and C. However, this is unlike IPD where there is a cross of contractual relationship between every party involved. It is also noteworthy that D & C do not hold a contractual relationship.

- **Integrated Specialty Work Subcontracting (ISWS):** Figure 1e is similar to the traditional approach at the upper tier. However, in this case, C engages 2 different SC. One of these SC sublets a portion of their work to the other SC in the same project.

These subcontracting models were diagrammed as shown in Figure 1. This figure was shown and explained to all the contractors who were interviewed thereafter.

![Organization chart](image)

**Figure 1: Organization chart**

On-site interviews were conducted with selected survey participants to study in greater detail the different subcontracting approaches adopted in Washington State. In addition, the interviewees were asked if they encountered multiple roles in a project, the influence of the Project Delivery Method and Procurement Method on the decision, the advantages, disadvantages, opinion and consideration on such practices. A special focus was given to identify situations where subcontractors have contractual relationships with more than one other party in the project.

3 SURVEY DATA AND ANALYSIS

Data collection involved contractors and subcontractors in Washington State. The questionnaire was sent to a total of 271 participants using the contact list extracted from AGC and CIAC. Out of the 271 questionnaires sent out, there was a 33.9% response rate for a total of 92 respondents. Among the respondents, 65 were executives, 15 were project managers, 10 were estimators and 2 were superintendents. In particular, data indicated that 68% of the respondents worked for general contractors, 25% for specialty contractors, and 7% for suppliers. This response rate suggests the results are deemed reliable. In fact, Owen and Jones (1994) suggested that 20% would be an acceptable response rate whereas Black et al. (2000) leaned toward 30% as an acceptable response rate.
Figure 2 shows the results regarding Individual’s Background. Figure 2(a) shows that contractors with at least 15 years of construction experience (senior contractors) are the largest percentage of the participants (88%). No contractors with less than 2 years’ experience participated. Figure 2(b) shows that 40% of the respondents had stayed with the same company for more than 15 years, while 39% had maintained the same position for a period between a period of 5 and 15 years. This suggests that most of the respondents are well experienced in the construction industry and with their employer’s practices.

![Pie chart showing years of experience in the construction industry and years in the same position with the company](image)

(a) Years of experience in the construction industry  (b) Years in the same position with the company

Figure 2: Individual’s Background results

Figure 3 shows the results regarding the Individual’s Company. Figure 3(a) shows that 47% of the respondents have been fully involved and somewhat involved in the subcontracting administration, and 5% are aware but not involved. One respondent was removed from the data analysis, as the individual was not aware and not involved in the process. Figure 3(b) shows that the respondent’s company acts primarily as a prime contractor for 71% of the respondents, while it acts as a subcontractor for 29% of the respondents.

![Pie chart showing administrative involvement in subcontracted work and major business role of the company](image)

(a) Administrative involvement in subcontracted work  (b) Major business role of the company

Figure 3: Individual’s Company results

Figure 5 shows the percentages of respondents who were aware of situations where a subcontractor shared contractual relationships with multiple parties in a single project.
Last, survey participants were asked if they were willing to participate in follow-up interviews. Out of 92 respondents, 61 agreed to participate in the follow-up. Among all those who were willing to be interviewed, we selected only those who were familiar with the situation where a subcontractor shares a contractual relationship with more than another party in the project (Yes in Figure 5) or were unsure about this fact (Unsure in Figure 5).

4 INTERVIEW DATA AND RESULTS

Twenty-four respondents were invited for follow-up interviews, including 19 prime contractors and 5 subcontractors. In the end, the authors conducted 14 interviews with 11 prime contractors and 3 subcontractors. Job titles included 10 executives, a retired executive, a project manager, an estimating manager and a safety manager. Each interview lasted approximately 45 minutes. One of the interviews, a prime contractor, did not produce meaningful data because we discovered during the interview that the interviewee only had a limited involvement in subcontracting. Interviewee No.1 helped the research team to refine the list of subcontracting models, which aided in drawing Figure 1. Later interviewees were shown diagrams in Figure 1. They were asked to describe which contractual strategies were most commonly used under which circumstances.

4.1 Traditional Subcontracting (TS)

All the interviewees described the model represented in Figure 1.a as the most traditional form of procuring subcontractors and sub-consultants where the owner will hire a designer and a general contractor and they will hire their own sub designer and subcontractor respectively. According to the interviewees, this model is used commonly in public projects particularly for lump sum contracts awarded to the lowest bidder. While it may seem inefficient from a communication standpoint, most contractors curb this inefficiency by communicating directly to other contractual parties by requesting and organizing joint meetings.

4.2 Traditional Subcontracting with Design Assist (TS-DA)

All the interviewees agreed that the model represented in Figure 1.b is the most common. This is particularly true for private projects where the subcontractor and the sub designer will share a functional Design Assist relationship. According to the interviewees, this is particularly true when the contractor is on board at a later stage, which requires the sub designer to produce preliminary drawings to be included in the bidding documents for the general contractor. This general contractor will then require the subcontractor to establish a Design Assist relationship with the sub designer with the purpose of facilitating collaboration on the production of detailed design documents. This is the most preferred approach for all contractors regardless of trades. One of the interviewees also said that it works well for subcontractors who do not employ individuals who are qualified to be engineers of record, and, therefore, cannot use the Design-Build subcontracting model.
According to most of the interviewees (8 of 13), the Design-Build Subcontracting model shown in Figure 1.c is not as common as those represented in Figures 1.a and 1.b. While all (13 of 13) interviewees encountered it, they have suggested this subcontracting model is used only for specific specialty trades, such as precast concrete structures for parking, curtain walls or Mechanical, Electrical and Plumbing (MEP) works. This model is also commonly used for smaller projects where a sub designer is typically not needed. At least three interviewees explained a variation where even the consultant designer is under the general contractor, which ultimately makes it a traditional design-build contractual strategy. Figure 1.c is also a growing trend and is getting more common in the industry, particularly in projects with early contractor involvement.

The Design-Construction Integrated Subcontracting model shown in Figure 1.d describes a contractual structure where both the general contractor and the designer select the same subcontractor to perform a scope of work that integrates design and construction services. However, different from Design-Build Subcontracting, this subcontractor holds two separate contracts with the general contractor and the designer. According to 9 of 13 interviewees, this approach is rarely adopted, but it is present in the industry. At least four interviewees explained that the general contractor may have a contract with the subcontractor, similar to Figure 1.c, but the subcontractor may share a functional relationship with the designer. At least six interviewees have faced this situation. This situation happens, however, only on highly specialized projects where there is a large scope for the subcontractor.

Those interviewees (7 of 13) who had never faced this situation were asked to provide their feedback and opinions based on their personal experience. All the interviewees stated that an MEP contractor would be one who could be part of this contractual strategy. Apart from the general contractor, an MEP contractor could be contracted either by the owner or the architect or in some cases, the structural engineer. At least five interviewees stated that the next most common trade was the curtain wall or shop front contractors. Some other trades include the Structural Steel, Precast, Surveyor, Quality Assurance and Quality Checks, Kitchen Equipment, Data Cabling and Door Hardware. The majority of interviewees (9 of 13) suggested this method is commonly used for private projects rather than public ones due to its flexibility. In cases where the interviewee had experience with this situation, the decision to contract the same subcontractor is usually a joint decision between the designer and the general contractor, to provide the best solution for the project. This is where the designer will contract the subcontractor to do the design work, and the general contractor will contract the subcontractor for the construction work.

The decision to use this contract strategy is usually weighed by the relationships the different parties share. For example, the designer and the contractor agree to use the same subcontractor when they share a strong relationship with each other as well as the subcontractor. In this way, a strong relationship is necessary to carry out this strategy. It also depends on the complexity of the project. It is encouraged for proprietary or specialized works where the engineer or architect is not familiar with the system and would require a high level of expertise. The project delivery method used by the project also impacts this decision. In a Design-Build project, the parties have a greater flexibility in using this approach as compared to traditional Design-Bid-Build projects. In General Contractor/Construction Manager (GC/CM) however, it varies depending on the complexity of the project, as it is more likely to proceed with Design-Build Subcontracting (Figure 1.c).

The interviewees were asked about the advantages of the Design-Construction Integration model (Figure 1.d). The advantages suggested by the interviewees included, but were not limited to the followings:

- **Triggers economic efficiencies** in terms of cost and resources because it encourages labour and cost efficiency due to the sharing of resources;
- **Promotes communication efficiencies** because it forces good communication between the parties due to the contractual binding. It is more efficient as it eliminates the “back and forth” communication between the subcontractor and the designer; it also eliminates the learning curve to working together.
while generating detailed design due to the specialty designer having a better knowledge of the construction phase, as they are essentially the same team with the specialty contractor;

- **Facilitates lean construction**, as the designers are more knowledgeable and takes constructability into consideration when designing;
- **Provides consistency** in the project, as the party who is designing is also doing the installation and construction. There are lesser chances of scope gap as one party will be in charge of the whole system and they can highlight if there are any gaps found;
- **Improves price prediction** as all parties have a better understanding of the construction and installation process;
- **Improves project quality** by reducing amount of design and construction rework;

The interviewees also raised some concerns and provided some disadvantages of this subcontracting model. The disadvantages suggested by the interviewees included, but were not limited to the followings:

- **Misalignment between designer and general contractor**: The subcontractor may be subject to discording instructions from the designer and the general contractor due to the different expectations and intent. For example, the contractor will be focused on cost driven approaches while the designer will expect better design quality. Whose instructions take precedence? There is also potential for the subcontractor to be bias towards one party, usually the one who they share a better relationship with. Therefore, influence over the subcontractor is less as it is split between two parties. Interviewees identified this risk factor as high;
- **More paperwork and risk of contractual complication**: "who pays for what" issue between the contractor and the designer. There is also a liability issue, as there is less control over design. If a part of the project is not designed right, besides the subcontractor, who will be responsible contractually? Will it be the designer or the general contractor? There is a risk of blaming the other party;
- **Internal coordination failures**: Potential of a subcontractor who has different teams to do the design and construction within the same company and they may not coordinate as expected; therefore, the expected results may not be achieved.

While all interviewees mentioned one or more of these disadvantages, eight of the interviewees felt that these issues can be overcome through the establishment of a collaborative team that shares a trusting relationship involving trust. This strategy works well if the contractual implications are explicit in the contract and all the parties have a clear understanding of the objectives, intents and risks involved in this strategy.

Eight of the interviewees highly encouraged this model as long as there is no increased risk. This depends on having the right team with good, honest and collaborative relationships with everyone being clearly aware of the contract and the factors involved in the contractual strategy. Some interviewees feel that having the owner fully aware of the situation benefits the project while some feels that it is better for the owner to not be involved. Three of the interviewees felt that it was not ideal, as a single point of contract is preferred to avoid liability issues. These interviewees feel that there is a need to have one responsible party to be in charge of the on goings of the project rather than split responsibility. To the rest (2 of 13) of the contractors, the approach doesn’t matter as long as everyone is fully aware of their scope and responsibilities.

**4.5 Integrated Specialty Work Subcontracting (ISWS)**

This model was found to be very common between subcontractors where a subcontractor on a project engages another subcontractor on the same project to complete part of their works. This is usually a small portion of the works and interviewees suggested there are plenty of occasions where the subcontractors do not share a contractual relationship with each other, and the works are done on a trust basis. In such a scenario, subcontractor ‘A’ helps subcontractor ‘B’ on a project, and subcontractor ‘B’ returns the favour on another project they work with together. Whether or not these subcontractors share a contractual relationship, most general contractors encourage this approach as it shows a collaborative relationship between their subcontractors, which in turn provides a better quality project. It also ensures
that the subcontractors with the right set of skills and resources are doing the right work. A common example from the interviewees is the electrical contractors who will engage either the earthwork or utility contractor to do trenching works for them.

This strategy is very situational where some interviewees prefers contract involvement to deal with payment and warranty issues while some interviewees feel that the lack of contracts provide less paperwork to deal with, which in turn saves time. When interviewing the subcontractors, some prefer having a change order by the general contractor rather than add on another contract, while some prefer to share the resources without getting the general contractor involved. When interviewing the prime contractors, some prefer the subcontractors to manage the contract on their own without their involvement to avoid any conflicts and additional paperwork due to change orders. However, there are some prime contractors who prefer to have control over their subcontractors.

5 CONCLUSIONS

Based on the surveys and interviews completed to date, the authors found that the subcontracting model used on a project is primarily situational, and that there are many factors involved in the decision of selecting a contractual strategy. The interviewees confirmed that all of the subcontracting models presented to them are used in Washington State. All models are relatively common except for the Integrated Design-Construction Subcontracting (Figure 1.d). Such results expand upon previous findings of Clevenger and Khan (2014) that have first identified the occurrence of ICDS. Since that previous study had linked this model to the increasing use of BIM, we explored this issue with our interviewees. When asked about the impact of Building Information Modeling (BIM), it was found that although BIM does not have a direct impact on the changes of the contractual strategies over the years, it does play a role and accelerates the changes in contractual strategies found. The general consensus of the interviewees (9 of 13) is that BIM is just another tool used in construction yet it forces collaboration and a functional relationship between the project team members involved, and that BIM provides an overall advantage to the industry.

The authors delved into the reasons, benefits and barriers of ICDS, while comparing it against the remaining models. With regards to the remaining models, such approaches have been used under different circumstances depending firstly on whether the project is a public or private project. While most public projects are less flexible, there are exceptions where the owner is willing to test out alternative contracting strategies. The project team involved, the complexity of the project and the type of building (residential, commercial etc.) also determines the strategy used.

The use of ICDS relies on many factors. One major factor is the trade of the subcontractor, which may be involved in this model. For example, while the bigger trades like MEP and curtain wall frequently practices this approach, trades with less complex scope of work, such as concrete, do not. Another factor is the complexity of the project, and a larger, more complex project is more likely to explore the different strategies as compared to smaller, “cookie cutter” projects. It was also found that while most interviewees encourage the approach of closing the contractual circle on the lower levels, its success depends a collaborative team with a good relationship, and a clear contract.

Some limitations faced by this research was that the data set is only collected based on contractors located within a 45 mile radius of the University of Washington, Seattle. It was also noted during the interviews that some contractors felt that the designers may have a resistance towards ICDS.

To externally validate the research, the authors had concurrently conducted a smaller study with contractors in Colorado. Based on the set of 13 surveys completed, three were shortlisted for an interview. An interview will be conducted to validate the responses of the existing interviewees. Based on these responses, the authors will develop a survey instrument addressed to a larger nationwide pool of participants to provide an extensive data set. We will also consider expanding the data set further by including designers and developers as part of the research to fully understand the acceptance and resistance of this contractual approach.
Acknowledgements

The authors would like to express our deep gratitude to all the interviewees, including Ben Behnke (Ceco Concrete Construction), Carl Zarelli (Merit Construction Northwest), Craig Greene (Lydig Construction, Inc.), Dan Peyovich (Howard S Wright Const. Co.), Greg Primm (Korsmo Construction, Inc.), John Wallace (Edifice Construction Company, Inc.), Jon Deeny (Deeny Construction Company, Inc.), Mark Stoeser (Korsmo Construction, Inc.), Mark Webster (MacDonald-Miller Facility Solutions), Phil Lovell, Robert Guymer (Foushée & Associates, Inc.), Shawn Marvin (Flatiron Constructors, Inc.) and Steve Grasso (Bayley Construction, GP) for their help in sharing their knowledge and industry experience with us.

Abstract: Construction sites contain vast amounts of information. Recent advances in image-based visualization techniques enable monitoring construction progress using interactive and visual approaches. Photographs capture construction information in great detail while allowing the user to absorb as much information as they need. Construction as-built images captures great detail yet excludes portions of the site which may become of interest to the project participants. To overcome limitations of existing image-based monitoring techniques, this research focuses on an image-based virtual walk-through visualization approach to monitor construction sites. The use of a 3D model to create a virtual walk-through enables a comprehensive record and delivers the information in an intuitive manner. A pilot study is conducted to create several as-built 3D models from construction photographs. Then these 3D models are visualized in a 3D walk-through model. Within such an environment, the as-built construction objects are visualized to generate the status of construction progress. The study shows that this 3D image-based walk-through system introduces an advanced model that enables the user to have a realistic understanding of the construction site.

1 INTRODUCTION

Research has been conducted on image-based walk-through virtual reality technologies for monitoring construction projects (Rankohi et al. 2013). Dang et al. (2011) proposed a panorama-based semi-interactive 3D reconstruction framework for indoor scenes. Their framework overcomes the problems of limited field of view in indoor scenes and has the desired properties of: robustness, efficiency, and accuracy. Bradley et al. (2005) present a system for virtual navigation in real environments using image-based panorama rendering. Roh et al. (2011) proposed an object-based 3D walk-through model for interior construction progress monitoring.

Virtual Reality Documentation or VR Doc (www.vrdoc.ca) records construction progress through high resolution 360 degree panoramas (Rankohi et al. 2014). An intuitive VR Doc user interface allows the user to view panoramas from a specific date and location. Although VR Doc panoramas provide great detail through zoom capability, items out of view may become important as construction progresses. Therefore, increasing VR Doc coverage beyond predetermined locations creates a comprehensive photographic record of construction which is of value to the entire construction team. Moreover, using VR panoramas to capture an entire construction site would result in an overwhelming amount of data and
requires a significant amount of time to capture and process. Using photogrammetry techniques to compile site photographs into a single 3D walk-through environment provides a simple method of displaying and navigating a large and detailed data set.

The walk-through is seen as a “global” tool to be used at all levels of management and through all stages of construction. Before construction even begins the walk-through could assist with site planning and disaster management. During construction, inspectors would be able to perform quick assessments of the work being performed. Safety personnel could perform routine safety audits. Subcontractors would better predict their schedule by checking on the status of the work preceding them. Use also continues long after construction is complete by leveraging the ability to locate hidden items when planning upgrades and renovations. The technology could even be expanding to perform measurements, incorporating surveying and material quantity calculations. This paper investigates generating a low resolution walk-through model, which retains sufficient detail to visualize and document progress that would complement current features. To reach this goal, different software and photography techniques have been tested and the results are compared. Finally based on the achieved results, a first person Walkthrough model of an interior hallway is developed.

2 GOPRO CAMERA

A GoPro camera (www.gopro.com) was chosen to incorporate 3D model photography into the existing VR Doc workflow. The GoPro Hero 2 is an 11 megapixel camera capable of capturing both HD video and still images. The camera measures 42 mm x 60 mm x 30 mm, and has many mounting options that allow attachment to your body, helmet and various other objects or vehicles. The lens provides a 170 degree horizontal field of view which is captured by a 1.0160 cm CMOS sensor. The size and ease of portability makes it ideal to integrate into current VR Doc workflow. A time lapse option lets the user specify a capture interval of 0.5, 1, 2, 5, 10, 30 or 60 seconds. An interval of 2 seconds was chosen as it allows sufficient time to pass at a walking pace between images. Using this mode, the camera could be mounted to the photographer during VR Doc capture to simultaneously capture 3D model data.

Using the GoPro for photogrammetry purposes poses some problems. While able to capture a large field of view and minimize the number of photographs to cover a scene, the lens produces images with significant optical imperfections that affect the construction of a 3D model. The most visible imperfection is barrel distortion. Overlapping images are difficult to match as objects become different shapes in each image. Figure 1 compares the barrel distortion produced by the GoPro to an image taken with a Canon EOS 60D (a 17.9 megapixels camera with a 22.3 × 14.9 mm (1.6x crop factor) sensor). Corrections were applied to help reduce imperfections found in the GoPro images. Table 1 summarizes corrections applied using Dxo OpticsPro 10 (www.dxo.com).

3 BUILDING A 3D MODEL

3.1 Photography

A 3D model generated from photographs has different photography and post processing requirements than VR Doc panoramas. While capturing the twelve photographs for a VR Doc panorama the camera
remains in a fixed position as it rotates about the nodal point of the lens. The objects in the scene may be
distilled or moving in non-overlapping regions and overlapping regions should contain objects with texture and
contrast. Post processing identifies and matches key points in overlapping regions, stitching the images
together.

To generate a 3D model, photographs of the entire scene must be captured with the camera changing
position between images. Overlapping regions are significantly larger than in VR Doc panoramas; some
images may overlap 100 percent. Key points are extracted and matched over the entire photograph,
therefore texture and contrast must be present over the entire scene. Objects should also be stationary
during photography. The photography process which has performed well for uncluttered interiors involves
taking photographs perpendicular to the surface of interest with subsequent photographs of the same
surface continuing on the same camera plane. When approaching a corner, the camera should follow a
smooth curved path, avoiding abrupt changes in angle. This ensures sufficient overlap is achieved and
that key points will be detected and matched. After photography is complete many post-processing steps
are required to produce the final model.

3.2 Post Processing

Several different software packages were evaluated to build the 3D model. Agisoft Photoscan
(www.agisoft.com) was found to be the most suited to large unordered photo collections. The post-
processing described in this section pertains to Photoscan although the steps are similar across all
software evaluated.

![Figure 1: Barrel distortion correction: Cannon 60D image (a) before and (b) after correction; GoPro image (c) before and (d) after correction](image)

After adding the photographs to Photoscan, they must be aligned. The alignment process involves
identifying and matching key points across images. Setting the accuracy to high provides the best
solution but takes significantly longer to process. Disabling pair selection allows each image to be
matched across all others which provides better results for large unordered photograph collections.
Processing time varies with the accuracy chosen and the number of photographs used. Aligning the
photos creates a point cloud which is the first step in creating the 3D model. Building the geometry is
performed after the point cloud is generated which creates a mesh connecting the points together using
polygons. Photoscan has some basic mesh editing capabilities and if more editing is required the mesh
can be exported for refinement in third party software and re-imported. At this point the model resembles
the captured scene. The final process is to apply a texture to the mesh. Build textures feature creates a
texture which is overlaid on the mesh by incorporating the images used in the model. The textured model
completes the processing performed in Photoscan which is exported to create the virtual walk-through.
3.3 **Virtual Walk-through**

A first person walk-through is an intuitive method to explore the model in detail. The user is free to move around the model as if they were walking on foot with control of the direction of view as well as forward and backward and side to side movement. Many video games employ this type of viewpoint which is achieved using a video game engine. The video game engine is used to design and publish multiplatform video games, where in this case, the video game is simply the 3D model.

The Unity (www.unity3d.com) game engine was chosen to build the walk-through as it has a free version with sufficient capabilities. After building the model in Photoscan, it is exported in .fbx format with textures exported as .png. These two files are then imported into a Unity project. Before adding the model to the scene, picture normal vectors were set to calculate; otherwise the model was displayed inside out. Colliders were also enabled to form a rigid surface over the entire mesh, creating boundaries on floors, walls and objects. Textures are a separate component from the model and must be applied to the mesh. Unity has many options to apply a texture and introduce artificial lighting. For this application we wish to preserve the original scene and use the unlit texture option. Once rendered, the walk-through can be exported as a standalone executable file to be viewed on a personal computer. There is also a web delivery option which would facilitate delivery to a client.

3.4 **Description of Variables/Challenges**

Various challenges were encountered during the photography stage. Errors typically only become evident after photography is complete when building the 3D model. It is also difficult to determine the exact cause of the error as they tend to produce similar results; therefore it is important to pay close attention to all details during photography. Table 2 highlights the main challenges and expected solutions associated with photography.

<table>

</tr>
<tr>
<td>Low detail in model</td>
<td>Increase photo resolution</td>
</tr>
</tbody>
</table>

The number of photographs required to build a 3D model depends on the size of the scene, the lens used and the amount of overlap between images. A wide angle lens is recommended for interior photography in order to obtain sufficient overlap while minimizing the amount of images. A wide angle lens also aids in scenes with low texture, providing more opportunities for key point detection. Holes will appear in the model if portions are not sufficiently covered during photography. In extreme cases entire sections of the model will be left out or multiple sub-models will be created if there is not enough information to link sections together. Distortions or holes will also be created if objects move or if the scene contains repeating patterns. Repeating patterns have similar key points that can be confused during matching.

Several camera settings influence the outcome of the model. Interiors typically have lower light levels than exteriors and require increasing the ISO. High ISOs introduce noise into the image making key point identification difficult. Wide apertures are also often used in low light and have a large impact on the depth of field. Many photography factors contribute to a sharp image including: ISO, shutter speed and focus point. A sharp image is critical to key point identification and therefore attention to focus point and shutter speed is essential, especially while hand holding the camera. A properly photographed scene will proceed through post processing with little difficulty. Another challenge in post processing is the time required to build the model. Projects which contain hundreds of images with high quality settings can take upwards of twelve hours to process. More processing resources would reduce this time and allow more trials to be performed. Post processing related challenges encountered are identified in Table 3.

4 MODEL BUILDING SOFTWARE

The following section examines each variable independently using panoramas taken in a laboratory setting. Each variable has a base image with which the effects of the variable are compared. Base images were taken in Room H135 Head Hall using artificial overhead lighting with one window providing exterior light. The software that have been used in this pilot study are Agisoft PhotoScan, Photomodeler, Autodesk 123D Catch, Visual SFM, and Unity 3D.

Agisoft Photoscan (www.agisoft.com) is a fully automated commercially available software package. Photoscan is also a complete 3D model building package creating 3D point clouds, meshes and textured models. Limited tools are available for point cloud and mesh editing, although it is possible to export either for further refinement. Photoscan performs very well with large unordered photo collections.

Similar to Photoscan, Photomodeler (www.photomodeler.com) is a complete 3D model building package. Photomodeler provides the user a great amount of control throughout the building process. Large unordered photo collections of the interior of a building were not one of Photomodeler’s strengths. The models generated were very distorted. Photomodeler appears to be better suited to stereo pair photography with the use of coded targets. While it is possible to create dense point clouds without targets, this type of work is largely seen in aerial imagery.

Autodesk 123D Catch (www.123dapp.com/catch) is a free web based service provided by Autodesk. As many as seventy images, three mega pixels or larger can be uploaded to their servers where all of the processing takes place. Model construction is fast as local computing resources are not a limiting factor. Poor results were obtained when building 3D models of interiors. Models were very distorted, incomplete, and many of the photos were unable to be matched.

Visual SFM (www.ccwu.me/vsfm) is an open source program which facilitates the use of a collection of scripts developed by various researchers by incorporating a GUI. There are no limitations on the number of images although the largest dimension must be no greater than 3,200 pixels. Once a point cloud is created it can be exported for further processing or for use in other software to continue with 3D model generation. Unity 3D (www.unity3d.com) was the only video game engine tested and produced satisfactory results. Standalone and web based delivery options are possible and fit well with the current workflow of VR Doc.

5 PILOT STUDY

5.1 Initial Model Testing

Testing was originally performed to evaluate each software package. The three packages evaluated are Photoscan, 123D Catch, and Visual SFM. Several other dimensions of building a 3D model became evident throughout testing. These included the camera used, which was further divided into post processing steps, as well as the location of photography. In order to compare the test results, tests have been conducted by using different cameras and in different locations.
The GoPro Hero 2 was the first camera used as it fit well within the current VR Doc workflow. The Canon 60D was added to the tests as the GoPro was producing poor results. A comparison would help direct efforts in determining sources of error. Initial testing was done in Room H135 to remain consistent with previous testing on change detection in panoramas. Two other locations were added to overcome low texture and contrast in Room H135.

With the original goal of evaluating the software in mind, the following discussion is organized by location with the other dimensions discussed within each section.

5.2 Room H135

Low texture walls combined with repeating patterns found in the desks and chairs presented significant challenges in this location. Seventy nine images were taken with the GoPro camera in Room H135 and loaded in Photoscan. Using a medium alignment setting and pair selection disabled, 20 images were aligned and included in the point cloud. Photoscan was unable to move further in the processing due to the low number of key points. The point cloud did not resemble any specific section of the room. Using the Canon 60D, 99 photographs were taken and loaded in Photoscan. Using a medium alignment setting, a model was able to be produced with 81 images although significant distortions were present. Fifty seven of the 79 images from the GoPro camera could not be matched in 123D. The images which were matched produced a distorted and hole filled model indicating the matches were poor. Slight improvements were noted using images from the 60D although key point matching is still poor with only 32 of the 102 images matched. 123D Catch shows great difficulty matching key points of interior photographs.

The point cloud generated by Visual SFM with the GoPro images was broken into 3 models. Without sufficient key points to match images Visual SFM will create sub models with the matched images. Thirty nine images were match with the sub models containing 18, 12 and 9 images. All of the sub models included components of the same objects and excluded the same portions of the room. Excluded portions contained little texture and were highly repetitive. Using the images from the 60D Visual SFM produced 4 separate models which included similar components to those in the GoPro model. The geometry of the models appears to be correct in both the GoPro and 60D models. The 60D model has notably more points than the GoPro model, 124,413 vs. 28,899 respectively. The different 3D models created for Room H135 are shown in Figure 2.

5.3 Room H229B

Room H229B (office) is much smaller than Room H135 (classroom), but contains more texture and randomness. The number of photos taken with the GoPro was increased to 102 in an attempt to capture occlusions generated by the furniture. The arrangement of the furniture and size of the room made photography difficult, therefore only two walls were captured for reconstructed. Photoscan was expected to produce better results than those obtained in Room H135 due to the added texture. One hundred images were aligned in the point cloud but Photoscan was unable to continue with the model due to a lack of key points. A significant improvement was noted with the 63 images taken using the Canon 60D. All 63 images aligned and produced a clean textured model with minimal holes or distortions.

123D Catch produced a slightly better model with the GoPro images from Room H229B than ROOM H135. While there were very few holes, the geometry was visibly incorrect as noted by the angle between walls. The texture was also distorted indicating poor key point matching. The improvement over ROOM H135 demonstrates the necessity of texture. The added texture was also noted in the images taken with the Canon 60D which produced a significantly better model than Room H135. The textured model did contain holes but geometry was visibly correct.

Multiple models were again created with the GoPro images in Visual SFM indicating a disconnect between key points. One main model contained the majority of the images and the geometry was visually correct. A significant improvement was noted with the images from the 60D. Visual SFM created a single model with a dense point cloud consisting of 365,970 points compared to 24,976 points in the main GoPro model. Comparing the results between Room H229B and Room H135 across all software reveals
some weaknesses in the GoPro camera. Inspecting the images reveals a considerable amount of noise in the GoPro images, similar to that seen when using high ISO. This increases the difficulty in identifying and matching key points and therefore building the model. The different 3D models created for Room H229B are shown in Figure 3.

Figure 2: Room H135; (a) Photoscan GoPro, (b) Photoscan Canon 60D, (c) 123d Catch GoPro, (d) 123d Catch Canon 60D, (e) Visual SFM GoPro, (f) Visual SFM Canon 60D

5.4 Head Hall Exterior

Reconstructing the exterior of Head Hall was done in attempt to overcome challenges encountered during the interior tests. This location provides a large open space and ample light. The increase in light reduced the amount of noise visible in the GoPro images. Interior GoPro images were taken with an ISO of 400 and exterior images with an ISO 100. All of the 70 photographs taken with the GoPro were aligned in Photoscan. This performance is attributed to the decrease in image noise resulting in more points being identified and detected. This was the first GoPro model which would successfully build in Photoscan signifying the importance of sharp, low noise images. The textured model contained moderate distortions and low detail compared to the model generated with photographs from the 60D. The GoPro model contains 12,636 points while the 60D model contains 149,031. While the reduced noise improved the GoPro model, there are still significantly less points being identified.

The importance of texture is demonstrated well in 123D catch using the GoPro images. Only one of the 70 GoPro images was not matched which is a major improvement compared to previous results. The model does contain a large amount of holes but the geometry is generally correct. 123D Catch has a limit of 70 images per project and crashes when trying to upload the 143 images taken with the 60D. It is
speculated that these images would produce a better result than the GoPro. Another trial with fewer images is required. Testing with Visual SFM failed using both the GoPro and 60D images. Both sets of images are similar to those used successfully in the past. Failures occur during sparse reconstruction which performs well on other data sets. Further investigation is required to determine the cause of failure. The different 3D models created for Head Hall Exterior are shown in Figure 4.

Figure 3: Room H229B; (a) Photoscan GoPro GoPro, (b) Photoscan Canon 60D, (c) 123D Catch GoPro, (d) 123D Catch Canon 60D, (e) Visual SFM GoPro, (f) Visual SFM Canon 60D

5.5 Walk-through Model

A new location was chosen to implement the walk-through to overcome the challenges encountered during testing. The location consisted of a wide hallway approximately 15 feet wide and 45 feet long and contained ample textured objects. The hallway had minimal clutter and low traffic. Connected at one end is a narrow hallway and small room. The goal of the walk-through was to connect the main hallway to narrow hallway and small room. The Canon 60D was used due to its performance during testing.

Photography for each of the three components was performed separately and three models built independently to narrow any errors to specific locations. Once the models were successfully generated, the components were compiled into a single model and processed as a single element. The final textured walk-through was exported as a standalone executable file. The largest errors are located in the small room. This is attributed to the low texture, making key point identification and matching difficult. This difficulty was compounded by the use of a high ISO due to low light. The room is also cluttered making photography challenging.
The effort required to produce a virtual walk-through depends largely on the photography. The ideal scenario is to physically walk-through the construction site with a set of calibrated cameras that are able to capture the required information in a single pass. The path of photography would consist of the perimeter of rooms and around objects. Performing the walk-through at the end of a shift would eliminate the problem of moving objects and capture the most recent work completed. The effort required to photograph the site thus depends only on the time required to walk all perimeters. With post processing programmed to run sequentially through each step, the user would only be required to download the images and start the program.

Figure 4: Head Hall Exterior; a) Photoscan GoPro, b) Photoscan Canon 60D, c) 123D Catch GoPro

The effort required to build the hallway virtual walk-through was mostly photography based. A single Canon 60D camera was used with a Sigma 20 mm lens. The field of view was further restricted as the 60D does not have a full frame sensor. Accounting for this, the lens provides a field of view comparable to a 32 mm lens. Many trials were performed to fine tune and reduce errors in the model but if photography were to be completed in a single session all three components could be captured in approximately 15 minutes. After capture is complete, the user is required to download the images to the computer and start post processing. With the appropriate settings determined, the user is only required to start each processing step. Each step varies from minutes to hours.

Figure 5: First Person Walkthrough

6 ALTERNATIVE WALK-THROUGH METHODS

Other methods of creating a virtual walk-through have been identified as a result of this research. GoPro cameras are of great interest due to their portability and functionality in multi-camera panoramic heads. These panoramic heads incorporate six to eight GoPro cameras arranged to capture a full spherical panorama. Unlike traditional panoramic photography, the user is not required to rotate the head and can therefore capture a spherical panorama in the time it takes to capture a single image. This type of system could be programmed to capture panoramas at a specified rate as a user walks through the site. The end result would be similar to Google Earth Street View with the ability to choose your location on site. The
system could be expanded to capture spherical video instead of photographs, providing complete coverage of the site. These methods would require software development as there are no off the shelf solutions.

7 CONCLUSION

Construction sites contain vast amounts of information. Photographs capture this in great detail while allowing the user to absorb as much information as they need. The photographic recorded provided by VR Doc panoramas captures great detail yet excludes portions of the site which may become of interest. The use of a 3D model to create a virtual walk-through enables a comprehensive record and delivers the information in an intuitive manner. With further refinements, the virtual walk-through could become a key component to construction personnel. Future efforts would be well spent investigating photography workflows and automating post processing. Improvements in these areas would reduce the workload involved and make integrating the technology into live construction sites simpler. Methods of cleaning up the model are also an avenue worth exploring.

This paper investigates different image-based modeling methods to improve VR Doc applications. Pilot studies have been conducted to test different hardware (GoPro camera and Canon 60D) and software (Agisoft PhotoScan, Photomodeler, Autodesk 123D Catch, Visual SFM, and Unity 3D) available for creating a 3D walk-through model. The results show that although GoPro is a portable, light, and handy camera for the construction sites, it has significant distortions due to the wide angle lens. Although corrections are applied in Photoscan, better results were found if distortions were corrected in DxO before attempting to build the model. The built-in corrections were sufficient when using the Canon 60D with a Sigma 20 mm lens. Moreover, results show that the Unity walk-through software with its web delivery option fits well with the current delivery of VR Doc and could be easily integrated into the workflow. However, the current walk-through model contains distortions which would need to be refined in future studies before implementation in the construction industry.

Abstract: The upkeep of the building requires continuous monitoring to maintain the safety aspects as well as aesthetic elements of the building including facades, marble constructions and gardens. With the decrease of the amount of green areas, human race will face climatic catastrophes, which will affect the quality, type and life longitude of the Earth habitants. To tackle this issue, vertical gardens were designed to fit in the overwhelming world of concrete and to adapt in order to do photosynthesis. The growth of the plants is supported by spraying insecticide periodically. In this paper, we offer to use an unmanned aerial vehicle, to recognize the targeted green areas using HSV algorithm, track the generated trajectory and perform the spraying process all along the recognized area. We believe this will automate the maintenance of the gardens, improve the effectiveness of the treatment and assist to the ecologic factor, by applying the necessary amount of chemicals on the targeted place only.

1 INRODUCTION

Recently unmanned aerial vehicles are used to perform several civil tasks. Particularly, in construction fields, the idea of aerial robot is directly related to photogrammetry, site scanning and buildings status. In this regard, many literatures supported the cost efficiency, safety and quality control for such technological implementation (Bulgakov A. et al. 2014; Emelianov S. et al. 2014; Rango, et al. 2009. Chao, H et al. Shang et al. 2010)

Similarly, aerial robots can be used to scan vertical gardens and improve the irrigation system by controlling the quantity of water supplied to a certain site. This can be of great importance when talking about large agricultural areas, mega-polis with limited greenery and quantifying forest fire impact.

The technology being used to sense is based on satellite inspection. The limitation of such technology consists of the low resolution and the update ratio of the images provided. On the other hand, UAVs are more cost effective, can reach difficult scanning corners and provide more accurate visual information, as they can be equipped with high definition cameras. In this paper, we offer to use a vertical take off and landing aerial robot to perform visual inspection for vertical gardens.
2 RELATED WORKS

UAV’s successful results in improving military tasks have pushed the developers of such technology to try it in the civil market. The verdict: we got a miniature class of rotorcraft assisting in fire fighting, cinematography, television broadcasting and so on. The technology is being used to improve irrigation systems (Chao H, et al.), to address the climatic changes in the north and south poles (Lucieer A. et al. 2012), inspection of bridges and facades (Bulgakov A. et al. 2014; Emelianov S. et al. 2014).

As a sensing technology, band-reconfigurable fixed wing UAV were used more frequently. This is due to the optimized flight range, lifting capability and improvement in Micro (MEMS) and Nano electromechanical systems (NEMS). The sensors used are based on thermal infrared and machine vision. But these sensing technologies have limitations, especially the thermal infrared: the cost involved and the reliability of the acquired data especially in a humid atmosphere (Lucieer A. et al. 2012). The other limitation is the UAV itself: stability problem leads to false reading.

Having analyzed the pros and cons of aerial inspection, the optimization problem can be divided into two subtasks:

1. Coverage control problem consisting of path planning and control of the UAV;

2. Geo-reference problem consists of registration of each acquired pixel from the aerial images including temporal and spatial information (time and location).

Both of the subtasks can be addressed in either of two ways: global path planning consisting of trajectory planning before the flight and local planning that generates the trajectory during flight.

3 AIM OF THE PAPER

The aim of the paper is to address the aforementioned subtasks in order to inspect vertical gardens in the cities using quadrotors. As it is noticeable in most of the megapolises in the world, where green areas are lacking. The uncontrollable population growth is destroying the remaining of “mother nature”. Engineers and social workers have invented the concept of green wall or vertical gardens. The idea, as shown in figure 1, consists of planting wall climbing trees and plants on vertical walls. Due to the ergonomics involved the idea is widely spread.

![Figure 1: Vertical garden concept](image)

The role of the quadrotor is to acquire visual information such as images and pictures and spray the insecticide on the target area.

3.1 Coverage Control Problem

This subtask is divided into two points: path planning and control. Since, for the geo-reference problem, we will be using GPS data to acquire the temporal and spatial information, we will limit ourselves with the control part of it. As it is known, a quadrotor is a take off and landing rotorcraft, having six degrees of
freedom. But this miniature aircraft can perform only four flight regimes: roll, pitch, yaw and hover. This mechanical limitation makes the quadrotor nonlinear system. The dynamics of the quadrotor can be described as follows:

\[ x' = (\sin \psi \sin \phi + \cos \psi \sin \theta \cos \phi) \frac{u_1}{m}; \]

\[ y' = (-\cos \psi \sin \phi + \sin \psi \sin \theta \cos \phi) \frac{u_1}{m}; \]

\[ z' = -g + (\cos \theta \cos \phi) \frac{u_1}{m}; \]

\[ \dot{p} = \frac{i_{yx} - i_{zz}}{i_{xx}} q r - \frac{i_{rp}}{i_{xx}} q \dot{\Omega} + \frac{u_2}{i_{xx}}; \]

\[ \dot{q} = \frac{i_{zz} - i_{xx}}{i_{yy}} p r - \frac{i_{qp}}{i_{xx}} p \dot{\Omega} + \frac{u_3}{i_{yy}}; \]

\[ \dot{r} = \frac{i_{xx} - i_{yy}}{i_{zz}} pq + \frac{u_4}{i_{zz}}. \]

Where,  \( x, y, z \) are the projection of the linear acceleration of the quadrotor in the Earth fixed axis,  \( \dot{p}, \dot{q}, \dot{r} \) are projection rotational acceleration of the quadrotor in the body fixed axis,  \( g \) – the gravitational acceleration,  \( i_{rp} \),  \( i_{qp} \),  \( i_{qr} \) – the torque generated from the rotors,  \( m \) – the mass of the quadrotor,  \( i_{xx}, i_{yy}, i_{zz} \) are the projection of the Inertia of the quadrotor,  \( \dot{\Omega} \) – is the rotational speed of the propellers,  \( \phi, \theta, \psi \) are the roll, pitch and yaw angle consequently,  \( U_1, U_2, U_3 \) and  \( U_4 \) are the aforementioned flight regimes.

### 3.2 Fuzzy Logic Position Controllers

As it is important to know the value of the error, it is similarly critical to understand how it is changing over time. The error and its derivative in time are one of the possibilities to configure a Fuzzy logic controller. It is an artificial intelligence approach that computes mathematical operations based on degree of truth rather than the conventional True-False Boolean logic. The Fuzzy logic allows having more adaptable controller specially when dealing with nonlinearities (i.e. nonlinear aerodynamic model of the quadrotor as described in equations 1-6) and uncertainties (i.e. permanent changes in the flight circumstances, wind, temperature, obstacles positions etc.).

Although in many cases, heuristic algorithms were ruled out, due to the time consumption, we saw a need to include this algorithm in our survey to cover most of the techniques used. We would like to clarify that the term heuristic is used to describe the estimation ability in artificial intelligence. Moreover, the linguistic power of the fuzzy logic may be extremely useful while navigating in totally unknown areas. The trick in such controller is how to set up the linguistic rules for input and output.

We fine tuned the rules by using the resulting graph (figure 2) for the function  \( de(t) = f(e(t)) \), where  \( e(t) \) is the deviation in position of the quadrotor with reference to the desired trajectory and  \( de(t) \) is the variation of the deviation.

![Figure 2: Resulting Graph \( de(t) = f(e(t)) \)](image-url)
Using the graph in figure 2, we assign the following labels for the numeric values: Negative big (NB) = -1, Negative Small (NS) = -0.5, Zero (Z) = 0, Positive Small (PS) = 0.5 and Positive Big (PB) = 1. As a result, we obtain the linguistic rules listed in table (1). A linguistic rule defines the output of the fuzzy controller based on discrete logic (i.e. if $e(t) = \text{NB}$ and $d(e(t)) = \text{PB}$, then the output is $Z$). The graphical representation of the linguistic rules is illustrated in figure 3.

Figure 3: Graphical Representation of the linguistic rules

The inputs of the fuzzy controller $de(t)$ and $e(t)$ are represented using triangular membership functions as shown in figure 4a and 4b. The output of the fuzzy control is also 5 triangular membership functions (figure 4c).

Figure 4a: membership function for input “e(t)”
The results of controlling the quadrotor using fuzzy logic regulators are shown in figure 5a and b for position and rotation control consequently.

Figure 5a: Quadrotor position control with reference to GPS waypoints. Horizontal axis – time [s], vertical axis- position [m]
The results shown in figure 5a and 5b give a fair idea about the reliability of the fuzzy controller. For instance, figure 5a illustrates the fact of stabilizing the linear movement of the quadrotor (described in equations 1-3, X (red curve), Y (blue curve), Z (green curve)) without overshooting. This allows the quadrotor to move along Earth-axis OXYZ smoothly. The other advantage of avoiding overshooting is contributing to better energy-efficient control systems (i.e. overshooting in altitude control means flying higher and consuming more power).

Taking into consideration the nonlinearity of the aerodynamic model of the quadrotor, linear movement cannot be achieved unless stabilizing Euler angles (roll (red curve), pitch (blue curve) and yaw angles (green curve)) as shown is figure 5b. Control signals are generated in order to increase or decrease Euler angles (equation 4-6) with reference to linear position control task (equations 1-3).

### 3.3 Geo-reference Identification Problem

Identification of the vertical garden can be done using the green pattern. Many machine vision algorithms are dedicated to recognize colors. We will be using the HSV algorithm due to its mathematical model, which is more reliable than the other methods. The HSV consists of giving a certain color 3 coordinates: Hue, saturation and value as shown in picture 4. HSV is used is many literatures in order to detect static and dynamic agents/objects based on histogram criteria, such as recognition of traffic lights (Yixin Chen et Al. 2013), gesture identification (Mokhtar M. Mohsen et al. 2010), image and structure retrieval (Durgesh N. et al. 2013) and face detection (Naresh Kumar R. et al. 2014, Sayfeddine D. 2013).
From figure 6, we can see clearly that the green color is varying between 60 and 180 degrees. Hence, the role of the algorithm is to identify the green patches on the wall and apply the insecticide on the recognized area. This can be done by dividing the frame of the camera mounted on the quadrotor into 9 identical cells. Hereafter the registered pixel coordinates will be modified to metric using the following equations:

\[ d(x) = H_k = H \cdot \tan(\psi + \alpha); \]
\[ d(y) = H_y = H \cdot \tan(\theta + \beta); \]
\[ x_n = \frac{X}{11} \cdot \cos\left(\arctan\left(\frac{H_y}{H_k}\right)\right); \]
\[ y_n = \frac{Y}{11} \cdot \sin\left(\arctan\left(\frac{H_y}{H_k}\right)\right); \]
\[ \rho_x = \sqrt{x_n^2 + y_n^2} \cdot \cos\left(\arctan\left(\frac{H_y}{H_k}\right)\right); \]
\[ \rho_y = \sqrt{x_n^2 + y_n^2} \cdot \sin\left(\arctan\left(\frac{H_y}{H_k}\right)\right). \]

Where, \(d(x)\) and \(d(y)\) — the projection of the altitude on the pixel coordinates, \(H\) — is the flying altitude, \(x_n\) and \(y_n\) are the horizontal and vertical pixel coordinates of the recognized area, \(\Pi_x\) and \(\Pi_y\) are the scale factors, \(\rho_x\) and \(\rho_y\) are the rotation of the quadrotor in the pixel axis, \(\alpha\) and \(\beta\) are the rotation of the diaphragm of the camera from the body axis.

After identification of the desired pixels based on color criteria, Cartesian subtraction is computed to identify the distance between the center of the fixed camera and the centroid of the detected colored surface. The subtraction result represents the distance that the quadrotor has to fly in pixels. The following approach is known as visual odometry. Depending on the position of the centroid, metric control task is generated for flight altitude stabilization (equation 7 and 8), linear movement (equations 9 and 10) and rotational movement (equation 11 and 12).

Using the concept of reactive control and based on the results obtained in equations (8,9 and 11,12), control signals are generated to initialize one of the four available flight regimes described in equations (3-6).

4 REAL-TIME RESULTS

HSV and visual odometry algorithms were tested in real-time in order to trace the possibility of their implementation on high-rise structures covered with vertical gardens. As figure 7 shows, the identification process was successful and the generation of the pixel coordinates was obtained.

Figure 7 can be interpreted as follows; the green surface is detected by algorithm HSV (i.e. position Middle-Middle in the 9-cells frame). The green pixels are generated (i.e. \(x_n = 69, y_n = 72\)). The Cartesian subtraction is obtained and metric control task is formed. The graph is figure 7 shows how the quadrotor changes its position (\(X\) (green curve), \(Y\) (purple curve)) with the changes of the pixel coordinates \(x_n\) (blue curve) and \(y_n\) (red curve).

A comparison between real time two dimensional flight results (figure 7) and simulation results (figures 5a/5b) shows that the deviation in sensors readings is as follows: roll reading (0.045°/s); yaw reading (0.125°/s); pitch reading (0.15°/s). The reasons of such deviations can be caused by the Euler angles MEMS gyroscopes, asymmetric structure of the quadrotor, influence of shifted center of gravity on the control systems, and propellers non-uniformity. The obtained deviation values lay in the tolerance interval and allowed Metrologic norms (deviation of real-time results ±5% from the simulation results).
5 CONCLUSIONS AND FUTURE WORK

The paper focused on how to use the quadrotor to maintain vertical gardens on high-rise structures. The adopted concept was to divide the autonomous flight problem into control of the quadrotor over an identified area using HSV algorithm. The control was performed using fuzzy logic position regulators based on reactive control concept interconnecting the rotation speed of the propellers with the positioning of the quadrotor. No overshooting was registered in the simulation results. Regarding the identification of the green area, HSV algorithm was used. The pixel coordinates were modified to metric in order to create flight mission. The identification and control algorithms were tested in real time using a commercial quadrotor (AR DRONE) linked to a stationary computer using datagram protocol UDP through a Wi-Fi connection.

Although the results were outstanding and the computational power was enough to drive the quadrotor to the end of the experience, we have noticed the influence of the light nature and temperature on identifying the green color. Having just the color as tracking criteria, the stationary computer could run into local minimum problem (between green and blue). This issue was addressed earlier as extrapolation of motion function. A solution was suggested based on nonlinear neural network model with exogenous input (NARX). The results can be accessed in the following literatures (Sayfeddine D. 2014, Sayfeddine D. et al. 2014).

ADAPTIVE CONTROL OF BULLDOZER’S WORKFLOWS

Alexey Bulgakov¹,⁴, Thomas Bock² and Georgy Tokmakov³
¹ South West State University, Russian Federation
² Technical University Munich, Germany
³ South Russian State Polytechnic University, Russian Federation
⁴ a.bulgakow@gmx.de

Abstract: The most important task for bulldozer’s traction mode control is to use its traction capacity in full by means of its end-effectors control. To keep traction mode at maximum or at a given resistance value applied to end-effectors automatically is difficult due to a great number of stochastic factors affecting the bulldozer. Bulldozer is taken as a mechatronic system [1, 2]. The study presents analytic dependences for the sub-processes where analytic modeling based on bulldozer’s parameters correlation knowledge is applicable. Models of the sub-processes are included into the general structure of bulldozer’s workflow simulation model. Simulation technique is demonstrated through model development of the bulldozer as a universal machine operating in modes of soil movement and subgrade surfacing. In developing the models mathematical apparatus of the theory of random processes, transfer functions, table interpolation, numerical solution of algebraic equations and ordinary differential equations in the Cauchy form was used. A dynamic model of the drawing prism formation was developed describing the dependence of the volume of prism on the variable digging depth and variable bulldozer speed. A general structure of the model of bulldozer’s workflows [3] due to the working process control objectives was developed.

1 INTRODUCTION

Bulldozers equipped with modern navigation and information systems are mobile mechatronic objects, and they can be integrated into general process of intellectual construction. The integration will provide optimal efficiency of the construction cycle and will ensure lean production process.

On the basis of bulldozer’s workflow dynamics modeling and analyses described in a variety of works, we have concluded that the models to describe kinematics and dynamics of its working equipment, hydraulic and transmission features tend to be analytical formulas derived from well-known laws of physics and from information on bulldozer’s structure and mechanisms. If some parameters of the workflow are unknown or constantly changing, the models are either statistical tables or empiric dependences summarizing experimental data. The models depict interaction of end-effectors, engines and environment as well as statistic features of bulldozer’s complex units.

Application of regulators based on classical control theory is difficult due to the frequent changes in workflow conditions. Thus, it is necessary to develop adapted control systems to eliminate the difficulties described. The system includes both the bulldozer’s dynamics modeling and bulldozer’s workflow control method to take into consideration the complex non-linear dependencies between workflow parameters and incomplete information on its working conditions changes.
Having reviewed adaptive and intellectual control methods [4, 5], we propose to create an adaptive control system for technological processes to increase efficiency of bulldozer’s control in comparison with traditional control methods.

2 MOBILE MECHATRONIC OBJECT - MATHEMATICAL DESCRIPTION TO PERFORM EXCAVATION WORKS ON THE BASIS OF A DOZER

When researching a dozer’s working process usually a number of design schemes are considered – straight line, thread milling, wedge and exponential cutting. Meanwhile, a dozer moves along the surface that is formed by its blade. Therefore, when driving onto any surface roughness resulting from the dozer blade control or the change in its position due to any reason, causes position changes of the machine frame and along with the cutting edge that is any face deviation from a straight line in some extent is copied by the dozer.

Observations [1] show that quite often while designing a face its roughness is progressing, reaching a size at which the control over the workflow is lost. In this case, the operator has to align the face deliberately, trying to ensure its “tranquil” profile that allows doing excavation works smoothly, without frequent control system switching and reducing the dozer’s operating speed that causes a slowdown and shows inferiorities of the blade control system. Obviously, if the control system operates in the antiphase towards deviations of the tractor frame with sufficient accuracy, the initial face roughness will not evolve and will be gradually cut. One of the most likely causes of the opposite phenomenon observed in practice, is the disparity between the velocity of the dozer \( V_p \) and actual conveying speed of the working body \( V_{ot} \) required in certain areas \( S_i \) of the digging operating cycle, where \( i \) - is the number of the speed change \( V_{ot} \). Speed ratio depends on the dozer’s geometrical dimensions (Figure 1) and its control system.

![Dozer’s geometrical dimensions](image)

Mathematical model of the dozer’s movement on a straight line tracking (frame alignment) is built using the Lagrange equations of the 2nd kind, under the assumption that the contribution to the dynamics of the drive gears and a track is small, compared with the contribution of the remaining parts of the dozer.

\[
\begin{align*}
\frac{d}{dt} \left( \frac{\partial T}{\partial \dot{x}} \right) - \frac{\partial T}{\partial x} &= Q_x \\
\frac{d}{dt} \left( \frac{\partial T}{\partial \dot{\varphi}} \right) - \frac{\partial T}{\partial \varphi} &= Q_\varphi
\end{align*}
\]

where kinetic energy:
\[ T = \frac{1}{2} m_1 \dot{x}^2 + \frac{1}{2} m_2 (\dot{x}^2 + (l_2 c_2 \dot{\varphi})^2 + 2x l_2 c_2 \dot{\varphi} \sin(\varphi)) + \frac{1}{2} J c_2 \dot{\varphi}^2 + \frac{1}{2} \sigma h x (\dot{x}^2 + (l_2 \dot{\varphi})^2 + 2x l_2 \dot{\varphi} \sin(\varphi)) + \frac{1}{2} \sigma h x i_{c_2}^2 \dot{\varphi}^2 \]

Generalized forces acting on a dozer:

\[ Q_x = -\sigma h g l_2 \sin \varphi + F_t - F_{\text{comp}}; \]

\[ Q_\varphi = -(m_2 l_2 + \sigma x h) g l_2 \cos \varphi + M; \]

\( m_1 \) – tractor mass; \( m_2 \) – blade frame mass; \( \sigma \) – soil surface density; \( h \) – depth of the soil cutting; \( l_2 c_2 \) – center of the blade mass; \( i_{c_2} \) – gyration radius of the dumping soil.

\[ m_1 \ddot{x} + m_2 \ddot{x} + m_2 l_2 c_2 \ddot{\varphi} \sin \varphi + m_2 l_2 c_2 \dot{\varphi}^2 \cos \varphi + \sigma h \dot{x}^2 + \sigma h x h \dot{\varphi} \sin \varphi + \sigma h x l_2 \dot{\varphi} \sin \varphi +
\sigma h x l_2 \dot{\varphi}^2 \cos \varphi \right) - \frac{1}{2} \sigma h \dot{x}^2 - \frac{1}{2} \sigma h x i_{c_2}^2 \dot{\varphi}^2 \right) \right) = -\sigma h g l_2 \sin \varphi + F_t - F_{\text{comp}}; \]

\[ m_2 l_2 c_2 \ddot{\varphi} + m_2 x l_2 c_2 \cos \varphi \dot{\varphi} + l_2 \dot{\varphi} + \sigma h x l_2 \dot{\varphi} + \sigma h x l_2 \sin \varphi + \sigma h x l_2 \cos \varphi + \sigma h x l_2 \dot{\varphi} + \sigma h x i_{c_2} \dot{\varphi} - m_2 x l_2 c_2 \cos \varphi - \sigma h x l_2 \cos \varphi = -(m_2 c_2 + \sigma x h) g l_2 \cos \varphi - (m_2 c_2 + \sigma x h) g l_2 \cos \varphi + M; \]

The system (1) solution allows getting the differential equations (4) and (5) that describe the dozer’s movement on a straight line track, and determining control actions through the parameters of the machine in areas \( S_i \) of the digging operating cycle as the coefficients \( a_i \) in the dependence \( V_{ot} = a_i V_p \). Such a dependence is typical for dozers with a single-motor drive with a hard pump hydraulic drive connection to the motor shaft.

\[ S_1 \]

\[ +V_{ot} \]

\[ S_2 \]

\[ \text{Figure 2: The movement of the tractor frame the beginning of digging.} \]

At the beginning of digging (Figure 2), the frame of the tractor makes a strictly forward movement over a distance of \( S_1 + S_2 \) without hesitation relatively its mass center. The blade cutting edge in the area \( S_1 \) dives into the soil to a depth equal to a predetermined cutting thickness \( h \). Thus, the control action \( a_1 \) may be determined by the formula:
\[ a_1 = \frac{30i_{tr} m_2}{m_h F_{zp} C_0 n} \]

where \( i_{tr}, i_{pr} \) - tractor transmission and hydraulic pump ratios;
\( n \) - number of hydraulic cylinders;
\( m \) - fluid mass in the hydraulic cylinders;

In the area \( S_2 \) the movement is made with \( a_2 = 0 \) until the mass center of the tractor won’t move to the buttonhole edge.

On further movement the dozer "dives" in the drawn buttonhole (Figure 3), so in the area \( S_3 \) it is necessary to lift the blade at a rate of \( V_{ot} \), determined by the coefficient \( a_3 \):

\[ a_3 = \tan \beta \left[ e^{a_{1} V_{o_{t}}} \left( 1 + \frac{a_{C_1}}{C_1 + V_{o_{t}}} \right) - 1 \right] ; \]

The area \( S_3 \) ends after the dozer’s back gear hits the edge of the face and reverse alignment of tractor frame starts. Length of the alignment area is \( S_4 \approx S_1 \). Obviously, during this period it is necessary to start dropping the blade. The \( a_4 \) determines the rate of dropping the blade in the given area:

\[ a_4 = \frac{c_{3} S_1}{(c_4 + S_3 + V_{o_{t}})^2} ; \]

To implement control actions \( a_i = f(S_i, t, h) \) the dozer must be equipped with a vertical blade control system.

3  NEURAL NETWORK MODEL OF BULLDOZER WORKFLOW

The Autoregressive model structure with external inputs (Figure 4) is a dynamic two-layer recurrent neural network. It is found from the autocorrelation signal functions that the autocorrelation coefficient is greater than 0.8 in the time interval 0.1 sec. for speed \( v(t) \) of 0.5 sec. for digging depth \( h(t) \) and 0.2 sec for the resistance force \( P(t) \). Length of delay lines TDL taking into account the sampling frequency of 10 Hz are up to 1, 5 and 2 accordingly (Figure 4).
Vector for adaptive model adjustable parameters comprising weights and displacements of neural network,

\[ X = [b^1; b^2; IW^{1,1}; IW^{1,2}; LW^{1,2}; LW^{2,1}] \]

Criterion for neural network model optimal tuning, i.e. current learning error at a given moment of time we take as follows:

\[ F(X) = e(t) = P(t) - a^2(t) \to 0 \]

The network learning task is the task of multiple non-linear optimization

\[ X = \arg \min_X F \]

The author propose the bulldozer workflow neural network model adaptive learning algorithm based on the recurrent least square method (exponential forgetfulness method) and on the algorithm of Forward Perturbation or dynamic back propagation.

In the process of learning the neural network accumulates information on workflow dynamics, new tendencies of process development prevail on the earlier ones at that. Degree of importance for the previously learned information is considered with forgetfulness parameter \( \lambda \). Network optimal learning criterion gradient comprises frequent derived learning errors based on neural network model adjusted parameters:

\[ \nabla F = \frac{\partial F}{\partial X} = \left[ \frac{\partial F}{\partial b^1}, \frac{\partial F}{\partial b^2}, \frac{\partial F}{\partial IW^{1,1}}, \frac{\partial F}{\partial IW^{1,2}}, \frac{\partial F}{\partial LW^{1,2}}, \frac{\partial F}{\partial LW^{2,1}} \right] = -\nabla a^2 = -\frac{\partial a^2}{\partial X} = \left[ \frac{\partial a^2}{\partial b^1}, \frac{\partial a^2}{\partial b^2}, \frac{\partial a^2}{\partial IW^{1,1}}, \frac{\partial a^2}{\partial IW^{1,2}}, \frac{\partial a^2}{\partial LW^{1,2}}, \frac{\partial a^2}{\partial LW^{2,1}} \right] \]

Software algorithm of adaptive learning for neural network model of bulldozer workflow has been designed and implemented. The weight vector and bias network \( X(t) \) are adjusted in accordance with the recursive expressions at each time step:
\[ X(t) = X(t-\Delta t) - P(t-\Delta t) \times \nabla F(t) \times \epsilon(t), \]

Covariance matrix of the vector \( X(t) \) of neural network parameters used in the algorithm:

\[
P(t) = P(t-\Delta t) - \frac{P(t-\Delta t) \times \nabla F(t)}{\lambda}.
\]

4 ADAPTIVE CONTROL OF BULLDOZER’S WORKFLOWS

Applying a hybrid neural network consisting of a combination of traditional neural networks and neural networks of higher order (Figure 5.). Thus, the neural network has the ability to switch between linear connections and connections of high order that can be described by the following dependencies.

Linear coupling:

\[ y_i = \sum(w_{ij}x_i + b_j); \]

High order coupling:

\[ y_i = f \left( \prod x_i^{\beta_{ij}} \times 1^{\beta_{jj}} \right); \]

Activation function:

\[ f(x) = \frac{1}{1+e^{-ax}}; \]

where \( w_{ij} \) – coupling weight coefficients; \( y_i \) – output neuron signal; \( x_i \) – input neuron signal;

![Hybrid Neural Network Structure](image)

This implies that each layer depending on the operating mode, may change the type of connection between neurons. For example, for a neural network consisting of 3 layers, the following options are possible (linear - L, higher order - HO): L-L; L-HO; HO-L and HO-HO.

To optimize the created neural network is possible with the help of the genetic algorithm adaptation (Figure 6).
It is a method of random search with elements of adaptation, which is based on principles similar to the Darwin’s evolution process of biological organisms. In this case, three types of operations are performed: crossing, mutation, selection. The fitness degree (how the population corresponds to the given task) is defined through the fitness function that can also include penalty functions for violation of additional restrictions on variable variables. There are various forms of crossing [5]. They make a selection of the fittest specimen, which constitute a parental pair and the crisscrossing of the chromosomal chains takes place, i.e. the descendant line code inherits fragments of codes of parental chromosomes. The mutation operator produces a local change in the line code of chromosomes with a given probability, which is one of the configurable parameters of the genetic algorithm [5, 6].

The selection operator allows creating a new population from a set of specimen, generated and modified descendants of specimen after mutation. The genetic algorithm is used to adjust the membership functions that are defined within the accuracy of a few changeable parameters, such as triangular, trapezoidal, radial functions. When simultaneously configuring several membership functions, the parameters of each of them are coded by their own segment of the chromosome, so that during the process of crossing the code sharing occurs only between chromosome segments of the same type. To configure a rule base to a specific chromosome fragment, some variant of the rule base is corresponded and in accordance with the accepted coding the choice of the genetic operators’ type is performed. Thus, the architecture of the management and control system can be represented as follows (Figure 7).

To conduct researches on the basis of fuzzy modeling, quite versatile software have been developed [7] that greatly simplify the creation of new control systems using neural networks and fuzzy models. The use of different aspects of evolutionary modeling as a new direction of computing technology allows applying principles of learning for the management and control system and adaptation of the described hybrid neural network allows getting the following results.

![Diagram](attachment:image.png)

*Figure 6: Hybrid neural network optimization algorithm*
5 CONCLUSIONS AND RESULTS

Automatic control function of blade positions precisely adjusts the cutting edge. Depending on the content of correction signals, the regulating dual hydraulic valve automatically lifts or drops the cutting edge of the blade, constantly keeps it in position that ensures the accuracy of work and ensures an optimum level of productivity.

Identification technique of the dozer’s working processes and models obtained on its base, are intended to be used in the development of adaptive systems of automatic control of the dozer’s working process.

Methods of development of adaptive systems of control of the dozer’s working process, is based on neural network technology. For the formation of control actions on a dozer, and of the electrical switch signals of the hydraulic directional valves of the lifting and dropping hydraulic cylinders of the working body, in particular, the structure and functioning algorithms of the adaptive neural network controller have been designed.

Abstract: The article deals with issues of the use of photoreactors with growing algae as an element of urban construction. Using microalgae photobioreactors can solve multiple tasks: getting a third-generation biofuels, carbon dioxide recycling, wastewater disinfection, oxygen regeneration, and water purification from nutrients. The paper considers a wastewater purification plant where the major element is such a photoreactor. As examples of such a kind of facilities, we could mention as follows: BIQ House, Hamburg International Building Exhibition; Urban Algae Canopy Module by ecologic Studio; photoreactors at the incineration plant, Alcéade Nantes, France; etc. Unlike the existing projects, we study all the system as a whole. Considered treatment facility includes an algae photobioreactor, a bacterium mineralizer and a desilter as well as a control system that regulates concentration of biogens, oxygen, and carbon dioxide by governing flow between devices. The article investigates the opportunity of incorporation of the photobiological treatment facilities into a building’s architectural shell. Structurally, we propose to make the main technological nodes from the translucent membrane of Ethylene Tetrafluoroethylene (ETFE). Photoreactors with algae are placed on the building facade. That location significantly reduces the required area and provides optimal natural lighting. It also allows using solar radiation for heating and adaptive lighting. The construction form is optimized with using a genetic algorithm. The engineering solution which is given in this article can be used for already existing treatment plants as well as for urban structure directly.

1 INTRODUCTION

The article deals with issues of the use of photoreactors with growing algae as an element of urban construction. Using photoreactors with algae in construction can solve multiple tasks: getting a third-generation biofuels, wastewater disinfection, oxygen regeneration, and water purification from nutrients. One more property that is important is that a photoreactor perfectly works as a natural filter absorbing flue gases and greenhouse gas. All these unique features of algae attract the attention of biologists, construction engineers, and architects. Examples of architecture projects with photoreactors, which have been presented at the exhibitions recently include: BIQ House, Hamburg International Building Exhibition [The Building Exhibition. Smart Material Houses, 2013]; Urban Algae Canopy Module by ecologic Studio [EcoLogicStudio, 2014]; the projet “SymBio2 photoreactors at the incineration plant [Des capteurs solaires biologiques élaborés au laboratoire GEnie des Procédés, 2014]; the project “ENERGY.2010.3.4-1: Bio-fuels from algae” [Co-financed by the EU Commission within the FP 7 programme, 2010].

In our previous publications [Buzalo, Bock, and Bulgakov, 2014], [Buzalo, Ermachenko, Bock, and et al., 2014] the concept of the local photobiological wastewater treatment plant was described. Unlike the
existing projects, we study all the system as a whole. Considered treatment facility includes an algae photobioreactor, a bacterium mineralizer and a desilter as well as a control system that regulates concentration of biogens, oxygen, and carbon dioxide by governing flow between devices. The example of a possible organisation of a technological scheme is shown in Figure 1.

Figure 1: Technological scheme of purification system, where (1) is the photobioreactor, (2) is the desilter, (3) is the methane tank, (4) is the boiler plant

The basic elements of the system are units with microalgae. The cultivation of microalgae under artificial illumination conditions is very energy-intensive. We focus on the use of natural light. The article investigates the opportunity of incorporation of the photobiological treatment facilities into a building’s architectural shell when, to save the useful area, the main elements, photobioreactors, are placed on a special carcass covering separately located facilities or directly on the facade of a residential building. In the context of our work we consider photobiological treatment facilities located within the city. Therefore, it is necessary to take into account shadows of surrounding buildings. The goal is to optimize the illuminance of a carcass with photobiological units to provide the best conditions for algae growth. That can be reached due to the variation of an architectural shell shape.

One if the disputable issues is the construction cost of a facade with algae photoreactors. For a long time this technology have been held back because of the price of one square meter of photobioreactors made of glass and steel exceeds the cost of solar panels. However, the use of modern membrane structures from Ethylene Tetrafluoroethylene (ETFE) can significantly reduce the cost of construction. This is the way, that we propose for a structural solution of main technological nodes.

2 OPTIMIZATION OF ARCHITECTURAL SHELL SHAPE

2.1 Statement of Problem

Algae cultivated in the water purification system of a treatment plant are considered as a source of biofuel. In addition to providing the necessary level of water purification, the second important goal of the system is to produce the maximum algae biomass.

Factors affecting the rate of growth of microalgae:

- The amount of available solar radiation;
- The amount of nutrients coming from organic waste;
- Availability of sources of carbon dioxide;
- Thermal characteristics of the medium.
In this article, we consider the influence of insolation on the algae growth. The optimization problem is to maximize the function of total amount of algae biomass cultivated for a year divided by the surface area of the shell:

\[ \text{max } F(\Omega), \]

where \( \Omega \) is the shape of an architectural shell.

The geometric shape of an architectural shell foundation is fixed. There are also constraints for the maximum and minimum height of the structure.

The maximizing functional in [1] is as follows:

\[ F(\Omega) = \frac{1}{d\Omega} \int_{\Omega} \mu \cdot \exp \left( -\frac{(I(x,y,z,\Omega,t) - c)^2}{2 \cdot \sigma^2} \right) d\Omega \, dt, \]

where \( \mu \) is the dissolution rate of oxygen; \( I(x,y,z,\Omega,t) \) is the level of illumination of a photobioreactor: the function of coordinates \( (x,y,z) \in \Omega \), time \( t \), and shape of an architectural shell \( \Omega \); \( c \) is the optimal insolation; \( \sigma \) is the tolerance interval. The period of integration is one year.

Despite the fact that the obvious goal is producing the maximum amount of biomass, normalization of the objective function by the surface area of the shell is necessary in order not to ‘overblow’ the shape extremely. We would also like to emphasize that the design corresponding to the maximum brightness of a surface is not the solution. Microalgae can use only 5% of solar radiation for photosynthesis and the majority of solar energy is spent to heating. The solution of the optimization problem is also necessary to avoid critical overheating, which is deadly to living organisms.

2.2 Optimization Algorithm

The algorithm takes into account the shadow cast by the surrounding buildings. That make it possible to integrate photobiological treatment plants in the urban environment efficiently.

For solution the shape optimization problem, the genetic algorithm of the plug-in Heliotrope of the software Rhino / Grasshopper is used [Grasshopper. Algorithmic Modeling for Rhino, 2015]. The program has a set of geometric tools for the insolation analysis. It includes the calculation of parametric components of solar vectors for a certain date, time and place.

The calculation algorithm:

1. Parametric description of the architectural shell in the software environment Rhino / Grasshopper;
2. Time discretization and discretization of the curved surface of an architectural shell by a finite number of planar polygons;
3. Calculation of average components of solar vectors for every time step and polygon with the plug-in Heliotrope by geographical coordinates, time, and date;
4. Projection of the shadow from surrounding buildings on polygons uniformly for every time step;
5. Setting proportions of direct and scattered light and calculation of the amount of solar radiation on polygons for time steps;
6. Calculation of average growth of microalgae biomass for every time step on each polygon;
7. Using a genetic algorithm for the search of architectural shell parameters corresponding the maximum of the objective function [2] that is being calculated numerically for each iteration in accordance with steps 1-6.

2.3 Model Problem

As an initial approximation for the optimization algorithm, we consider the architecture shell of treatment facilities of the surface area of 16119 m². Free area between the buildings is 150 m × 150 m. Height varies from 9 to 28 m.

The algorithm takes into account the shadows cast by the surrounding buildings. The computational domain is shown in the Figure 2. Green color corresponds to the minimum value of insolation, red color - the maximum value.

![Figure 2: Views of the architectural shell before the optimization](image)

Design is located at coordinates 51°02' N 13°44' E (coordinates of Dresden, Germany). Changing the position of the sun at its zenith is shown in the Figure 3.

![Figure 3: Changing the position of the sun at its zenith over the computational domain during the year](image)

Figure 4 presents the architectural shell before and after optimization. Views of the shell are shown with different angles. Calculation parameters: the proportion of scattered light is 40%, the density of the solar radiation is 1000 W/m², $\mu = 10$ g/m²h, $c = 650$ W/m², $\sigma = 95$ W/m².
The results of the optimization:

- Before optimization:
  - The surface area of $\Omega$ is $s(\Omega) = 16119.2 \text{ m}^2$;
  - The average daily specific growth of biomass per unit area $f = \frac{1}{365} F(\Omega) = 51.6 \frac{\text{g}}{\text{m}^2\text{day}}$;

- After optimization:
  - $s(\Omega) = 11061.2 \text{ m}^2$;
  - $f = 95 \frac{\text{g}}{\text{m}^2\text{day}}$.

3 PHOTOBIOLOGICAL MODULAR BUILDING BLOCKS MADE OF THE TRANSLUCENT MEMBRANE OF ETFE

Structurally, we propose to make the main technological nodes from the architectural translucent membrane of ETFE. The architectural membrane can sustain the temperature from $-80^\circ\text{C}$ until $155^\circ\text{C}$. The capsules are transparent, have heat-reflective properties, and inert to acid and alkaline mediums. They do not lose their chemical features during their term of service (approximately 25 years). Membrane are self-cleaned by the action of water flow due to the adhesive properties and a very smooth surface. This property is particularly valuable, taken into account biofouling of bioreactors. Figure 5 and 6 show an architectural shell of the installation for photoreactors with algae and photoreactor units.
The modular building blocks of the membrane translucent with integrated photobioreactor can be located into an architectural shell as an insulating walling. Sanitary zone around the facilities can be greatly reduced due to the recovery of carbon dioxide, shell hermeticity, and transparency of material. The design of an architectural shell generated by genetic optimization algorithm blends harmoniously with the natural landscape and has aesthetically pleasing appearance.

4 CONCLUSION

This paper discusses the problem of shape optimization of an architectural shell with photobioreactors. The parametric approach to the design of engineering structures is the most suitable for the creation of urban objects in accordance with the principles of biosphere compatibility. For example, to maximize the use of natural lighting. In this paper, the algorithm of integration of an architectural shell of photobiological treatment facilities in dense urban areas was considered. The algorithm takes into account shading from neighboring buildings and provides the maximization of the specific growth of microalgae biomass. In the future work, we plan to improve the proposed optimization algorithm in order to take into account the effect of the scattered and reflected light, as well as the spectral composition of the radiation, which influences on the efficiency of photosynthesis.

EVALUATION OF ORGANISATIONAL CONTEXT AND REQUIREMENTS FOR LEVERAGING BUILDING INFORMATION MODELS TO SUPPORT HANDOVER AND OPERATIONS & MAINTENANCE

Hasan Burak. Cavka¹,³, Sheryl. Staub-French¹ and Rachel. Pottinger²

Abstract: The handover of building information upon completion of a project is a critical and challenging step for owners. It is at this stage that the owner gets all the relevant information about the facility to support operations and maintenance (O&M) over its lifecycle. However, experience has shown that this step is often given little attention and that the information that is obtained is often erroneous, incomplete or unstructured. The increasing use of Building Information Modeling by architects, engineers and contractors and the resulting models that are created during the design and construction phases are now starting to be handed over to the owner as part of the as-built facility information. While BIM has the potential to consistently represent systems and equipment with the required information to support O&M, traditional design and construction models need to be significantly reworked to make them useful for O&M tasks. In order to achieve a digital BIM-based handover process we need to understand how a model-based process aligns with a given organizational structure. This paper presents the findings from a retrospective study of a large public owner and the handover process for a high performance institutional building. On this project, we analyzed the owner’s technical guidelines, interviewed numerous O&M personnel, analyzed the software and systems used and the associated information flows, and analyzed the building handover artifacts. In particular, this paper focuses on the analysis of the handover BIM for mechanical systems and its compliance with the owner’s technical guidelines and user requirements with the intent of characterizing the model structure and content required to support the owner’s O&M activities. This analysis identifies the extensive processing required to configure design and construction BIM’s to satisfy owner’s O&M needs. For example, geometric and non-geometric content needs to be added, the models need to be re-structured to define space-equipment-system definitions and relationships, and equipment names and system definitions need to be aligned with the technology infrastructure within the organisation. The findings suggest that in order to have a consistent and useful BIM for O&M at handover, the model structure and content should comply with the owner/user requirements and they need to be in alignment with the organisational and technological processes and infrastructures of the owner organisation.

1 INTRODUCTION

The handover of asset information upon completion of a project is a critical step for owners. It is at this stage that the owner gets all the relevant information about the facility which is essential for O&M personnel to operate and maintain equipment and systems in buildings efficiently and effectively, to extend the service life of equipment, to optimize maintenance activities, to achieve energy efficiency and
to minimize labour time and downtime. We found that the current handover and operations phases suffer from numerous challenges including poor information fidelity, poor interoperability and poor maintenance. Poor information fidelity leads to issues during the operations phase there are related with not having consistent, up-to-date, and reliable data. According to East and Nisbet (2010), 30% of the content of document-based O&M manuals contains some type of errors. Gallaher et al. (2004) concluded that inefficient interoperability cost the construction industry more than $15.8 billion in 2002. Two thirds of this cost was borne by the owner and operators. According to a survey done by the Netherlands Organisation for Applied Scientific Research, %85 of complaints on comfort and high energy consumption are caused by handover and maintenance problems. Many have looked into the promises of BIM for the handover and specific uses in O&M. BIM promises can be summarised as; reducing redundant data collection and data re-entry and improve decision making (NRC, 2012), enabling better information exchange between project phases (Wu and Issa, 2012), supporting O&M functions (Fallon and Palmer 2007, Foster 2011), and improving access to information during operations (Francisco Forns-Samso D. 2010). BIM promises new approaches to the handover and organisational problems related with O&M by enabling data integration, structured information exchange, automated population of databases, facilities management information management, support organisational processes, support decision making through visualisation, evaluation of the models for compliance with the organisational requirements.

The use of Building Information Modeling (BIM) by architects, engineers and contractors is increasing and the resulting models that are created during the design and construction phases are now being provided to owners as part of the handover sequence of as-built facility information. BIM is becoming a delivery requirement for an increasing number of owner operator institutional organisations for its potential to address many of the challenges related to project delivery and handover, and to support O&M of the facility throughout its lifecycle. However the use of information models in handover and O&M is relatively new and numerous issues and challenges remain. The reality is that implementing BIM in large owner organizations is a complex challenge. Each organisation is a complex structure of departments, processes, cultures, networks of systems and databases that are used to support processes and people from different backgrounds and with different information needs.

This paper describes the results of a long-term case study of a large owner-operator institutional organisation that demonstrates the many challenges owner organizations face when considering the adoption of a new technology like BIM. We investigated the organization to better understand how BIM might impact or disrupt this large owner organization, focusing on the structure, processes, culture, work force, supporting IT systems and networks. We also analyzed numerous design models to better understand how the models being delivered were aligned with the organizational needs. This paper will summarize the challenges of aligning a given building information model with the organisational and technological processes and infrastructures of the owner organisation.

2 RELATED RESEARCH

The proposed research analyses the organisational context of BIM through the lens of functional alignment as defined by Henderson and Venkatraman (1993). Internal functional integration between business and information technology is used to understand the characterisation of organisational alignment. The functional alignment definition is extended around handover and delivery of projects. We propose integration of artifacts and requirements into the functional alignment to be able to understand the alignment in the organisational context. The owner organisations need to adapt to changing market where information management and integration are becoming increasingly important, and BIM implementation is being seen as an enabler to reach this goal. In the absence of clear strategy and cultural differences required to compete in both current market and also in a market that is changing according to the developing technologies organisations may fail to harvest benefits (Tushman and O’Reilly, 1996). This implies that organisations should develop clear strategies and consider adjustments to their cultures to be able to harvest benefits from BIM adoption. This requires an understanding of how to manage the change in the strategy and culture according that is required by BIM implementation.

In organisations, people require different sets of O&M information to perform their tasks. However, currently information required by different users is not formalised. Without such formalisation of
requirements, it gets challenging to agree on the content and structure of an handover BIM. Liu et al. (1994), Clayton e al. (1998) and Becerik-Gerber et. al. (2012) listed the information needed for operations and maintenance as shown in Table 1. A model intended to be used for O&M ideally should represent all required data in an accurately computable way.

Wani and Gandhi (1999) proposed a procedure based method developed for evaluation of maintainability index of mechanical systems. The study identified features which characterise or ease in maintenance of a system and named them as the “maintainability attributes” (Table 2). These attributes and their correlations are used to evaluate index. Wani and Ganhi identify maintainability as the design attribute of system which facilitates the performance of various maintenance activities. The particular maintenance activities are listed as inspection, repair, replacement and diagnosis (Wani and Gandhi, 1999). However the handover and O&M specific information and modeling requirements are still yet to be identified.

3 METHODOLOGY

The research is based upon a long term analysis of an owner-operator organisation and its handover and O&M processes, requirements and artifacts. The organization studied was the University of British Columbia (UBC) as the owner organisation, and the specific building studied was the Center for Interactive research for Sustainability (CIRS). Different approaches were used for data collection during this research which are summarised in Figure 1.

Figure 1: Different methods used in the research to analyse organisation, requirements and model.

We conducted interviews with the Building Operations department personnel in UBC were used to understand information requirements, available tools and processes, areas of improvement and areas
that would benefit from BIM implementation. A number of processes within UBC Building Operations were mapped to better understand people involved, information required, tools used, effort involved to complete these processes. The processes that were mapped so far are; service call management and leading steps in the field by O&M personnel, gathering data from the field for asset database for existing buildings, and getting the received records documents ready for the users. Mapping the process of gathering equipment and system data from the field helped understanding the complexity of the information collection and data entry during the operations phase. Process mapping also helped identifying the bottlenecks and inefficiencies, and also helped evaluating potential areas for BIM adoption to eliminate bottlenecks or improve the overall performance. Walkthrough of the CIRS building with the maintenance personnel was used understand the requirements of O&M personnel to perform maintenance efficiently, compared to the handed over building characteristics that hindered the performance. Walkthrough information was also used to evaluate the maintainability of CIRS mechanical systems and equipment. Shadowing of maintenance personnel was used to understand how a work request is received, what steps are taken afterwards, what kind of information is required to do the job, types of building mechanical room or equipment design characteristics that affect the performance of maintenance activities, problems with the current maintenance practices and information that is available to the O&M personnel.

Handover artifacts, owner’s Technical Guidelines and interview findings were analysed to identify requirements. The handover documents were investigated specifically to understand the characteristics of the information set for metrics like usability, reliability, consistency, accessibility. Combined with the interviews, this approach enabled evaluation of the fit between user requirements and handover artifacts and available technology that was used to manage, store, and access this information. The investigation of the Technical Guidelines documents helped understand requirements of the owner which led to a better understanding of the gap between what was required and what was delivered at the end of the construction. This also helped understanding the reasons behind the gap like owner accepting whatever delivered as part of the handover, owner not having the tools or resources to evaluate handover information for metrics like accuracy and reusability. The technology structure within the organisation was mapped to better understand the silos of organisational information, complexity of the network of tools and databases used for managing information.

The design model analysis was used to evaluate the model’s fit for handover and O&M use. Model analysis was performed on the CIRS project’s final version of the model that was developed during design. The project’s handover documents were investigated to understand the characteristics of the information set for metrics like usability, reliability, consistency, accessibility. Combined with the interviews, this approach enabled evaluation of the fit between user requirements and handover artifacts and available technology that was used to manage, store, and access this information. In order to understand the complexity of the model content analysis process and the output quality, different methods of model content evaluation were used, including Revit schedules, COBie outputs (using Revit COBie Toolkit), lifecycle information management tool (Ecodomus), Navisworks visualisations and Solibri Model Checker. The goal of the model analyses was to understand the model contents, contents’ fit with O&M requirements and required model structure to create and exchange information.

4 ANALYSIS OF BIM AND ORGANIZATIONAL ALIGNMENT

In the context of university campuses, there is an interest in integrated approaches for FM information management and leveraging BIM for handover and O&M. Implementation of BIM necessitates a need for developing a better understanding of the organisational context, characteristics and forces within an organisation that have an influence on the BIM adoption. BIM is a disruptive technology, which changes the way organisations are structured and the way they work.

It is important to understand where the information for O&M comes from, internally and externally to an organisation and how information flows down to users. All owners have unique requirements which affect how alignment can be assessed. Building information is handed to the owner after construction and this information flows within an organisation through complex networks of IT systems, databases, and departments and is finally accessed by the user (Figure 2).
Figure 2: Complex structure of organisation and technologies used to manage and support FM
Our analysis of the organisation indicated a number of issues in the current handover and O&M practices like fragmented organisational structure. Within the observed organisation two separate groups within the organisation are responsible for projects before and after the handover. One group is responsible for the project from start to handover, and their main goal is to deliver the building on time, on budget and with quality. The operators of the buildings take over the buildings at handover but have limited influence on the previous phases. Problematic commissioning practice, not having the input of the operations personnel’s during design and construction leads to issues during operations phase. There are no processes (and requirements) defined to gather required information from the project participants to populate FM databases for O&M. Maintenance history information has been kept in the personnel memory and person-to-person communication has been the method to transfer maintenance history information. The organisation has a complex IT structure that supports the performance of FM tasks performed by departments. Non-integrated FM information leads to duplication of effort to manage, create, maintain, and update information. It also leads to information inconsistencies between different databases, and inefficiencies in tracking and monitoring maintenance activities. There is currently no process for automated population of FM databases with required information for the new buildings.

The analysis of the CIRS building and the projects handover artifacts resulted in a number of compliance issues related with the quality, reusability, accuracy, timeliness, accessibility of the handover information. O&M personnel require information (Table 3) to be in different levels of detail, in a reusable format, and information visualisation depending on the O&M function. The interview data shows that while the head of mechanical maintenance project requires equipment information like performance data, manufacturer, and inventory information, a millwright is interested in system layouts within a building or equipment accessibility, information such as what equipment do, which system it belongs to or which areas it serves.

Table 3: Information required by different personnel to perform O&M functions (from conducted interviews)

Technical Guidelines contain owner design requirements for systems that the building design should comply with, however there are issues related to compliance of handed over artifacts and the building to the equipment design criteria such as installation requirements, equipment accessibility and clearance requirements for accessibility (Table 4).

</tr>
</tbody>
</table>

Model analysis was done using the perspectives of content and structure to understand the gap between design and construction BIMs and a BIM for FM, and to identify issues with current design and construction BIMs. The goal of the model analyses was to understand the fit of the model contents with O&M requirements and the required model structure to create and exchange information. Analysis of the CIRS design model resulted in identification of missing geometry, missing information related with component and systems, LOD issues and modeling problems. We indicated model content and structure related issues that have to be addressed in order to bring these models to a required FM BIM level (Table 5). Content problems consist of completeness and availability of geometric and non-geometric information within a model. The model content needs to comply with the requirements of the owner and users for specific BIM uses, and the structure is supposed to enable exchange of the right model information in a format and structure that is meaningful to the owner. Analyses also indicate that each method required model manipulation to get required information output. Besides the missing content and structure, required model manipulation necessitates a level of expertise in using the modeling software that most owners lack. Analyses indicated that the models were lacking structure that was required for exchange of O&M information, organisation of model components in a way that is aligned with users’ requirements and models were also lacking both geometric and non-geometric information. The examples are intended to illustrate the gap between a handover BIM and design/construction BIMs.

</tr>
</tbody>
</table>
Problems like overlapping space defining model components lead to issues when assigning equipment to spaces. Solving this issue gets complicated if the building design has hard to define spaces like spaces that extend multiple floors or mezzanines.

5 CONCLUSION
The handover of BIM for operations and maintenance is a complex challenge for owners. Our detailed analysis of an organisation and a specific design model indicates the extensive processing required to configure the design BIM to satisfy O&M requirements. Within the model geometric and non-geometric content needs to be added and the models need to be re-structured to enable transfer of model information in an accurate and reusable way. Spaces and room boundaries in the model should be accurate, space-equipment-system relationships need to be defined. Equipment names and system definitions need to be aligned with the organisational technology infrastructure to enable information exchange. There are also organisational issues of alignment and compliance that need to be addressed. In order to support the transition to BIM, organizations need to reshape the way they manage their facility information both before and after the building handover. There is also a need to reshape the way owner organizations function so that they are better aligned with a model-based workflow.

Abstract: We conducted an ethnographic study of design coordination meetings to better understand the challenges faced by project teams as they coordinate designs in multi-disciplinary meeting environments. This ethnographic study involved observation and analysis of twenty-seven design coordination meetings from the design development phase of a high performance institutional research building. Design coordination and conflict detection are two of the most common and highly valued uses of Building Information Modeling (BIM). However, in our observations of these meetings, we found that BIM tools were extremely under-utilized. This research identified and characterized the bottlenecks encountered during these in-person design coordination meetings. We observed meeting bottlenecks when meeting activities were performed inefficiently, when the meeting process was slowed down, when meeting workflow was interrupted, or when decision-making was hindered. We identified and characterized meeting bottlenecks in a framework that illustrates the nature of each bottleneck and the frequency of its occurrence. According to our observations, we identified five types of bottlenecks that hindered the efficiency of design coordination meetings: people, meeting environment, drawings, interaction/access and information. We anticipate that these findings will help to inform the development of better meeting processes, the design of new interaction, visualization, and integration technologies that better support the meeting processes of design teams.

1. INTRODUCTION

During the design phases of a project, design teams meet regularly to control and monitor the design process, to share design information, and to coordinate the various disciplines’ designs. The system designs are iteratively updated to accommodate each discipline’s requirements. Successful management of this design process is critical to the efficient delivery of cost-effective and quality projects (Chua et al. 2003). Coordination among stakeholders is critical to ensure that a design meets the functional, aesthetic, and economic requirements of the owner. Timely delivery of a coordinated design and a less problematic and on time construction process also depends on the effectiveness of the coordination meetings. However, Liston et al. (2007) found that teams spent only 20% percent of time on “coordination” activities. The remainder of the meeting time was spent for “direct discussion of design” (50%), “taking stock”, “digression and other” project activities. Although digital technology has become integral to the design process, design coordination is often still accomplished using paper printouts of 2D schematic diagrams and other related project information. However, there are limitations of paper for coordination. Design coordination is challenging and needs to be understood so it can be better managed.
This paper presents the results of a long-term ethnographic field study that investigated the challenges faced by project teams as they coordinate designs in multi-disciplinary meeting environments. This study involved observation and analysis of twenty-seven design coordination meetings from the design development phase of a high performance institutional research building over 16 months. We identified and characterized meeting bottlenecks in a framework that illustrates the nature of the bottleneck and the frequency of its occurrence. We observed meeting bottlenecks when meeting activities were performed inefficiently, when the meeting process was slowed down, when meeting workflow was interrupted, or when decision-making was hindered. According to our observations, we identified five types of bottlenecks that hindered the efficiency of design coordination meetings: people, meeting environment, drawings, interaction/access, and information.

2. LITERATURE REVIEW

This section summarizes relevant literature on group work, coordination meeting challenges, and group decision making. Group decision making is a complex process in construction given the fragmented nature of the construction industry, the barriers set up by traditional contractual relationships, and the conflicted roles and responsibilities of project teams (Issa et al., 2006). In Grønbæk et al. (1993), the bottlenecks in daily work and collaboration were divided into three subsections: bottlenecks related with sharing materials, coordination and communication. Liston et al. (2001) looked at challenges in visualization, sharing, exchange and interaction with the electronic information in multi-disciplinary project team meetings. Their main focus was on interactive information workspaces. When compared to this study; rather than documenting overall meeting bottlenecks, the paper proposed an approach for dealing with a number of specific bottlenecks. Tory et al. (2008) described meeting bottlenecks related to navigating digital information, individual information lookup, and accessibility of information. However, this work was focused on low level interactions with artifacts rather than high level meeting processes. These different efforts provided important points of departure in terms of understanding the different types of bottlenecks that we were observing in building design coordination meetings.

An important consideration in design coordination is that project teams must contend with numerous and diverse types of information. The participants use a variety of visual representations of project data in different formats (paper and digital documents, physical models, sketches etc.), to convey information within the group. Participants share, view, coordinate, and manage design information during coordination meetings. Several research efforts focused on activities performed by meeting participants in workspaces. In their study of small group design meetings, Olson et al. (1992) categorized meeting activities as issue, alternative, criterion, project management, meeting management, summary, clarification, digression, goal, walkthrough and other activities. In a subsequent study, Liston et al. (2001) built on this categorization of meeting activities and classified meeting activities as descriptive, explanatory, evaluative, and predictive.

Luck (2007) investigated artifact use in design and described how artifacts are used to mediate understanding in design conversations between people with different levels of understanding of design schemes. Luck concluded “it was only through the use of these artefacts and conversation about these artefacts that the users’ understanding of the design became explicit”. Meeting discussions mostly evolve around different forms of information artifacts. Participants interact with information in numerous ways, including pointing, mark-up, changing (Liston et al. 2007), and perform physical interactions, such as gestures, annotation, and navigation (Tory et al. 2008). Tory et al. (2008) described how a building design team used design artifacts during design coordination meetings as part of an effort to identify effective input methods for a digital system. They presented possible directions for future Computer Supported Collaborative Work (CSCW) technologies based on observations, like simplifying and enhancing navigation, design mechanism for digital bookmarking, enriching pointing techniques, augment pen functionality and supporting information access by both groups and individuals. Researchers have also recognized that group dynamics play an important role in collaborative work and may have a significant impact on meeting performance (e.g., Nunamaker et al. (1991) and Garcia et al. (2004).

This research builds on previous efforts mentioned in this section by developing a taxonomy of bottlenecks that captures the social, contextual and technical aspects of design coordination.
3. METHODOLOGY

This research is based on a sixteen month field study of design development and coordination meetings for the Centre for Interactive Research and Sustainability (CIRS) project (Figure 1). CIRS is a 58,000 square foot research facility that aspires to be the most innovative and high performance building in North America. The CIRS design coordination meetings were held weekly in the architects’ office and typically included structural, electrical and mechanical consultants, the owner’s representative, and construction manager’s representatives.

Figure 1: Left; 3D renderings of the Centre for Interactive research on Sustainability (courtesy of Busby Perkins + Will), Right; typical setting of the meeting environment.

We conducted an ethnographic field study involving the observation of design coordination meetings, and analyzed our results using a grounded theory (Phelps et al., 2010) approach. The work practices of project teams were observed in the field and qualitative observational data about meeting processes was systematically collected in the form of observer notes, video footage and a few targeted interviews with participants. Instead of observing many meetings from different phases of projects, observations on pre-construction design coordination meetings were chosen. Over a sixteen month period, twenty-seven consultants’ coordination meetings were attended in the architects’ office. Each meeting took between one and two hours. During the observational study, researchers looked for inefficient meeting practices: situations where the meeting workflow was interrupted or situations where the observers thought that the meeting tasks could have been performed more easily or more efficiently. Team members’ interactions with information artifacts were observed in order to better understand the use of these artifacts during meetings and their role in contributing to or mitigating bottlenecks. The interactions between meeting participants and their effect on the overall meeting process were considered. Detailed notes were collected during each meeting, including the names of attendees, discussion topics, bottlenecks observed, and observations related to the decision making process. A document was prepared for each meeting using observer notes, notes on available artifacts, artifact use, observations about execution of meeting tasks, and interactions between meeting participants as much detail as possible. The meeting agenda and meeting minutes (if available) were added to this information set. Instances of observed live interactions were noted with actual time and descriptive notes by the observer and later a snapshot of the corresponding recorded video frame was added in order to reflect the context during the meeting. Additional instances were observed from viewing of the videos. This way, informative and descriptive vignettes were created from each meeting. The vignettes included textual information and provide contextual clues for the reader about the specific bottleneck. Formal and informal interviews were conducted with the meeting participants in order to crosscheck our intuition about the causes of the observed bottlenecks. The analysis and coding of project meetings were performed according to conventions of grounded theory as defined in Phelps et al. (2010). Open coding, axial coding and selective coding were used sequentially to develop the proposed taxonomy of meeting bottlenecks. An open coding process was performed on the data set created from the meeting documents. This process resulted in a list of observed bottlenecks. Among the list of all observed bottlenecks single events were eliminated. During axial coding, similar bottlenecks were grouped, resulting in a set of bottleneck categories. After the selective coding, the taxonomy of design coordination bottlenecks was structured.
4. CASE STUDY RESULTS

The proposed taxonomy of design coordination bottlenecks in building design coordination meetings that we developed using the findings from the CIRS case study is represented in Table 1. The case study is representative of typical projects in the industry.

Figure 2 shows the breakdown of the 294 identified meeting bottleneck instances from data collected during the 27 co-located paper-based meetings. The largest number of bottlenecks observed in the analysis was of interaction/access group of bottlenecks, followed by information, drawing, people and meeting environment groups of bottlenecks. When we look at the distribution of the bottlenecks in more detail, we see that visibility bottlenecks are the most observed meeting bottlenecks followed by remote pointing, content and information exchange bottlenecks. Parts of the taxonomy will be explained in detail in the following sections.

Figure 2: Distribution of observed meeting bottlenecks according to meeting bottlenecks categorisation.

4.1 People

4.1.1 Group Composition: The composition of a design team may change multiple times as the team players sometimes change throughout the project phases (Liston et al. 2001). When a team member changes, the knowledge about the evolution of the design may not be completely transferred to the successor. This creates breakdowns in the information flow between team members, and leads to iterations of coordination tasks like descriptive, explanatory tasks. Throughout the CIRS design phases, team members like the project architect, mechanical consultant and owner’s representative changed positions with people from the same organizations. The example below shows a captured conversation between the project architect and the new mechanical consultant who replaced a consultant from the same engineering firm. The new member of the team is not aware of and was not briefed about a previous discussion by his predecessor.

Architect asks for an update about a part of the mechanical system that was discussed previously. Mechanical consultant apologizes for not having that information. Architect says “it’s okay, you joined the team later during the design process, and we discussed this before you joined the team”
4.1.2 Group Dynamics: Meeting participants are often from various professional backgrounds, with different levels of experience, characteristics, responsibilities and authority. Sometimes a participant’s approach to a coordination issue may be influenced by responsibility to his/her firm or a specific goal related to the individual’s position in the project. This section covers bottlenecks that occur because of the clash between individual goals of meeting participants and the lack of a collaborative agreement on the project goals. The example below shows that team members have different concerns and goals about design process and the use of Building Information Modeling (BIM) and how individuals prioritize project goals differently.

Architect mentions resynchronization of drawings for digital coordination. Owner's representative wants to know why they need the project models and expresses concerns about starting with Revit. Owner's representative: "Should we coordinate at own offices? It is going to be a big loss of time if everybody … What will we be looking at on the model during the meeting?" [Architect's concern is implementing a coordination process through model use. But the owner representative’s main concern is speeding up the overall process and not spending time on trying to figure out requirements of this new process.]

4.1.3 Availability: This section covers bottlenecks related to not having the right group of people available in coordination meetings to make informed decisions. Sometimes people with the required information or knowledge are simply not present in the meetings to provide the necessary input on a discussion topic. There were two common reasons for this bottleneck type: (1) a team member who is a part of the regular meeting group was not available in a meeting, and (2) a person with the required knowledge and authority on a discussed topic is not included in the meeting. Availability bottlenecks caused delays in decision making or delays in getting required information. In the example below, the Construction Manager’s (CM) representative is not present during the meeting to clarify a concern about the sequencing of construction. The discussion ends without a clear answer to the consultants’ concerns.

The building is going to be built in phases and the participants are not sure when the auditorium is planned to be built by the general contractor. Mechanical consultant has a concern that the ground source cooling system construction (proposed to be located underneath the auditorium space) would lengthen the construction time but architect doesn’t think so, because he believes that the auditorium will be built last.

4.2 Meeting Environment

4.2.1 Access to Design Information: This section covers bottlenecks involving access to the large amount of project information that the design teams use during design and coordination meetings. Teams may need to access this information during any meeting, at any moment. Most of the time, it is difficult to know in advance which information will be needed. The observed design team used an online design and data management software (Autodesk Buzzsaw), but the technology was not used during the coordination meetings.

Structural engineer is giving an update on glulam frame details. The consultant did not bring any detail drawings with him to the coordination meeting. The drawings are at the consultant’s office. Architect goes to the white board and sketches the detail on the board.

4.2.2 Meeting Management: This section covers bottlenecks related to handling of the meeting process, including the facilitator’s preferred meeting management style, emphasis on the agenda and minutes, inefficient use of meeting time as a result of digression from the main topics, and forming the agenda from issues that do not interest most people in the group. Garcia et al.’s (2004) study on how to manage meeting agendas indicates that often a substantial number of agenda items concern only a few people in the meeting group. We observed that meeting productivity was impaired in the absence of an experienced facilitator or a well prepared meeting agenda. During one of the observed meetings the senior project architect, who was the regular meeting facilitator, was not present in the meeting. During this meeting, the discussion often shifted from the main focus of coordination and participants spent more time on details that did not necessarily concern all participants.
4.3 Drawings

4.3.1 Content: This section covers bottlenecks related to the content of drawings used during design coordination. The content of a design drawing is limited based on its intended use and a consultant’s drawing focuses only on information about a particular system’s design. During evaluation of the design from different perspectives, participants end up using multiple drawings and/or artifacts in order to effectively communicate design information with others. When participants need to use multiple representations to compare data from multiple drawings, they need to go through sets of printed documents in order to find the relevant information, and reconcile information from multiple related documents, which requires time.

The architect uses the physical model and the artist’s rendering at the same time because rendering has the ability to represent the visual effect of the materials used on the façade. It is not possible to see these effects on the physical model. Meanwhile participants can observe more than one facade at once on the physical model and compare facade characteristics to one another. They then will refer to plan drawings to get an understanding of the space use.

4.3.2 Symbols: This section covers bottlenecks involving a failure to correctly understand or interpret representations on a consultant’s drawing. Design drawings represent the consultants’ design intent—they contain domain specific language and information. The representation of information on drawings may even differ from one design phase to another in the same domain. The following is an example for a bottleneck caused by the architect’s representation of windows on the elevation drawings.

At the end of the meeting CM asks for clarification about components represented on architectural elevations. CM to architect: “Could you let me know which ones are the windows and which are the panels in drawing A301?” [It is hard to identify the panels and windows from the drawings and the information is required for a more accurate cost analysis.]

4.3.3 Visualization: This section covers bottlenecks related to drawings’ incomplete ability to communicate design information; for example, not representing all component characteristics or system designs’ interaction with other systems or components. Visualization of design information on paper drawings (especially on 2D drawings) have shortcomings that hinder communication. For instance, within 2D plan drawings, it is not easy to understand systems or components that are above a certain height. In the example below the project architect requires additional information from the mechanical consultant because the 2D design drawings do not visually represent 3D characteristics of the mechanical system components. Visualization bottlenecks were also observed when the meeting participants were examining an issue about a vertical component that extended across multiple floors.

“So the equipment is tall?” Architect is evaluating different options about a mechanical room layout. He is asking the mechanical consultant about the physical characteristics of mechanical system components. [3D characteristics of the equipment are not represented in the drawing. Participants have to mentally visualize the component in order to evaluate different layout options.]
4.4 Interaction/Access

While design teams perform meeting tasks they use information artifacts such as drawings, documents and physical models. In order to perform meeting tasks efficiently, design teams need to be able to easily access and interact with these artifacts. Interaction/access bottlenecks include remote pointing, annotation, navigation, visibility and manipulation bottlenecks related with the artifacts.

4.4.1 Remote Pointing: Observations in this study showed evidence that the lack of tools for remote pointing on digital and physical artifacts created interaction bottlenecks, which in return slowed down meeting processes and interrupted workflow. Participants did not take advantage of information artifacts that were available in the meeting room, just because they did not have instant access to the artifact or did not have the proper tools for remote interaction. Instead, they preferred longer verbal descriptions.

While the owner's representative is talking about an issue about the site and one of the neighbouring streets, he does not use the physical model which sits on a table in the room, simply because he does not have an efficient way to interact with the artifact; he would need to stand up to get closer to the model.

4.4.2 Annotation: During meetings, team members perform sketching, annotating, and note-taking activities on different information artifacts. Annotations are often used to clearly express an idea, propose a design change, and create meeting notes. Observations in this study showed that annotations, which are used often during meetings and can be very explanatory, are often not used efficiently. Annotation bottlenecks were observed when participants were making annotations on physical and digital artifacts (which cannot be kept as a record if required), communicating an idea using sketches, note-taking, viewing and manipulating annotations of other people, keeping a record of these annotations, etc. The following example shows a need for personal annotations (in this case sketches) to be easily accessible and viewable instantly by other group members in order to solve problems faster:

While discussion continues on the drawing board, the architect is sketching a detail on his notepad, which will be used in a minute to help solve the discussed issue. If he could have used a common display to show his sketch remotely on this surface, he could have helped others solve the issue faster, and other participants would be able to view the explanatory sketch much easier on the display rather than trying to see the sketch on a notepad.

4.4.3 Navigation: Navigation bottlenecks were observed when participants were searching for the most relevant data amongst different forms of information sets. During the meetings, consultants had to go through stick sets of drawings in order to find relevant drawings. The example below explains an instance where the architect navigates in a stick set. The architect had to move back and forth in the stick set during a discussion about mechanical system layout. In this case the actual navigation time takes virtually as long as the discussion itself. Often the participants preferred to bring smaller scale drawings so that it would be easier to navigate through pages and the drawings would take less space in the meeting environment. But this caused visibility problems when looking at detailed information on drawings.
The architect is going through different plan drawings to point out areas on floor plans while discussing space requirements for the supply and return for the cistern. He spends time finding the first related drawing page in the drawing set. Then he flips back and forth between the different plan drawings as he talks about the mechanical system routing.

4.4.4 Visibility: This section includes viewing problems (group viewing, individual viewing etc.) that were observed while the participants were working with paper drawings and documents, digital representations of information and physical models. During observed meetings, there were often times when team members had problems viewing artifacts. Visibility of information artifacts was noted as a bottleneck during this study since it was one of the most common observations. However, the effect of this problem was not usually noticeable from the workflow perspective. People were often observed having difficulty on viewing artifacts but most of the time they seemed comfortable with it.

Meeting participants often passed around drawings during discussions to have a better look at relevant information. Participants talk about the design as they view the drawing. However, not all participants have access to the drawing during the discussions. It is hard for the participants to view and interact with the artifact collaboratively at the same time.

4.4.5 Manipulation: Traditional 2D drawings do not allow many interactions that project teams need to perform during a meeting such as zooming in on a part of the drawing and getting quick measurements. Lack of such interactions can affect the efficiency of the team and hinder the effectiveness of information flow between participants. In the following example design team was using a small scale paper drawing. The plumbing consultant needed to zoom in on the problem area to be able to take an accurate measurement.

Plumbing consultant says, “I have to measure this distance. I have to blow this up,” as he is trying to answer architect’s question about the spacing of the sprinkler heads. [The architect’s question remains unanswered since the required manipulation (zoom in and measure) cannot be done on paper drawings.]

4.5 Information

4.5.1 Exchange: A great amount of information is exchanged between consultants throughout a project. Design progresses fast, especially in the early design phases. The nature of design process makes seamless information exchange an important factor for a project to be successful. We observed numerous bottlenecks resulting from delays in information exchange between consultants. There was often a time lag between a design change and notification of other consultants about the change, which led to inefficiencies in the design process and created bottlenecks in information flow. In the following example, it turns out that CM’s budget calculations, which were discussed earlier in the meeting, were from an older version of the design drawings.
The design team is discussing the auditorium design. CM's representative: “the drawing that I am working with right now doesn’t have that detail.” [It turns out that the CM, who is working on the project's cost estimate (a very important aspect about the progress of the project), has not been working with the latest version of the design drawings. The CM was not informed about recent design changes.]

4.5.2 Interdependencies: Interdependency between the consultants’ design information were noted as one cause of inefficiency in decision making. Design decisions and discussions are multidimensional and interrelated with the decisions made by other consultants. Although discussion of interrelated items is considered as a natural part of problem solving, the observed issues were more about (a) not being able to move forward (or make a decision) because of complexity or the absence of information required, (b) moving away from a discussion topic that is in the meeting agenda, to a number of different topics that requires detail information or considers only specific members of the design coordination team. During the coordination meetings, consultants have to evaluate scenarios together to come up with a solution that works well with everyone’s design criteria. That is why discussion of a topic sometimes triggers other discussions.

The owner’s representative explains a storage area requirement in the building. Topic of accessibility to the storage area comes up and the team evaluates the possibility of moving washrooms to the storage area. The solution also depends on other system designs. Dropping the washrooms might trigger problems with the plumbing. Washrooms can be below the utilities level from the street, but in this case pumps and extra mechanical equipment may be required. The discussion takes too long and the issue remains unresolved. Team decides that they need mechanical consultant’s approval or ideas about moving the washroom to the storage level and they move on to the next issue.

4.5.3 Availability: When information was not available during a meeting, the design team could not make informed decisions, issues remained unresolved, questions remained unanswered, and the design team moved on to the next topic on the meeting agenda without a final decision. We observed three main reasons for this bottleneck: (a) the required information was created, but was not available in the meeting, (b) more information was required to make a decision or (c) needed information was not created yet. In the following example, the discussion was about the size calculation of the emergency generator fuel tank. The team realizes that the required information was simply not available to make a final decision.

Q: “How long does it (the generator) have to run?”
Q: “Is it thirty minutes (until everybody is out) or does it have to run longer?”
Q: “Where does ‘the generator has to be able to run for 12 hours’ come from?”
[After discussing the same issue for about fifteen minutes the team understands that available information is not enough to make a decision on the subject. Additional information is required from consultants before making a final decision.]

4.5.4 Analysis: Project teams evaluate different design options throughout the evolution of a project, in an effort to find the best fit to achieve the project goals. We observed a lack of technological support during the evaluation of different design ideas or solutions. The analysis required by the team includes evaluating the effect of a proposed design option according to compliance with other parts of the design, cost, schedule, construction sequencing or code requirements. The following is an observation where a participant would like to know what the incremental cost of a design change would be.

Partnering consultant asks “what if” questions about the cost: “what if ...... then what would be the incremented cost?” [There may not be a quick answer to these types of questions since further analyses and calculations have to be done before answering them.]
5. CONCLUSION

This paper described the results of a 16-month ethnographic field study that involved observation and analysis of twenty-seven design coordination meetings during the design development phase of a high performance institutional research building. We identified and characterized meeting bottlenecks in a framework that illustrates the nature of each bottleneck and the frequency of its occurrence. The taxonomy of design coordination meeting bottlenecks provides a more holistic characterization of meeting bottlenecks than what has previously been represented in the literature. This research studied the existing work practice of project teams in design coordination meetings. Our observations point out the need for improved information sharing amongst team members, new tools to help design team to be able to more easily and quickly understand and analyze design issues and options, and make informed decisions. During a meeting information artifacts should be accessible by all participants. Project teams need to be able to view information both publicly and in private to better understand and evaluate discussion topics. When an artefact is being used by a participant, other participants should still be able to view or be able to interact with the same, or the digital representation of the same artifact. Personal interaction with the artifact should not hinder other participants’ interaction with the same information. Our hope is that by better understanding the meeting process and the bottlenecks observed, we can design technologies that provide better support for the unique needs of building design teams. In particular, technologies that enable better interaction with information artifacts, seamless exchange of data in meeting settings, and advanced visualization technologies for better communication and decision-making.

Abstract: Engaging workers from construction companies of various sizes and ensuring their participation in construction safety research is often very difficult. Voluntary participation is typically limited by industry-specific recruitment challenges such as the transient nature of the workforce, industry perception of safety research, schedule limitations, and economic constraints. This paper uses the lessons learned and best practices from several years of data collection experience to present a data collection framework for research within the construction industry. The framework includes organizational support, research instruments, data collection processes, and measures of data collection efficiency. The framework was developed following an intensive six-month data collection period, resulting in 370 completed surveys. A 95\% survey completion rate following survey site visits was observed, however the overall recruitment time per survey was 3.8 hours. It is clear that data collection itself is often one of the most challenging and time consuming activities related to construction safety research. Clear communication protocols, strict confidentiality measures, and effective incentive strategies are discussed. Methods of engagement are also provided: often a hybrid of a top-down and bottom-up approach is required ensuring participation and worker/company buy-in. The data collection framework in this paper provides a point of departure for researchers to improve their data collection processes and in turn, work toward improving safety performance more efficiently in the construction industry.

1 INTRODUCTION

The construction industry is a dynamic and evolving environment where the employees can experience disproportionately high injury and fatality rates (Hallowell and Gambatese 2009). Although significant improvements in safety performance continue to be made in Ontario following the development of the Occupational Health and Safety Act in 1978, construction worker safety has become forefront in recent years (Government of Ontario 2002). Therefore, ongoing and consistent safety research to improve practices and worker-hazard interactions is required (Hallowell and Gambatese 2009). Moreover, recruiting workers to participate in voluntary safety research and data collection is necessary to understand the ever-changing, remote, and transient nature of the industry (Kidd et al. 2004).

Construction safety problems are ubiquitous and are rarely unique to a specific trade, employer, region, province, or country (Hinze 2008). Thus there is an opportunity to solve safety problems on a global level by addressing many facets including managerial components, behavioural aspects, technological advancements, and cultural characteristics (Hinze 2008). Construction projects are defined by various
unique factors including frequent crew changes, exposure to adverse weather conditions, and ever changing topology, topography, and general work conditions. This makes construction site safety more difficult to measure and research (Rozenfeld et al. 2010), requiring a universally effective data collection program and approach.

The effort, time, and resources required to recruit and retain participants for construction safety research is often far greater than anticipated at the project outset. The top two reported reasons for nonparticipation in safety research projects is the time required to complete the survey process and participants’ and supervisors’ perception of the safety record of their company or site (Kidd et al. 2004). Lessons learned from the recruitment stage of safety studies are useful when engaging participants in future safety research initiatives. Lessons learned include understanding the stability of the construction companies, ensuring sufficient time is provided to recruit participants, oversampling to meet data set targets, approaching both owners and workers during the initial recruitment stages, and understanding the burden perceived by the participants and providing tailored incentives to overcome this burden (Kidd et al. 2004).

Time demands, economic constraints, worker turnover, industry perceptions, and various worksite conditions often limit worker participation in data collection and research. A gap in the research exists in that a systematic and pragmatic data collection framework has not been proposed to overcome participation issues related to construction safety research. Methods to overcome recruitment challenges in small construction companies have been suggested however a comprehensive and universally applicable data collection framework has not been put forward (Kidd et al. 2004).

1.1 Objective and Scope

This paper outlines a practical and efficient framework to identify and recruit participants in construction safety data collection initiatives. This will involve selecting potential construction sites, engaging and gathering initial site contacts, connecting with site and company representatives, coordinating and scheduling site visits, and managing onsite survey distribution and collection.

Lessons learned and best practices from the researchers’ construction safety improvement initiative are presented in a case study format to capture data collection challenges and successful mitigation techniques. The case studies were obtained while researching construction safety to better understand the behavioural and cultural aspects of the industry, nature of the work, attitudes, and demographics. The data presented in this paper was gathered by surveying workers from construction sites across Ontario. The need for a data collection framework was identified by reviewing the rate of buy-in from the engaged site/employer contacts (site participation rate), the ratio of actual participation verses expected participation, the overall recruitment effort (time), and the onsite feedback obtained during survey distribution and collection.

2 THE FRAMEWORK

This framework was developed after several years of data collection experience that took place from 2004 to 2006 (McCabe et al. 2008), and in 2014. In particular, data on the safety climate of construction workers in Ontario were collected through self-administered surveys. The process of engaging site management to allow access to the sites helped the team hone their practices in an effort to maximize the yield. Embedded in the framework are our best practices. The assumptions of this framework are:

- Access to individual workers is desired versus having one person represent the site
- Data collection is completed in person as opposed to on-line surveys
- The sample should be representative of a broad target population. This is different from working with one or two employers to collect data on their sites.

Figure 1 shows a data collection framework with four main parts: organizational support, research instrument, data collection processes, and measures of data collection efficiency.
2.1 Organizational Support

In most cases, the two major parties in this endeavour will be the research team and the construction team.

The construction team includes head office management, site management and supervisors, and workers. To gain access to the site and therefore the workers, permission was required from those ultimately responsible for the site – head office management. As noted in the third part of the framework, the path that the request may take depends on the way in which they are approached. However, it is noted that a lack of enthusiasm at any level can end the conversation quickly. Finding the right champion, therefore, is important.

The research team at University of Toronto comprised the principal investigators (PI), two graduate research assistants (RA) and three undergraduate research interns (RI), who assisted with site identification and data collection. The RAs coordinated their responsibilities to eliminate duplicated effort and missed opportunities. As such, RA1 worked directly with the three RIs to implement introductory site visits and data collection. RA2 was responsible for follow up communications with the employers (corporate and site managers) and for scheduling survey collection visits. Having RA2 also invest some time in the onsite data collection efforts allowed for an enhanced understanding of the on-site needs and dynamics, while also allowing for relationship building at the site level. This proved useful during the implementation of top down engagement strategies. Communication protocols such as updating experience diaries and site contact lists daily were established to facilitate quick and complete information sharing between the two teams.

It was essential that the team have safety training before gaining access to any site. They all had their own personal protective equipment (boots, hardhat, and vests) and completed training for WHMIS, Ministry of Labour’s Worker Health and Safety Awareness, and Fall Awareness. They also carried a letter of introduction from the PI, and a letter from the university outlining its insurance coverage for registered students undertaking research off-campus. This did not preclude individual sites requiring the team to undergo site-specific training.
2.2 Research Instrument

Preparation of the research instrument, finalizing approvals, and establishing protocols are next. The survey should be prepared carefully to ensure that the questions being asked will result in targeted responses to the research questions. One way in which this can be achieved is by using validated safety climate scales. These scales are available in the psychology literature for a large number of topics, as shown in Table 1. Each scale is described by several questions. Although these scales have already been validated, they should be re-validated when applied to new industries. Principal component analysis (PCA) in conjunction with other statistical methods (e.g. collinear test) was used to achieve this. Consequently, the questions that were either not correlated with any others or were highly correlated with others were removed. Cronbach’s alpha reliability test was also run. As shown in Table 2, seven out of 13 alpha values are between 0.7 and 0.9, which suggests good internal consistency. Three alpha values are between 0.6 and 0.7, which is acceptable. For the remaining 3 scales (Conscientiousness, Leadership, and Role overload), the alpha values are below but around 0.6, which is acceptable but weak. These three scales should be reviewed and adjusted in subsequent research.

The participants’ demographics and incidents are also measured in this survey, and their relationship with safety climate is analyzed.

The PIs must decide if the participants are to be assured confidentially with respect to their responses, and how that will be achieved. In our case, the surveys were confidential, and several strategies were used to ensure that confidentiality. First, participants completed the survey on their own under the oversight of the research team and not their bosses. Once completed, the surveys were put through a slot of a locked box, which was taken away by the researchers at the end of the data collection visit. Participants did not put their names on the surveys, and we even brought pencils with us to ensure that individuals could not be identified by the colour of the ink they used. In the office, the surveys were entered into the database.

Even if confidentiality is ensured, participants must sign a Consent Form before completing the survey. It contains important pieces of information, written in language that is appropriate for the participant population. This form is required by the research ethics review panel and includes:

- Contact information for the researchers and for the Office of Research Ethics should they have any questions.
- The purpose of the research, its sponsor, and the time commitment expected from them as participants.
- Conditions for participation, and it must explicitly state if it is voluntary, and how they can withdraw from the research should they wish to.
- Risks and benefits to participants due to their taking part in the research.
- Explaining who will have access to the data, how it will be used, and how it will be published.
- Procedures for maintaining confidentiality, both of hard and electronic data.

PIs and the RAs are strongly encouraged to complete research ethics training to better understand some of the issues that relate to their specific research.

To improve the uptake and acknowledge the contribution of the participants, an incentive strategy may be employed. That strategy should acknowledge each level of participation, and it doesn’t have to be expensive. In is our case, when participants completed their survey and put it in the box, they were given a sports drink and a hardhat sticker that was made specifically for this project (see Figure 2). It is interesting to note that many workers chose to have the stickers but refused the drink. Site managers were also given a certificate of participation.
We had the survey translated into various languages (English, Italian, Spanish, and Portuguese) to facilitate the participation of those who were less comfortable in written English. Without regard to the language, it was observed we often needed to explain what some questions meant. This reinforced the benefits of going to the sites to collect data.

2.3 Data Collection

This discussion examines the process of implementing the research instrument, from first contact to completion of the data collection. Engagement of the industry is the first challenge; top-down or bottom-up methods can be employed.

Top-down means that the team first contacts the head office management, in this case the person responsible for safety, to introduce the project. If the person is enthusiastic about the project, then they will engage their site managers and schedule data collection visits. This method involves three steps: RA2 contacts the corporate management and if permission is given, schedules site visit(s), and RA1 collects data.

The bottom-up method involves engaging the site managers first, who then work to gain corporate permission. It has four steps: initial contact at the site by RA1, follow-up by RA2 and communication with the site and/or the corporate management until approval is given, schedule site visit(s) by RA2, and collect data by RA1.

In either case, the first contacts must be introduced to the project with sufficient detail to allow them to make informed decisions whether to move forward or not. Details may include:

- The objectives of the research
- Who on site is being targeted (e.g. everyone, only specific trades)
- The process being used to collect data (e.g. interviews, surveys, observation)
- The time commitment that would be needed by the participants and when that time would be needed (the start of the day is best in most cases).
- A small sample of the survey
- The overall benefits of participating
- Safety training of the research team
- Documentation summarizing the information

The challenge with the top-down method is identifying the companies and then identifying the right person to contact. The challenge with the bottom-up method is finding construction sites. In the ideal case, engaging a site manager resulted in many more sites from that contractor if the corporate manager was equally engaged. We used a combination of top-down and bottom-up methods. The research team often went to site before the workers started work, e.g., 6 to 7AM, so that the normal work was not overly disrupted.
Factors that can negatively affect the willingness of management (corporate or site) to participate include being behind schedule, poor communications with the company representatives, and negative attitudes of the supervisors toward safety research. Factors that reduced the number of surveys collected on a particular day included poor weather, a high proportion of workers with limited English, generally poor morale on-site, lack of acceptance from the site supervisors, poor introductory explanations about the survey by the research team, and the research team arriving late at the site.

One example that demonstrates these factors was when using the bottom-up method; a construction worker was approached at the site gate to ask where the site office was. He was very helpful and began to direct the team to the site office. However, as soon as safety was mentioned, his helpfulness vanished and he started making excuses about why he could no longer take the team to the site office. This was not an isolated case, and the team soon learned to avoid discussing the specific topic of the research in the first few minutes of first contact.

2.4 Data Collection Efficiency and Effectiveness

Data collection efficiency relates to how well the team is turning effort into surveys. It may be gauged using the measures outlined in Equations 1 to 6.

\[
\begin{align*}
[1] \quad & R_1 = \frac{N_1}{N} \\
[2] \quad & R_2 = \frac{M}{N_1} \\
[3] \quad & R_3 = \frac{\sum (a_i/b_i)}{N_1} \\
[4] \quad & R_4 = \frac{T}{M} \\
[5] \quad & R_5 = \% \text{ within bounds} \\
[6] \quad & R_6 = \text{no. surveys 90\% completed} / M
\end{align*}
\]

Where:
- \( R_1 \) is the site participation rate
- \( R_2 \) is the average number of surveys collected per site
- \( R_3 \) is the ratio of actual to expected number of surveys
- \( R_4 \) is the recruitment time per survey achieved
- \( R_5 \) is the sample representativeness
- \( R_6 \) is the survey completeness
- \( a_i \) is the actual number of surveys collected for site \( i \), \( i=1: N_1 \)
- \( b_i \) is the expected number of surveys for site \( i \), \( i=1: N_1 \)
- \( M \) is number of surveys collected
- \( N_1 \) is the number of sites that participated in the research
- \( N \) is the total number of sites that were visited without regard to whether they participated
- \( T \) is the total recruitment time

The calculation of \( T \) can be challenging. In our case, recruitment and data collection was conducted intensely from June to August 2014, and sporadically from September to November 2014, as shown in Table 3. This is a surprisingly high number.

Table 4 shows the performance of our research efforts thus far. 370 surveys were collected after initial contact with 68 sites. Eighteen of the 68 sites participated in the project. Among these 18 sites, 8 were contacted using the top-down approach and 10 sites were obtained using the bottom-up approach. The overall participation rate (\( R_1 \)) is 26.4% and the average number of surveys per site (\( R_2 \)) is 21. It is difficult to know the success rate of the top-down approach because the discussions about which sites will participate are typically internal to the corporation.
The overall ratio of actual surveys to expected surveys (R3) is 0.76 with values ranging from 0.25 to 1.5 on individual sites (Figure 3). Thirteen of 18 sites over-promised the number of surveys on their sites, with 3 of them resulting in less than 40% of the surveys anticipated. Two sites provided the exact number of surveys expected and 3 provided more than promised.

Figure 3: R3 distribution

Representativeness is to verify that the sample being collected is not biased or skewed, and is representative of the target population. It can be determined by comparing the collected data with publicly
available workforce data (Koehoorn et al. 2013). This should be checked part way through the data collection period so that adjustments can be made to correct any unintentional biases or gaps in the data.

In our case, the data were compared to Statistics Canada Ontario workforce data on age, gender, and company size. The age distribution is reasonably similar, as shown in Table 5. A higher male percentage was found in our sample. The employer size distribution is skewed to larger companies, however, and will be addressed immediately.

Completeness reflects how much of the survey has been completed by the participants, as shown in Table 6. In our case, 95% of the 370 surveys have a high degree of completeness. We believe that this high rate is due to having the research team on site to immediately respond to any questions about the survey.

3 Conclusion

There are many challenges when collecting reliable data for safety research. In addition to the data collection process itself, safety tends to be a sensitive topic associated with liability. This paper describes a framework for facilitating that process and includes many lessons learned and best practices. The
framework consists of four main parts: the organizational structure, the survey instrument, data collection, and effectiveness measures.

The survey instrument portion examined the process involved in developing a survey, including research ethics review, confidentiality issues, and participation incentives. Data collection itself is one of the most challenging activities, and some of our lessons learned are included. With respect to effectiveness, our sample shows a high completeness and representativeness of age but not for employer distribution. Recruitment time per survey is a surprisingly high 3.8 hours.

Acknowledgements

We are indebted to all of the managers, safety coordinators, and workers who participated in this study. Special thanks go to those who took extra time to share their experiences and insight. We gratefully acknowledge the funding support of Ontario’s Ministry of Labour Research Opportunities Program.

Abstract: Although mediation is a topical research topic in construction management studies, building management dispute mediation is rarely reported in academic community. This study was conducted in the light of marked increase in the number of building management dispute settled by mediation. Within the context that the parties’ behaviours during the course of the mediation would influence the outcome, the focus of the study is to examine the behaviours adopted by mediators and disputants. Data was collected with specially designed questionnaire and Relative Importance Index (RII) was used to rank the significance of the behaviours. The findings reveal that disputants often adopt aggressive approach to push their counterparts in defending their case as well as pressing for concessions. Mediators moreover, prefer establishing a trusting relationship with the disputants. In this regard, mediators seldom criticise and challenge disputants’ point of view and argument. Instead, they would attempt to establish a harmonious environment by engendering heartfelt feeling and rational understanding. Mediators would refrain from responding inappropriately to the pressing behaviours of disputants. The research findings also suggest further research in building management disputes mediation would further provide insight to the public at large in understanding how building management disputes can be settled more effectively through mediation.

1 INTRODUCTION

Hong Kong is a small place and possibly the most densely populated city in the world. Most of the Hong Kong people live in multi-storey buildings having a large number of units. The common areas of their buildings (hereafter building management) are managed collectively by the property owners. These building management tasks include, inter alia, the daily maintenance and cleaning of facilities. In addition, larger scale maintenance activities like external wall renovation are regularly conducted. However, these tasks are not straightforward in view of complicated ownership involved. Having consensus view on tender and schedule etc. is always difficult if not impossible. Collecting the necessary funds is the most daunting task. As such, lack of maintenance and indifference to common areas become the key issues of building management. Having said that, it is clear that inadequate maintenance can present risk to the public at large.

An Owners’ Corporation (OC) is usually formed to represent the interests of the owners. OC is a body corporate set up under the Building Management Ordinance (BMO) by the owners and registered with the Land Register to exercise and perform the rights, privileges and duties of the owners…. (ICAC 2010). OC can also appoint a Management Committee to oversee the building manager or property management
company responsible for building management functions. Maintaining common areas of the buildings and the improvement of facilities are normally managed by the property management company. Other regular services such as security and cleaning may further be outsourced to other specialist companies. The web of contractual relationship so established adds to the complexity in effecting the building management functions.

Despite the fact that the operation of OC can facilitate the incorporation of property owners to carry out building management functions, disputes remain common in the operation. The practice of outsourcing exaggerates the incidences of building management dispute where quality of the service providers are at stake (Chan 2009, HAD 2011). These disputes can be very complicated in terms of the relationship among the parties. For example, difficult cases often involve substantial element of human issues where the building management company, property owners and tenants are having conflicts and differences. Typical examples include the liability of the maintenance of the common areas/facilities, the payment of management fee and the building maintenance fee shared by the property owners. For the period of 2008 to 2011, the Hong Kong Judiciary has reported 1,361 building management dispute cases. Among others, 18.7% are related to maintenance funds, 6.2% involved water leakage and 15.3% are having illegal structures. It can be observed that building management issues often create disturbance to the residents one way or the other. The parties concerned may not know each other and if tenants are involved, convoluted communication is inevitable. As a result, it is not easy to identify the real causes and who should be responsible. Disputes in this connection among the owners, management companies and occupants are therefore quite common.

1.1 Mediation – A Way to Resolve Building Management Disputes

The increasing number of the building management dispute in recent years is raising concerns. The Hong Kong Judiciary is keen to streamline the settlement of these disputes through mediation so that courts' time can be saved. Mediation is considered as an effective way to resolve building management disputes. It is a sensible and economical way to handle these disputes where maintaining harmony with the community is desirable. For example, the Land Tribunal of Hong Kong introduced a pilot scheme to encourage disputing parties of building management disputes to resolve their differences by mediation. A Building Management Mediation Co-ordinator’s Office (BMMCO) was set up in January 2008 to facilitate the disputing parties in seeking mediation. Mediation is more likely to derive mutually acceptable settlement agreements that should well fit disputants who are living closely to each other. Thus, it is the preferred way of settling building management disputes than adversarial litigation (Bateson 1997; Fenn et al. 1998). The success of mediation depends on the joint efforts of mediator and disputants. Experienced mediators should be able to provide active assistance in managing time and building a harmonious atmosphere to make communication easier. With these, the chance of reaching settlement is improved. Likewise, disputants should be sincere and refrain from holding a confrontational attitude. Otherwise, reaching mutually beneficial mediation outcome is quite distant. On these notes, it is important to understand the behaviours of both mediators and disputants that would enhance the success of mediating building management disputes. Upon a literature review in this topic, it is observed that reported research studies in mediating building management disputes are very few. This study aims to fill the knowledge gap in this area in studying the behaviours of mediators and disputants. The findings should raise the awareness of the importance in promoting a climate of harmony, effective communication and encouraging cooperative behaviors in building management dispute mediation. The study is reported in the following sections: i) a comprehensive review on the behaviors of parties involved in mediating building management disputes; ii) the research methodology and data collection procedure; and iii) results and discussions.

1.2 Mediating Building Management Disputes – A Behavioral Study

As there is a lack of research on mediation for building management disputes, studies on mediation in construction, business and psychology provided valuable references to develop a framework for the study (Yiu 2006; Karim and Pegnetter 1983; Carnevale et al. 1989; Douglas 1962; Stevens 1963; Pruitt 1981; Eiseman 1977; Young 1972). Accordingly, behaviors of disputants and mediators can broadly be categorised into three groups: (1) emotion-related; (2) process-related; and (3) outcome-related. Emotion-
related behaviour is inherent in all human interaction. It is one of the key influencers in negotiation and would eventually affect the mediation process. Process-related and outcome-related behaviours are much more direct as far as the mediation process is concerned. The behaviours of disputants and mediators are listed in Tables 1 and 2 respectively.

1.2.1 Behaviours of Disputants

Five typical disputant behaviours on mediation are highlighted as follow:

1. Disputants with optimistic mindset would enhance the desire of the other to cooperate (Sebok 1993). This type of disputant tends to identify areas of agreement with the other parties, acknowledge the other parties’ perceptions and express desire to see the others to get as much of what they want as possible from mediation (Sebok 1993). Furthermore, those disputants who show concerns about future relationship would influence the mediation outcomes (Mareschal 2003). It has also been suggested that disputants might consider future relationship with the counterpart when they choose among mediation, arbitration and litigation (Madden 2001).

2. Being motivated to solve the dispute and reach a settlement are behaviours concerning motivation derived throughout the mediation process. However, there is quite a significant difference between them. Being motivated to solve the dispute refers to behaviour that the disputants are willing to solve the dispute, preferably with a settlement that will satisfy both parties. But being motivated to reach a settlement refers to behaviour that disputants only put the settlement in the first priority, with other concerns left behind, such as the satisfaction of the other party on the settlement.

3. Demonstrating behaviour of joint problem solving and effective communication is highly related to mediation success. With these behaviours, disputants would attempt to put their best effort to exchange ideas and come up with a settlement. As suggested by Zubek (1992), these can be achieved by cooperating to seek a settlement that meets mutual needs. Alternatively, one party would make his/her own effort in seeking for possible solutions, and then work on a solution that would satisfy both parties’ interest. The latter has proven to be able to enhance the likelihood of mediation success (Zubek 1992). Similar effect would be given if effective communication, which increases the exchange of idea and information, exists in the course of mediation (Zariski 2010).

4. According to Sebok (1993), demonstrating behaviours of paying attention to others would imply that disputant has been listening attentively, indicating that the other party ‘has a good point’ when he
makes a point you believe has merit. This type of behaviour demonstrates a real participation in mediation, and would enhance the overall mediation process.

1.2.2 Behaviours of Mediators

Mediators play an important role to steer a successful outcome (Goldberg 2005, Goldberg 2007, Stulberg 1997). Similar to the classification of the disputant behaviours, three types of mediator behaviours, emotion-related, process-related and out-outcome related behaviours are applied. From the perspective of mediators, emotion-related behaviours refer to those that will influence the emotions of the disputants. This type of behaviour such as showing empathy, applying pressure, building rapport, gaining trust, encouraging jointly solving of the dispute, and giving “face” to disputants would lead to a change of emotions of the disputants. These are the demonstrations of concern and perspective taking (Zubek 1992). The mediator is concerned about the interest of either party, and through verbal or nonverbal actions, expressed this concern so that disputants’ interests in all aspects will be taken good care of (Zubek 1992). These behaviours will lead to both parties’ interests becoming aware in the mediation, so it is suggested that it will benefit the mediation process. Furthermore, demonstrating these behaviours would reduce tension between the disputants, and make the mediation progress easier from a psychological aspect. Similarly, the mediator can demonstrate process-related behaviours to affect the mediation process. These include showing professional knowledge, criticizing disputants’ arguments, challenging disputants’ points, maintaining the order of mediation, bringing up unaware issues, listening to disputants effectively, facilitating understanding of disputants, promoting exchange of ideas, and avoiding social conflict between disputants. The influence of mediator is always critical to the mediation process. Mediator is appointed because his background is relevant to the subject matter of the disputes, and he does possess a high reputation for his expert knowledge. Finally, a mediator quite often adopts outcome-related behaviours in the course of mediation in facilitating settlement formulation. These include suggesting solution, introducing the consequences of not being settled, and developing a plan for settlement.

2 METHODOLOGY

This section presents the steps performed to study the behaviours of mediators and disputants in the process of mediating building management disputes. These include questionnaire design and data collection procedures and data analysis procedures.

Questionnaire Design and Data Collection Procedures.

A questionnaire has been designed to identify the disputant and mediator behaviours in mediating building management disputes. As such, the target respondents of this questionnaire survey are the disputants or mediators of building management disputes. They were invited to participate in this questionnaire survey. If the respondent is the disputant (or mediator), he is required to evaluate his own behaviour, and evaluate the mediator’s (or disputant’s) behaviours as listed in Tables 1 and 2. A Likert scale of 1 (least occurred) to 7 (most occurred) was adopted.

Data Analysis Procedures

The 7-point Likert scale described previously were combined and converted into Relative Importance Indices (RIIs) for each identified behaviours, the use of RII can determine the relative rankings of different behaviours by comparing the individual relative importance indices for different behaviours (Shash 1993, Kometa, et al. 1994 and Chan et al. 2002). The individual numerical ratings were therefore transformed to RIIs by the following formula:
3 RESULTS AND DISCUSSIONS

A total of 53 respondents participated in this questionnaire survey. With the RII technique, the overall RIIs can be calculated for the adoptions of each behaviour (Figures 1 and 2 refers). Examining the indices, it is observed that the top-three disputants’ behaviours are ‘D-EB3: Tend to argue with other parties’, ‘D_PB5: Defending himself for every argument raised’ and ‘D_PB3: Actively communicating with other parties’. ‘Tend to argue’ can be considered as a contending behaviour. It is a strategy to push counterpart in the direction of one’s wishes (Carnevale 1992). This behaviour would usually bring an agreement at the end of negotiation. The party with forceful use of contentious behaviour will be favoured. However, this behaviour would discourage joint efforts from both parties. Being defensive is one of the key features when building management disputes are mediated, disputants often express their point of view to exclude liabilities (e.g. water leakage problems). Most of the disputants aim to take the high ground in order to take advantage in the settlement terms. In this study, it is found that the low-ranking disputants’ behaviour is ‘D_PB6: Suspecting the mediator’, implying that most disputants have confidence in their mediators. This may be due to the fact that the mediators are often jointly appointed by the disputant themselves. Trust can be hence maintained.

![Figure 1: Results of RII - Disputants’ behaviours](image)

Regarding mediators’ behaviours, the top-three mediators’ behaviours are ‘M-PB7: Facilitating understanding of disputants’, ‘M_PB6: Effectively listening to disputants’ and ‘M_PB8: Promoting exchange of ideas’. These behaviours are inter-related in the sense that effective listening promotes...
communication, exchange of ideas, and enhances understanding among disputants. Moreover, these behaviours would be deemed to be ‘paying attention to the others’ words (Sebok 1993). They are conveying that the disputant has been listening attentively, indicating that the other party “has a good point” when he makes a point you believe has merit. All these behaviours mean a real participation to the mediation, and both parties will have to make an effort to solve the dispute, preferably with a settlement satisfying both parties. These findings suggest that mediators are well connected with the disputants at the level of heartfelt feeling as well as rational understanding. Promoting the exchange of ideas is a positive mediator’s behaviour. This enables the disputants to understand the way of thinking of the other side, and facilitates the generation of new ideas based on what others had been suggested or raised. Zubek (1992) suggested that challenging disputant would encourage him to think about the issues, and stimulates him to look over the unaware issues in their arguments.

Unsurprisingly, the mediators' behaviours, ‘M_PB2: Criticising disputants’ argument’ and ‘M_PB3-Challenging disputants’ point’, are low-ranked in this study. Criticizing other’s idea is always not a smart tactic, as this will upset the disputants. Disputants will be dissatisfied when they were criticized (Zubek 1992). For example, asking embarrassing questions, a more subtle form of criticism, would be negatively related to goal achievement (Zubek 1992). Therefore, the behaviour of criticizing disputants’ argument would inhibit mediation success.

4 CONCLUDING REMARKS

Building management disputes have become one of the major sources of disputes in Hong Kong Building Sector. In this study, a questionnaire survey was conducted to investigate the behaviours of disputants and mediators in building management dispute mediations. Relative Importance Indices were used to rank the importance of behaviours identified from a literature review. It was found that disputants often adopt an aggressive approach to press for concession, while mediators would try to establish a trusting relationship with the disputants by showing heartfelt feeling and rational understanding. This can cultivate a harmonious environment that is conducive for richer information exchange. It is also found that disputants seldom challenge the mediators. Furthermore, this study reveals that mediators would refrain from criticising the argument raised by the disputants. Instead, they prefer to engender a harmonious
environment whereby he would not be pushed to respond inappropriately. Using an inappropriate strategy would invite pressing behaviours of disputants. The research findings of this study are of significant value to the public to understand how mediation works in settling building management disputes.

A MULTI-PERSPECTIVE ASSESSMENT METHOD FOR MEASURING LEADING INDICATORS IN CAPITAL PROJECT BENCHMARKING

Abstract: This paper presents a new multi-perspective assessment method for measuring leading indicators deployed in the 10-10 Performance Assessment System that the Construction Industry Institute (CII) has recently launched. The CII 10-10 Performance Assessment System adopted a multi-perspective assessment approach for evaluating leading indicators that represent various management input measures throughout capital project delivery process. The leading indicators consist of 10 input measures, including four fundamental management functions such as planning, organizing, leading, and controlling as well as major management practices such as design efficiency, human resources, quality, sustainability, supply chain, and safety. This paper provides the theoretical background for the method through extensive review of existing benchmarking theories. Then it describes the development process for the assessment method. After this, it presents how the method was deployed to evaluate the system’s 10 leading indicators. Finally, this paper discusses how to practically utilize the input measure scores acquired from the method for performance improvement. The assessment method in the system will help project management teams to diagnose their project’s performances and thus allow them to set up proactive strategies for the subsequent phases of the project.

1 INTRODUCTION

Since 1996, Construction Industry Institute (CII) has initiated various industry specific performance assessment programs in order to reliably measure an organization’s performance against recognized leaders for the purpose of determining best practices that lead to better performance (CII 2015). As a big data repository of capital projects in the construction industry across the world, the CII Performance Assessment database has been used for benchmarking of capital projects collected from the CII member companies and various research efforts such as project planning (Gibson et al. 2006) and impact of technology use on project performance (Kang et al. 2013). The CII 10-10 Performance Assessment Program (the 10-10 Program), as the newest initiative, builds on this legacy by providing the industry with a benchmarked set of leading indicators for several project types and industry sectors (CII 2014a). All CII research studies and the existing CII Performance Assessment surveys were investigated in developing the questionnaires. Moreover, extensive industry experts’ inputs were also reflected on the 10-10 Program, which was acquired from a number of CII activities and events held from 2012 to 2014 such as CII’s Board of Advisors (BoA) meetings, CII Performance Assessment Community of Practice (PACOP) and CII Performance Assessment Workshop (PAW). The knowledge from industry expertise and previous academic researches thus forms the basis of the program.
There are three different sets of industry specific questionnaires in the 10-10 Program. Each set consists of five phase level questionnaires, which are front end planning (or programming), engineering (or design), procurement, construction, and startup (or commissioning). Thus, the 10-10 Program was designed to collect capital project data by project phase instead of at project closeout when previous performance assessment programs are typically conducted (CII 2014b). Notably, the 10-10 Program was developed to survey members of a project’s management team regarding their project's performance, team dynamics, and organizational relationships (Kang et al. 2014). Since 10-10 surveys by phase using simple statement-based questions, 10 leading indicators (i.e., input measures) are obtained throughout a project’s development, which can identify projects’ impending problems. On the other hand, 10 output measures (i.e., lagging indicators) is to provide certainty that the project is proceeding on target through various metrics related to cost, schedule, capacity, quantity, and safety. Together, these measures are the basis of the new program’s name of 10-10 (CII 2014b).

For the input measure section, the 10-10 Program adopted a multi-perspective assessment approach for evaluating leading indicators that represent various management efforts throughout capital project delivery process. The input measures consist of 10 leading indicators including four fundamental management functions such as planning, organizing, leading, and controlling as well as major management practices such as design efficiency, human resources, quality, sustainability, supply chain, and safety. Accordingly, questions in the input measure section are used to measure 10 scores representing 10 leading indicators so that they can be compared with the other similar projects. However, a structured process is required in order to obtain and benchmark the 10 input measures in an appropriate manner. This paper provides the theoretical background for the multi-perspective assessment method through extensive review of existing benchmarking theories. It then describes the development process for the assessment method.

2 RESEARCH BACKGROUND

One of critical issues in contemporary benchmarking is the lack of information supporting project decisions and influencing on project performance during project planning and execution (Kang et al. 2014). As project data is submitted to CII performance assessment database after completion of projects, the outcomes of benchmarking cannot directly benefit the projects being benchmarked. Rather, the results are typically used for their future projects. The fact motivated CII to develop a new program for gathering the information supporting project decisions and influencing on capital project performance through comprehensive review on references from academia and industry.

At the outset, CII benchmarking legacies were thoroughly reviewed including CII’s research publications (CII 1987, CII 1989, CII 1997, CII 2006a, CII 2006b, CII 2006c, CII 2008, CII 2010, CII 2010d, CII 2011b), implementation tools (CII 1995, CII 2003a, CII 2003b, CII 2011c), and survey instruments (CII 2011a, CII 2012a; CII 2012c). All existing survey questions created to capture the extent of implementation of CII best practices, which are defined as a process and method that leads to enhanced project performance when executed effectively, are thoroughly investigated (CII 2015).

Also, research results on performance assessment and benchmarking conducted in academia were reviewed (Kasunic 2008, Zhang 2005, Yu et al. 2005). In addition to that, survey instruments for the performance assessment developed by industrial practitioners were examined. Once the draft of the questionnaires were first generated from these multiple sources, questions were expanded, filtered, and combined later by industry practitioners’ expertise collected at several CII events and activities (Kang et al. 2014). Upon the completion of the questionnaires, the 10-10 Program intends to assess capital project performance by phase so that a capital project can identify if the project is properly positioned for success in that specific phase, as well as in subsequent phase (CII 2014a).

3 METHOD FOR MEASURING LEADING INDICATORS

Leading indicators are defined as the measurements of processes, activities, and conditions that define performance and can predict future results (CII 2012b). Moreover, leading indicators allow for proactive
management to impact project outcomes, revealed in a timely manner (CII 2006b). After thorough reviews on publications, tools, and survey instruments developed by CII, academia, and industry, the selected questions were organized and classified by leading indicators, which can be utilized during project planning and execution. Each leading indicator has linkage with potential CII resources for improvement of project performance (CII 2013). For example, when the organizing score of a project is low, this situation can be improved by looking at its linkage to applicable best practices and resources. This linkage will soon help the project identify which implementation resources should be considered for improvement (CII 2013). Among 10 leading indicators, planning, organizing, leading, and controlling have long been recognized as core management functions in a business organization (Tsoukas 1994). The other leading indicators have been accepted by the literature review and industry experts’ feedbacks (Kang et al. 2014). The first focus of this research was to define each of the 10 input measures so that each of the questions in the input measure section were grouped into the leading indicators with regard to industry group and phase. Figure 1 illustrates 10 leading indicators designed to perform a multi-perspective assessment framework for capital project benchmarking by industry group and phase.

Figure 1. Multi-Perspective Assessment Framework in the 10-10 Program

The 10 leading indicators are defined as below:

- Planning is the work a manager performs to predetermine a course of action. The function of planning includes the activities such as forecasting, objective setting, program development, scheduling, budgeting, and policies and procedures development.
- Organizing is the work a manager performs to arrange and relate the work to be done so people can perform it most effectively. The function of organizing includes the activities such as development of organization structure, delegation of responsibility and authority, and establishment of relationships.
- Leading is the work a manager performs to cause people to take effective action. The activities involved in the function of leading include decision-making, communications, motivation, selection of people, and development of people.
- Controlling is the work a manager performs to assess and regulate work in progress and completed. Management controls are achieved through the activities such as establishment of performance standards, measurement of performance, evaluation of performance, and correction of performance.
- Design Efficiency measures if the project team is exhausting all techniques to optimize the design in its use of material quantities to provide maximum capacity at minimum cost.
- Human Resources examines if the project is staffed correctly, with a minimum amount of staff turnover and appropriate training, and measures if people are capable of achieving project goals.
• Quality measures if the project team is strictly conforming to project requirements. Analyzes if programs are pursued to assure the delivery of material goods as intended.
• Sustainability evaluates steps taken by the project team to reduce the environmental impact of the project during construction and operation.
• Supply Chain examines the strategies used by the project team to promote enhanced working relationships amongst all project stakeholders including those in the project supply chain.
• Safety measures the practices followed by the project team to eliminate any possibility of personal injury or property damage on the project.

In order to effectively measure these 10 leading indicators as the multi-perspective assessment for capital project benchmarking, the 10-10 Program was designed to obtain the input measures by asking various types of questions that include yes/no, single/multiple selections, numeric open-ended, and Likert response scale from ‘strongly agree’ to ‘strongly disagree’ as presented in Figure 2. Fifteen 10-10 questionnaires have different numbers and types of questions so that they can measure phase- and industry-specific project performances.

Figure 2: Example of Types of Questions in the CII 10-10 Input Measures

Significantly, most questions in the input measure section were structured to be subjective on purpose. This approach makes respondents to invest less effort in data entry than when asked for real values that need additional effort to search and gather information such as actual project cost, duration, or number of cases (CII 2013). Often, statement-based assessment is criticized because of the presence of inconsistency in responses due to respondents’ subjective perceptions. For this reason, the 10-10 Program was designed to assess input measures by various members of the project’s management team (Kang et al. 2014). When numerous responses from a single project are collected, inconsistencies expected to be effectively reduced (CII 2013). Moreover, the assessment by multiple responses for a project benefits to identify what extent project’s team members are aligned during a project planning and execution (Kang et al. 2014).

The 10-10 Program can evaluate the level of managerial efforts for a capital project committed to implementing attributes of each leading indicator through a single representative value and compare the project with similar projects. These leading indicators then can be used for industry practitioners to identify where opportunities for improvement exist in the subsequent phases or next projects. A detailed procedure for quantifying the 10 leading indicators was established. The procedure can be applied to all industry groups and project phases as shown in Figure 3. The calculation procedure consists of four major steps; 1) score calculation of individual input measure question, 2) weighted score calculation, 3) aggregation of the weighted individual input measure scores, and 4) normalization of the aggregated input measure scores.
Score calculation of individual questions is first conducted by referring to point values defined according to each respondent’s answer for the input measure questions. From there, weights are reflected on the score with consideration of different impact of the question on the relevant leading indicator(s). Weighted scores are then aggregated to produce a single value representing the leading indicator score. Considerable effort of the research was made for the weight determination and question classification within leading indicators that each question impacts substantially on. Finally, the weighted score is normalized to a total of 100. The developed method and calculation procedures were reviewed and confirmed based on industry experts collected at several CII activities and event in 2013 and 2014. Each of the steps presented in Figure 3 is explained in detail as follows.

3.1 Score Calculation

As the first effort for developing the procedure, point values are defined for each question with regard to the question types and selections of respondents. The point values allow obtaining certain numeric values for further assessment analyses. It should be noted that statements of all questions are designed to measure positive impact of the leading indicators, which means that tendency to choose ‘agree’ or ‘yes’ for statements indicates high degree of effort or better implementation of certain practices represented in each question. It is also noteworthy that maximum point values of each question are five for all questions in the input measure section. For yes/no type questions, yes is converted into 5 points while 0 points for no. Taking over 70% of the input measure questions, Likert-scale questions uses five-point scales and are converted into points as presented in Table 2. In order for negative effort to get penalty, strongly disagree, disagree, and neutral are converted into 0, 1, and 2 respectively, rather than using scale ranging from 1 to 3 that applied to five point scales in general.
Table 1: A Five-point Scales Used for the Likert-scale Question

<table>
<thead>
<tr>
<th>Scale</th>
<th>Strongly Disagree</th>
<th>Disagree</th>
<th>Neutral</th>
<th>Agree</th>
<th>Strongly Agree</th>
</tr>
</thead>
<tbody>
<tr>
<td>Point</td>
<td>0</td>
<td>1</td>
<td>2</td>
<td>4</td>
<td>5</td>
</tr>
</tbody>
</table>

Differing from single choice questions such as yes/no and Likert-scale, multiple selection questions requires diverse point scales as positive and negative statements are mix-provided for the selection. Accordingly, positive and negative statements in the multiple choice questions are coded as negative and positive scales respectively, considering relative influence of statements in a given question. Again, the 10-10 Program surveys multiple project team members from a project. To mitigate inconsistencies and take a representative single score for the project, average scores are used to measure the level of implementation described in each question. Accordingly, the sum of point values acquired from multiple responses of a single project is divided by the number of the participants to evaluate the average score. Missing data is ignored when calculating the score, which indicates that the score is produced by measuring a project's average score for the variable for which respondents in the project have provided answers (De Vaus 2001). However, in case that nobody answers to a question, the point value for the question is recorded as zero based on the assumption that the project did not perform practice or implementation asked by the question.

### 3.2 Weighting and Aggregation of Individual Score

Answers on certain questions might have more negative or positive impacts on one or more input measures than those on the other questions might have. Weights were thus considered to address relative difference in influence of questions on the input measures. Additionally, in order to generate and then benchmark single scores of each leading indicator, each input measure question needs to be grouped into relevant leading indicator(s). Determining weights and classifying questions into 10 leading indicators were conducted simultaneously. To facilitate the process, all questions and 10 leading indicators were listed on a single column and a row in a spreadsheet in a matrix table according to phase and industry group. From there, industry experts' inputs were collected at CII activities and events in 2013 and 2014. Each participant provided opinion regarding relationship between questions and 10 leading indicators with relative strength of each relationship. Based on these feedbacks from the industry experts, the weights and linkage between questions and leading indicators finally were determined. The weights are used to calculate weighted individual question score by multiplying the score and weight. Thereafter, the weighted scores are aggregated in order to produce a single value.

### 3.3 Normalized Scores and Report

While the total weighted score can be used for benchmarking, it is hard to understand the exact implementation level of input measure without normalization. This is because different number of questions and weights were used for generating total weighted score of each leading indicator. Hence, each leading indicator has different scale by phase and industry group. In order to adjust total weighted score measured by different scale to a common scale, score adjustment is conducted so that the total weighted scores are normalized to a total of 100. The normalized scores of leading indicators are obtained by dividing total weighted score by the weights used for calculation in the total weighted score.

As a final score of each leading indicator ranges from 0% to 100%, high scores close to 100% represents a better implementation of relevant leading indicator than those of low scores. For the benchmarking purpose, the distribution of leading indicator scores of similar projects is necessary and the final score will be indicated in the distribution. To remove the scores differing greatly from the majority of a set of the other projects' scores, values excluding extreme outlying scores are only considered in the charts. Since the program is based on project phase, comparisons are made at the industry group and phase level. When necessary, further comparison can be made by secondarily respondent and project type. The difference in processes and characteristics of project and respondent types suggests that appropriate grouping is crucial for performance comparison (Hwang et al. 2007). The distributions of 10 leading indicators are illustrated by quartile information within comparison group. The fourth quartile is composed
of the 25% of the projects with the high input measure scores and the first quartile is populated with the 25% with the low scores. Result of a project is marked with a black dot within the quartile it belongs to. Through the information, projects can easily identify leading indicators they need to improve.

3.4 Case Study

To present how the 10-10 input measure report can be interpreted, a sample report was generated based on responses having collected from one of chemical manufacturing projects. Five project team members of the project responded the engineering phase of industrial projects’ 10-10 questionnaire. Score distributions of leading indicators in Figure 4 are presented within those of the other chemical manufacturing projects among all projects participated the engineering phase of industrial questionnaires. Thus, sample size (n), min (minimum), max (maximum), 1Q, 2Q, and 3Q (quartile) in the report are calculated by the scores of the similar project in terms of industry sector, phase, and project type. As can be seen in Figure 4, six leading indicators are placed in the fourth quartile. However, design efficiency, human resources, sustainability, and supply chain are located in the first or third quartiles. In particular, it appears that design efficiency in the engineering phase was poorly implemented rather than the other projects and it should be improved for the subsequent phases such as construction or procurement phases. Also, the project team needs to take attention on human resources, sustainability, and supply chain which is still better not the best in comparison to the other similar projects. To improve the situation, the project is recommended to implement relevant CII best practices and tools in order to enhance project performance and importantly, linkages between 10-10 leading indicators and CII resources can help the project to easily find which implementation resources should be considered for improvement (CII 2013).

![Figure 4: The Input Measure Report of the Case Project](image)
Although extreme outlying scores were already removed, relatively larger variations of supply chain and sustainability scores are identified in Figure 4. This fact indicates that management levels of the two areas have large deviations among chemical manufacturing projects during engineering phase. It implies that management skills and practices concerning supply chain and sustainability have not been well established in the chemical manufacturing projects.

4 CONCLUSION AND PATH FORWARD

The CII 10-10 Program adopted a multi-perspective assessment approach for evaluating leading indicators that represent various management input measures throughout capital project delivery process. The purpose of the study described in this paper was to develop a new assessment method for 10 leading indicators deployed in the 10-10 Program for benchmarking. To achieve this goal, attempts to transfer respondent’s answer to numeric values were made and score awarding criteria were developed. The concepts of 10 leading indicators are then defined. From there, each individual question was classified into 10 leading indicator(s) and weights of questions were determined with regard to the question’s level of influence on related leading indicator(s). Using the determined values, the study presented how to produce a representative single score of a leading indicator and how to report the outcomes with the most similar projects submitted to the 10-10 Program database. When necessary, projects are grouped by respondent and respondent types for performance comparison through leading indicators because project and respondent types involve highly different processes and characteristics of projects.

The method was developed based on a wide range of literature review as well as industry experts’ knowledge acquired from the CII events. The finding of this research is meaningful leading indicators can be evaluated and should be of significant value for capital projects performance assessment. Since 10-10 surveys by phase using simple questions, 10 leading indicators can be gathered throughout a project execution that can help projects to identify impending problems. More importantly, as established 10 input measures are based on the CII’s knowledge areas utilized during project execution and thus benchmarking outcomes direct the projects to easily find CII resources for mitigation of issues which projects can refer to.

For the future studies on the topic, continuous modification of the method should be considered with more data analyses. As data accumulate, more detailed validation on the accuracy of established assessment method will be possible. Also, the 10-10 Program questionnaires will be updated whenever required to ensure that they reliably measure the right leading indicators of all types of capital projects. Additionally, the relationship between input measure scores and output measure metrics in the 10-10 Program needs to be thoroughly examined. The finding can provide projects with which leading indicator should be conducted well to achieve better specific outcomes. For example, supply chain measure might have significant impacts on schedule performance in the procurement phase. In this case, project driven by schedule should focus on better supply chain measures. Overall, the developed method is expected to help project management teams clearly understand how their projects’ leading indicators are measured and also enable them to diagnose their project’s performances. Finally, it is strongly believed that the outcomes will allow them to set up proactive strategies for the subsequent phases of the project.

Abstract: The effectiveness and competitive advantage of an organization/project can be enhanced when its members possess an understanding, respect, acceptance, and capacity to manage cross-cultural differences. Ignoring or failing to manage such differences may lead to many problems in the project (e.g., project delays and productivity decrease). In fact, international/transnational projects involving participants from diverse political, legal, economic, and cultural backgrounds are on the rise. Hence, firms should be cross-culturally competent and capable of managing in contrasting cultural factors. However, a recent study conducted in 2013 by the Construction Industry Institute (CII) reported that one of the major concerns of construction professionals is a widespread lack of understanding of foreign cultures, ethnicities, and languages. The aim of this paper is to present a comprehensive review of the literature on cultural aspects in the construction industry so as to identify the knowledge gaps and to suggest recommendations for future research. To do so, the authors have identified and compared major studies on cultural factors. From the comparison, the authors have identified the categories that are considered the most central to understanding cultural differences; they are, “group attachment and relations,” “authority and status,” “uncertainty and rules,” “gender roles and assertiveness,” and “time and future orientation.” The authors also summarize the current research topics in culture in construction and recommend ideas for future research into culture as it pertains to a construction context.

1 INTRODUCTION

Globalization has led to construction companies performing more work around the globe. As the construction industry globalizes, it is becoming increasingly important to understand the impact of cultural and linguistic differences on performance (Comu, Unsal, and Taylor 2011). The emergence of more international/transnational projects has given rise to the involvement of participants from diverse political, legal, economic, and cultural backgrounds. Consequently, scholars are focusing on understanding the less tangible management aspects of construction projects, such as building trust and an organizational culture. Managing organizations and projects and handling dispute negotiation involves individuals and their beliefs, so cultural differences have a significant influence on management success (Hofstede 1983). This is in addition to the environment of the host country, which has an effect on the operation of the construction project. Thus, for contracting parties to function effectively, it is critical that they be aware of others’ expectations and priorities (Chan and Tse 2003).
Understanding, respecting, accepting, and managing cross cultural differences effectively in construction projects can enhance the organization/project’s effectiveness and provide a competitive advantage, while ignoring or failing to manage cultural differences may lead to many problems in the project, such as project delays and decreases in productivity (Kivrak, Ross, and Arslan 2008). Arising from a failure to properly manage cultural differences are such problems as expatriates’ culture shock, unfamiliar local work style, different negotiation style, different professional standards and construction codes, and codes of conduct and ethical standards (bribery and corruption), causing many ethical and moral dilemmas (Hall and Jaggar 1997). However, a recent study conducted by the Construction Industry Institute (CII) (2013) reported that one of the major concerns of construction professionals is the lack of understanding of foreign cultures, ethics, and languages. Thus, there is a need to study and better understand culture in construction.

The aim of this paper is: 1) to present a comprehensive literature review on cultural aspects in the construction industry, and 2) to identify the knowledge gaps and suggest recommendations for future research. After addressing its research methodology, this paper presents the findings from the literature review on culture on construction projects. The findings include 1) definitions of culture, 2) cultural factors, and 3) research on culture. Later, the paper summarizes, in the Conclusions and Recommendations section, what was learned from the analysis and recommendations for future research.

2 RESEARCH METHODOLOGY

This study was conducted through four steps: 1) obtaining and screening the literature, 2) identifying major studies on cultural factors and comparing them, 3) summarizing the current research topics in culture in construction, and 4) identifying the gaps of knowledge and proposing recommendations for future research. First, the literature was obtained from peer-reviewed publications (journal articles or conference proceedings) on culture and on organizational cultures in construction. The authors reviewed and analyzed over 60 peer-reviewed publications from major construction engineering and management journals, including the American Society of Civil Engineers (ASCE) Journal of Construction Engineering and Management, the Journal of Management in Engineering, Computing in Civil and Building Engineering, and the International Journal of Management in Engineering. The authors screened the literature unrelated to construction since the wide-ranging topic of culture is addressed in a variety of disciplines. This literature review, conducted between 2013 and 2014, covered studies published between 1983 and 2014. Although the review is not exhaustive, it provides a comprehensive basis for understanding culture and organizational culture in construction.

Second, to get a firm grasp on the two topics, the authors defined culture and organizational culture. Based on the aforementioned literature review, the authors identified, summarized, and compared four of the most remarkable and most commonly referenced studies that introduced cultural factors—Hofstede (1983), Trompenaars and Woolliams (1999), Schwartz (2004), and Brodbeck, Chhokar, and House (2007). From the comparison analysis, the authors identified the five categories most central to understanding cultural differences.

Third, the authors identified and summarized current research topics on culture in construction. Those are 1) cultural factors and differences, 2) organizational culture, 3) culture diversity and its impact, and 4) culture effect on contractual arrangements. This step was needed to identify the knowledge gaps and suggest recommendations for future research. Based on these findings, the authors provide recommendations for future research in the Conclusions and Recommendations section.

3 CULTURE

Many scholars consider culture to be one of the major issues affecting the management of international construction projects. The contextual environment of the host country greatly impacts the operation of the construction project. Thus, to be able to function effectively, it has become important for professionals involved in international projects with participants from different cultural backgrounds to comprehend others’ expectations and beliefs (Chan and Tse 2003; Hall and Jaggar 1997). However, this
comprehension seems to be somewhat limited in the construction industry (Hall and Jaggar 1997). Before the authors move into presenting the current research topics on culture in construction, it is important to start by introducing the definition and factors of culture as agreed upon by many scholars.

3.1 Defining Culture and Organization Culture

According to many scholars, one of the most complicated words in the English language is culture, as it touches on many topics and processes. Complex and divergent in its applications (Hall and Jaggar 1997), the word is defined differently, according to the research field where it is studied. Culture describes the social system that a group of people create in which they share common rules, norms, values, beliefs, perspectives, practices, and rituals (Chan and Tse 2003). In the construction industry, culture is about “the characteristics of the industry, approaches to construction, competence of people, and the goals, values and strategies of the organizations they work in” (Kivrak, Ross, and Arslan 2008).

The dictionary (Guralnik and Friend 1960) defines organization culture as “the integrated pattern of human behavior that includes thought, speech, action, and artifacts and depends on man's capacity for learning and transmitting knowledge to succeeding generations.” Three of the many definitions of organizational culture found in the literature are as follows: 1) “A pattern of basic assumptions invented, discovered or developed by a given group as it learns to cope with its problems of external adaptation and internal integration that has worked well enough to be considered valid and to be taught to new members as the correct way to perceive, think and feel in relation to these problems” (Schein 2010). 2) “An organization’s culture reflects assumptions about clients, employees’ mission, products activities and assumptions that have worked well in the past and which get translated into norms of behavior and expectations about what is legitimate, desirable ways of thinking and acting” (Laurent 1983). 3) “The values and beliefs that govern behavior in an organization” (Maloney and Federle 1991).

3.2 Cultural Factors

The literature review revealed a plethora of culture-type categorizations. For example, Wallach (1983) categorized culture organizations as bureaucratic, innovative, and supportive; Liu, Shuibo, and Meiyung (2006) categorized organizational culture in terms of risk-taking and power centralization. Culture type was also categorized in terms of factors or dimensions. These factors map the cultural differences in terms of values and practices embraced by the organization (Ankrah and Langford 2005; Liu, Shuibo, and Meiyung 2006). The defined factors (dimensions) form a continuum that allows a framework for analysis and management of cultural differences (Hall and Jaggar 1997).

3.2.1 Four Major Studies on Cultural Factors

Four of the most remarkable and most commonly referenced studies that introduce cultural factors (or “dimensions” as Hofstede and several other scholars often used this term) are Hofstede (1983), Trompenaars and Woolliams (1999), Schwartz (2004), and Brodbeck, Chhokar, and House (2007). First, Hofstede (1983), by studying the national cultures of 50 countries, introduced culture’s four independent factors: 1) individualism/collectivism, 2) power distance, 3) uncertainty avoidance, and 4) masculinity/femininity. Hofstede’s factors are considered the most extensively used in many management and organizational behavior studies. Smith (2006) referred to Hofstede’s factors as being a decades-long landmark for subsequent researchers.

Second, Trompenaars and Woolliams (1999) studied 40 countries to explore how every culture determines the solution to problems arising from relationships with other people, the passage of time, and from the environment. They identified how values differ between cultures, grouping them into seven factors—1) universalism-particularism, 2) individualism-communitarianism, 3) diffuse-specific, 4) affective-neutral, 5) achievement-ascription, 6) attitudes to the environment, and 7) attitudes to time (Trompenaars and Woolliams 1999). According to Trompenaars and Woolliams (1999), every culture distinguishes itself from others by the solutions it chooses to certain problems.
Third, based on data collected from many countries, Schwartz (2004) defined three bipolar cultural factors that represent alternative solutions to three main problems confronting all societies. The factors are 1) embeddedness versus autonomy, 2) hierarchy versus egalitarianism, and 3) mastery versus harmony.

Last, the Global Leadership and Organizational Behavior Effectiveness (GLOBE) Research Program conducted a study over 11 years on 1,000 organizations in 62 countries to investigate cultural factors that affect leadership and organizational practices (Brodbeck, Chhokar, and House 2007). These researchers grouped the 62 societies into 10 societal clusters. They established nine cultural factors that make it possible to capture the similarities and/or differences in norms, values, beliefs, and practices among different societies.

Other miscellaneous factors proposed by other researchers include: unemotionality, depersonization, subordination, conservatism, isolationism, and antipathy; holographic and ideographic; constructive, passive/defensive and aggressive/defensive; involvement, consistency, adaptability and mission; organizational values, task organization, organizational climate and employee attitudes; leadership, structure, innovation, job performance, planning, communication, environment, humanistic workplace, development of individual and socialization on entry; time, space, human relationships, human activities, and human nature (Ankrah and Langford 2005; Liu, Shuibo, and Meiyung 2006).

3.2.2 Comparison between the Four Studies on Cultural Factors

A comparison of the four studies summarized above shows that certain factors are central to understanding cultural differences (Table 1). These factors have been grouped here into seven categories based on similarity. Those are: 1) “group attachment and relations,” 2) “authority and status,” 3) “uncertainty and rules,” 4) “gender roles and assertiveness,” 5) “time and future orientation,” 6) “emotions,” and 7) “caring for others.” The comparison revealed that the first three categories were covered by all four studies, the fourth through sixth categories were covered by three studies, the fifth was covered by two studies, and the sixth and seventh were covered by one study each.
The first category “group attachment and relations,” dealing with group versus individual, was addressed by all four studies and enjoyed the greatest popularity in cross-cultural studies. Brodbeck, Chhokar, and House (2007) divided this category into two sub-factors—one concerned with the institution and the other with the in-group collectivism. The second category “authority and status accorded,” which deals with unequal distribution of power and how success is achieved, was also addressed by all four studies. Brodbeck, Chhokar, and House (2007) addressed “power distance” in one factor that deals with how power is equally distributed and addressed the “status accorded” in the “performance orientation” factor that deals with how performance and excellence are encouraged. Trompenaars and Woolliams (1999) addressed the willingness to accept power distances, which the authors partially reflected in this category, in the “achievement/ascription” factor.

All four studies discussed the third category “uncertainty and rules,” which deals with uncertainties and setting rules to regulate them. Hofstede (1983), Trompenaars and Woolliams (1999), and Brodbeck, Chhokar, and House (2007) all addressed uncertainty and the significance of rules, while Schwartz (2004) dealt with managing uncertainty only.

The fourth category “gender roles and assertiveness” was discussed by three studies—Hofstede (1983), Trompenaars and Woolliams (1999), and Brodbeck, Chhokar, and House (2007). The authors located Trompenaars and Woolliams’ (1999) “specific/diffuse” factor under the assertive category as it is related to masculinity and femininity where masculinity is more assertive and aggressive (facts) versus the more caring (relationship) femininity.

The fifth category of “time and future orientation” was discussed also by three studies—Hofstede (1983), Trompenaars and Woolliams (1999), and Brodbeck, Chhokar, and House (2007). However, their view of time seems somehow different. While Hofstede (1983) and Brodbeck, Chhokar, and House (2007) viewed the time aspect in terms of how people plan their future, look at their present and past, Trompenaars and Woolliams (1999) dealt with specific events and tasks relative to time. The last two
factors, covered by one study each, are 1) “emotions” - the affective/neutral by Trompenaars and Woolliams (1999) and 2) “caring for others” - the humane-orientation by Brodbeck, Chhokar, and House (2007).

From the comparison above, this paper identifies five categories most central to understanding cultural differences. These five deal with "group attachment and relations," “authority and status," “uncertainty and rules," "gender roles and assertiveness," and "time and future orientation."

### 3.3 Research in Culture in Construction

The current research topics on culture in construction are identified and summarized to identify the knowledge gaps and suggest recommendations for future research. Those topics are: 1) cultural factors and differences, 2) organizational culture, 3) culture diversity and its impact, and 4) culture effect on contractual arrangements. The corresponding researchers, presented in Table 2, are categorized by research topic.

#### 3.3.1 Cultural Factors and Differences

Several studies on different cultures were identified. Horii, Levitt, and Jin (2005) examined and characterized cultural differences into two factors: cultural values and cultural practices. The former refers to an individual’s preferences in decision making and the latter refers to the cultural norms for adopting specific coordination mechanisms to control organizations and tasks. Interestingly, other than studies on cultural factors, Riley and Clare-Brown (2001) investigated the culture found in construction companies by comparing it to that found in manufacturing companies. They held that, as the culture in construction significantly differed to that in manufacturing industries, substantial modifications were needed in adopting tools or practices from other sectors.

In addition to studies on types and factors of culture, several studies were identified that focused on cultural differences in different geographical locations. Ozorovskaja, Voordijk, and Wilderom (2007), by comparing Lithuanian and Dutch construction firms, identified significant differences in leadership and cultures. Tsai and Chi (2009) investigated the influences of Chinese cultural orientations and conflict management styles on construction dispute-resolving strategies using Hofstede’s cultural factors. Naoum, Alyousif, and Atkinson (2014) identified the impact of national culture on the management practices of construction projects in the United Arab Emirates.
3.3.2 Organizational Culture

Organizational culture constitutes one of the major topics in culture research. This study identifies numerous researchers who have conducted studies on organizational cultures. Maloney (1989) claimed that once an organizational culture has been established and strongly maintained, it greatly reduces uncertainty, leading to higher performance along with the organization’s members’ higher satisfaction level. To investigate organizational culture and to determine its relationship with other organizational variables, Maloney and Federle (1991) used a framework developed by Quinn (1988) that was applied to an examination of organizational culture in educational institutions conducted by Cameron (1982). Ozorhon et al. (2008) examined the effect of cultural similarity/difference relative to the national and organizational characteristics of partner companies on international joint ventures. They argued that the differences in organizational culture have a greater impact on international joint ventures' performance than differences in national and host country culture. They also highlighted the importance of culture in international joint ventures noting that the cultural distance between the partners has a significant impact on alliance performance.

Later, Ankrah and his colleagues conducted several studies on organizational cultural differences by comparing architects and contractors’ organizational cultures (Ankrah and Langford 2005) and by investigating factors influencing the culture of a construction project organization (Ankrah, Proverbs, and Debrah 2009). Similarly, Fong and Kwok (2009) characterized and evaluated the composition of organizational culture, the strategic approach for knowledge flow, and the success of knowledge management systems at different hierarchical levels of contracting organizations. They identified that what was favored at both project and organization levels in contracting firms were the clan culture, the culture of honest communication, respect for people, trust, and cohesive relationships. Most recently, Brunetto, Xerri, and Nelson (2014) identified the impact of perceived organizational support and leader-member exchange on organizational culture within asset management organizations and the positive impact of organization culture and employee engagement.

3.3.3 Culture Diversity and Its Impact

Individuals and organizations in a project have different values, beliefs, and norms (Hofstede 2001; Kogut and Singh 1988) and among project participants, this cultural diversity can impact knowledge transfer (Javernick-Will and Levitt 2009; Miller et al. 2000) relationships in a contract (Chan and Tse 2003; Rahman and Kumaraswamy 2004), and trust developments (Fong and Lung 2007). A number of studies have scrutinized cultural diversity and its impact on a project. For example, Kivrak, Ross, and Arslan (2008) studied the effect of cultural diversity on construction management practices to the success of a project by interviewing senior managers in the United Kingdom. However, a consensus has yet to be reached on whether cultural diversity impacts project performance positively or not. Barkema et al. (1997) claimed that cultural diversity decreases project performance and Mahalingam and Levitt (2007) argued that cultural diversity leads to increased transaction costs both in monetary and efficiency terms. Comu, Unsal, and Taylor (2011) also observed cultural diversity to have a negative impact on initial performance; however, projects with cultural and linguistic diversity achieved better adaptation performance on average. Miller et al. (2000) contended that, in the long term, the benefits of cultural diversity can be achieved due to greater creativity, better problem solving ability, and a more comprehensive approach to problem solving.

3.3.4 Culture Effect on Contractual Arrangements

Chan and Tse (2003) explored the characteristics of international construction activities and discussed cultural contexts to establish a groundwork on the impact of cultural issues on contractual arrangements, conflict on international construction activities, and the selection of dispute resolution mechanisms for international construction projects. They contended that international construction projects are more prone to disputes compared to domestic projects. They attribute the disputes to cultural clashes and inappropriate contract arrangements. Recently, Gad, Shane, and Strong (2010) reviewed different dispute resolution methods employed and suggested the effects of culture on the selection of dispute resolution methods in international construction contracts (Gad and Shane 2012).
4 CONCLUSIONS AND RECOMMENDATIONS

This analysis provides useful insights into the importance of the social science aspects in a "human-based" industry such as construction. The literature review has revealed an increasing trend in construction management research on culture in construction. The findings suggest that cultural aspects of construction deserve greater research attention as they can enhance the organization/project's effectiveness and provide a competitive advantage. Based on the literature review, this study has identified, and then compared, major studies on cultural factors. Four of the most remarkable and most commonly referenced studies that introduced cultural factors are: Hofstede (1983), Trompenaars and Woollams (1999), Schwartz (2004), and Brodbeck, Chhokar, and House (2007). From a comparison of these four, this study has identified five categories it considers the most central to understanding cultural differences. These five deal with "group attachment and relations," "authority and status," "uncertainty and rules," "gender roles and assertiveness," and "time and future orientation." This study has also summarized the current research topics on culture in construction. These are 1) cultural factors and differences, 2) organizational culture, 3) culture diversity and its impact, and 4) culture effect on contractual arrangements.

Accordingly, research gaps and ideas for future research into culture in construction area include the following:

- global study on the effects of culture on contracts negotiation and formation, selection of dispute resolution methods, and disputes occurrence
- best practices and critical success factors for dealing with cultural diversity in international projects
- cultural differences in construction projects in South America, East Asia, Africa, and Middle East

DEVELOPMENT AND UTILIZATION OF THE PROJECT DEFINITION RATING INDEX FOR SMALL INDUSTRIAL PROJECTS

Wesley Collins1,2 Kristen Parrish1 and G. Edward Gibson, Jr.1
1 School of Sustainable Engineering and the Built Environment, Arizona State University, United States
2 wes.collins@asu.edu

Abstract: Front end planning is arguably the most impactful activity in the management of construction projects. Organizations expend substantial effort in planning large projects, intending to minimize risk and promote project success. Small projects—typically classified as such based on their lower costs—often have minimal planning completed prior to the start of design and construction. To date, little research has been performed regarding the planning and management of small construction projects, especially those in the industrial sector. In 2013, the Construction Industry Institute (CII) set out to develop a Project Definition Rating Index (a front end planning tool) specifically for small industrial projects. CII Research Team 314 identified forty-one specific elements as most pertinent in assessing a small industrial project. Sixty-five industry practitioners reviewed and prioritized these elements through a series of focus group “weighting workshops.” The tool has been used to assess 12 separate small industrial projects to date, with positive results. This paper summarizes how the PDRI-Small Industrial Projects was developed, how the tool differs from the previously-developed PDRI-Industrial Projects tool, and how it has been utilized to date to assess small industrial projects. Future research opportunities are proposed, including use of the PDRI-Small Industrial Projects research methodology to develop similar tools for the infrastructure and building construction sectors.

1 INTRODUCTION

Poor scope definition has been shown to be one of the major factors leading to poor project performance (Gibson et al 2006). Many construction experts believe that planning efforts conducted during the early stages of a project (e.g., preproject planning or front end planning) have a significantly greater effect on project success than those undertaken after a project has begun. Since 1991, the Construction Industry Institute (CII) has created a suite of tools to be used to define project scope and assess the level of planning readiness during front end planning. These Project Definition Rating Index (PDRI) tools offer a method to measure project scope definition for completeness at any point prior to the start of detailed design and construction. These tools identify and precisely describe each critical element in a scope definition package, and allow project teams to quickly identify project risk factors related to desired outcomes for cost, schedule, and operating performance.

Prior to 2013, separate PDRI tools were developed for industrial, building, and infrastructure project types (CII 1995, 1999, 2011). Though effective in the planning of large construction projects, the PDRI tools were not developed or validated on small projects. Small projects were deemed by CII to be a significant portion of completed work across the industrial sector, including projects in oil/gas production facilities and refineries, chemical plants, manufacturing facilities, and electrical generation facilities to name a few. CII tasked Research Team 314 with developing a PDRI tool specifically for small industrial projects in the
summer of 2013. This paper summarizes how the PDRI-Small Industrial Projects was developed, how the tool differs from the previously developed PDRI-Industrial projects, and how the tool has been utilized to date to assess small industrial projects.

2 DEVELOPMENT OF THE PDRI-SMALL INDUSTRIAL PROJECTS

PDRI tools consist of two main documents that are used to assess a project: a set of elements (with comprehensive descriptions) that detail specific items that should be addressed during the front end planning phase of a project, and a score sheet that provides a hierarchy to the importance of each element relative to the total set of elements. The thorough analysis of planning tasks recommended for industrial projects completed by CII Research Team 113 led to the development of the PDRI-Industrial Projects in 1995. The tool has successfully been used to assess the level of scope definition on thousands of industrial construction projects across the globe since its initial publication. Research Team 314 felt it prudent to use this document as the baseline for developing the PDRI-Small Industrial Projects.

Research Team 314 was initially broken down into three sub-teams, each separately focusing on one of the three PDRI sections (Basis of Decision, Basis of Design, Execution Approach) to develop the element descriptions for the small industrial projects tool. The element descriptions in each section were reviewed and scrutinized by the sub-teams for applicability to small projects over the course of 10 months and 4 separate team meetings. Brainstorming sessions during team meetings, web-based conference calls, and individual reviews were all methods utilized to complete this review. Non-pertinent elements and "items to-be considered" bullets were removed, re-written, or combined with other elements. New elements were developed as necessary. All elements were then thoroughly reviewed by the entire research team during three separate team meetings. The team agreed upon a final set of element descriptions after rigorous discussion and debate. Figure 1 provides an example of one PDRI element description, specifically Element E.3, Electric Single Line Diagrams. Each PDRI element description is provided in this manner, starting with a description of the element. Additional items to be considered while assessing the project at hand follow the description. Pertinent renovation and revamp and program considerations are also listed.

<table>
<thead>
<tr>
<th>E.3 Electric Single Line Diagrams</th>
</tr>
</thead>
<tbody>
<tr>
<td>Electric single line diagrams document the components, devices, or parts of an electrical power distribution system. These diagrams portray the system layout from the public utility's incoming supply to the internal electrical power distribution system. Depending on the size of the electrical system, the single line diagrams may include several levels of distribution. Items to consider should include:</td>
</tr>
<tr>
<td>☐ Incoming utility with owner substation/distribution to high and medium voltage motors and substations</td>
</tr>
<tr>
<td>☐ Electrical load list</td>
</tr>
<tr>
<td>☐ Unit substations and switch gear</td>
</tr>
<tr>
<td>☐ Motor control centers with distribution to motors, lighting panels</td>
</tr>
<tr>
<td>☐ Other user defined</td>
</tr>
</tbody>
</table>

**Additional items to consider for Renovation & Revamp projects**

☐ Field verify existing single line diagrams to ensure they are correct and have been maintained to reflect the actual site conditions.

☐ Verify locations and availability of power for new or relocated equipment.

Figure 1: Sample PDRI-Small Industrial Projects Element Description

The 41 elements created by the Research Team were broken into three sections, and further broken down into eight categories (Note: the PDRI-Industrial Projects has 70 elements). This structure was used
to keep the same “look and feel” as the previously developed PDRIs. Table 1 provides a breakdown of the PDRI-Small Industrial Projects sections, categories, and elements.

A basic tenet of front end planning is that not all items to be assessed are equally critical to project success. Certain elements are higher in the hierarchical order than others with respect to their relative importance. An analysis was necessary to “weight” the elements accordingly. Focus groups were utilized to gain prioritization data from a subset of the total industrial construction stakeholder population. Focus groups are simply a group of subjects interviewed together, prompting a discussion (Babbie 2011). This method was successfully utilized by each of the previous PDRI research teams (Gibson and Whittington 2010). Five such focus groups, or “weighting workshops,” were convened to weight the PDRI elements. The weighting workshops were held in multiple locations in an effort to gain a variety of industry
perspectives related to typical small industrial projects. Workshop locations, dates, and number of participants are shown in Table 2.

Purposive sampling, also referred to as judgmental sampling, is a method in which individuals are selected to be part of the sample based on the researcher’s judgment as to which individuals would be the most useful or representative of the entire population (Babbie 2011). Industry experts with substantial experience in the management and/or design of small industrial projects were targeted to participate. Snowball sampling, or asking targeted individuals to suggest other individuals with similar expertise (Babbie 2011) was used to increase workshop attendance. Figure 2 provides some demographical background information about the workshop participants.

- 65 Workshop Participants
- 65 Weighted PDRI forms completed
- 1,299 Collective years of experience
- 20 years (on average) estimating/project management experience
- 64% of experience (on average) related to small projects
- 85% of experience (on average) related to industrial construction projects
- 29 Organizations represented

Figure 2: Workshop Participant Demographics

During the workshop sessions, participants were asked to assign a contingency amount (i.e., weight) to each of the PDRI elements, indicating the relative importance of each element as compared to the balance of elements in the PDRI. The weights provided by the participants were compiled and analyzed to develop the weighted PDRI score sheet. An excerpt of the weighted score sheet is provided in Figure 3. The workshop participants were also asked to provide feedback relating to any concerns they had regarding the element descriptions. Items brought up during workshop discussions were noted by the workshop facilitators. Each participant was also provided a “Suggestions for Improvement” sheet where additional thoughts could be recorded. The research team reviewed all comments collected during the workshops, and revised the element descriptions as appropriate. For more detail on the data analysis procedures utilized, please see CII (2015).
Figure 3: Weighted Score Sheet for Category A Project Alignment

Previously developed PDRI’s use a scale of 70 (i.e., sum of all Level 1 definitions) to 1000 (i.e., sum of all Level 5 definitions). A project with low definition would receive a higher score (i.e., closer to 1000) than a project with higher definition that would receive a lower score (i.e., closer to 70). Any elements deemed not applicable would lower the potential Level 1 and Level 5 scores on a pro-rata basis depending on the weighting of the element. Research Team 314 chose to use this same scale for the PDRI-Small Industrial Projects to keep constancy with the previously developed PDRI tools.

3 COMPARISON OF INDUSTRIAL PROJECT PDRI’S

3.1 Characterization of Small Industrial Projects

Industrial projects with substantial scope, complexity, schedule duration, and cost are typically considered “large”. Considerable effort is expended to ensure success on large projects, as they are viewed to be critical to an organization’s overall financial prosperity. “Small” projects - projects typically differentiated from large projects due to having lower costs – oftentimes have minimal emphasis placed on detailed front end planning. Small projects tend to be seen as having low risk, and thus not warranting a structured planning approach. Younger or inexperienced project managers and engineers are assigned small projects as training tools in preparation for work on larger future projects (CII 1991).

In reality, assuming that a small project inherently carries lower risk or is less critical to an organization is short-sighted. Based on an industry survey conducted by Research Team 314, seventy to ninety percent of all projects completed in the industrial sector (on a count basis) are considered small, making up a vast majority of completed work each year. While additional project cost or schedule overrun on one small project could possibly have a minimal impact on an organization, the cumulative effect of poorly planned small projects can have a major impact on an organization’s bottom line. The PDRI-Small Industrial Projects was developed to specifically address this important and prevalent project type.

Small projects should not be differentiated from large projects based on solely on static levels of project costs within an organization or the industry at large. Project complexity is the true differentiator between small and large projects. Complex is defined as “a group of obviously related units of which the degree and nature of the relationship is imperfectly known” (Merriam-Webster 2014). Complexity is the quality or state of being complex. Industrial construction projects can fall anywhere along the spectrum of complexity, from projects with little to no complexity (i.e., pure maintenance projects) to highly complex projects (i.e., mega-projects). The rigor of planning efforts expended on a project should match its level of complexity. The PDRI-Small Industrial Projects focuses on lower-complexity projects.

Table 3 below provides data from a study of ninety industrial projects with varying levels of complexity completed by Research Team 314. The averages of nine separate project attributes for typical small and
large industrial projects are given. Table 3 also provides direction in selecting the appropriate PDRI tool for use on an industrial project, but PDRI users are urged to not see the matrix as a strict guideline. For example, in some organizations projects with total installed cost of US$10 million may be very small, while in other organizations projects of this caliber may be considered very large. In choosing a suitable tool for a specific project, project teams assessing industrial projects are urged to consider these factors and choose the appropriate tool based on their organization’s internal project planning specifications.

<td>7.8 separate trade contractors</td>
</tr>
</tbody>
</table>

3.2 Process vs. Non-Process Industrial Projects

The PDRI - Small Industrial Projects was developed to assess both process and non-process related projects. Research Team 314 defines a “process” related project as any project in an industrial facility related to constructing or refurbishing the systems, equipment, utilities, piping, and/or controls that directly affect the production rate, efficiency, quantity, or quality of the product being produced. These projects typically have a stated Return on Investment (ROI) expectation directly related to improved production factors, and may affect how the product is marketed to consumers (e.g., higher quality than before, increase in quantities available). In most cases, documents pertaining to the ongoing operations of the facility (e.g., piping and instrumentation diagrams, process safety management plans) need to be created, or existing documents updated. A “non-process” related project is defined as any project in an industrial facility that is ancillary to production processes, but does not directly affect the quantity or quality of the product being produced. Examples of these types of projects include additions to or expansion of the infrastructure that supports a facility, facility updates necessary for environmental or safety compliance, replacement-in-kind of facility components (e.g., equipment, structural, piping) that do not directly affect the nature of the product being produced. If an ROI is required on these projects, it is typically attributed to improving the operating efficiencies of the facility that are not directly related to production, such as increased energy efficiency related to installing Variable Frequency Drives (VFD’s) on HVAC equipment, or installing solar panels to lessen the amount of power needed from a public utility provider. Documents pertaining to the ongoing operations of the facility (e.g., piping and instrumentation diagrams, process safety management plans) may or may not need to be created or updated.
Examples of small industrial projects can include:

**Process**
- Oil/gas Refining Facilities
  - Stack monitoring and flare line replacement
  - Replacement of desalter effluent cooler fin fans
  - Installation of gasoline cooler in pipeline
  - Addition of hydrogen plant within existing refinery
  - Replacement-in-kind of process piping
- Pulp/Paper Mills
  - Replacement of entangling section
  - Replacement of internal screens in digester vessel
  - Replacement of headbox section
  - Replacement of components associated with wood yard log chipping line
- Manufacturing Facilities
  - Installation of a new packaging line
  - Modifications to existing packaging line
  - Addition of a motor control center
- Breweries
  - Replacement of cooker coils
  - Upgrade coders on can line
- Chemical Plants
  - Installation of new technology nylon compounding extruder and pack-out
  - Replacement of injection molder

**Non-Process**
- Plant Upgrade/Retrofit
  - Replacement of existing elevators
  - Replacement of existing HVAC equipment
  - Repointing of existing masonry structures
  - Replacement or upgrades to existing power supply
  - Installation of raw material railcar offload station
  - Water conservation projects
  - Replacement of constant speed electric-feed-water pumps with variable frequency driven pumps
  - Addition of waste water clarifier to storm sewer system
  - Installation of new dust collection equipment and ducting
  - Installation of environmental monitoring or noise abatement equipment
  - Installation of new security cage and associated security system within an existing operating warehouse facility

### 3.3 Industrial PDRI Application Points

Previous PDRI research (CII 2008, 2008(b), 2010) has found that assessing a large project (from any of the construction sectors) is best performed four separate times during the front end planning process, as shown in Figure 4. This iterative “stage gate” approach allows project teams to assess how well planning activities have progressed prior to formally moving the project forward to the next phase.
The speed and concurrent phasing of small projects makes it more difficult to provide guidance on the best time to conduct a PDRI review. In many small projects, the entire project may be charged against a funding budget; hence the users will want to perform an assessment to “get on track”. In other situations, there may be a funding point after the initial decision to proceed with the development, and just prior to that funding decision may be the optimal time to use the tool. A small project may be phased such that Feasibility, Concept, Detailed Scope, and Design, Procurement and Construction are all overlapping. This may not be the optimum way to proceed with a project, but may reflect the reality of typical small industrial projects.

The PDRI-Small Industrial Projects was designed with the intent that it could be used multiple times throughout the FEP process, or as a one-time use tool. Project size, complexity and duration will help determine the optimum time (or times) that the PDRI tool should be used. To aide in the expanded use of this tool, Figure 5 illustrates suggested application points for the PDRI-Small Industrial Projects. By utilizing the tool multiple times, project teams can capture the benefits of an iterative review process in a timeframe consistent with a shorter project schedule. However, if used only once in the FEP process, the project team may find the tool comparably effective if deployed properly. Proper review-team development, effective capture, and follow up on action items, and open and honest discussion aimed at revealing project scope concerns best support using the tool only once. If a project is assessed only once, the earlier in the project life cycle this occurs the better.

4 PDRI-SMALL INDUSTRIAL PROJECTS USAGE TO DATE

The PDRI-Small Industrial Projects has been used on 12 projects during real-time planning exercises. Nine of the projects were process related, including a stand-alone manufacturing facility, additions to
existing manufacturing lines, structural replacement of an existing cooling tower support system, a natural gas pipeline meter station, replacement of a reverse-osmosis water treatment system, and a clean-room manufacturing suite. The three non-process related projects included a new stand-alone QC lab, a petroleum pipeline measurement skid, and a natural gas pipeline meter station. The average budgeted total installed cost was US $4.0 million, and the average construction schedule duration was 5 months. Each assessment was completed at the PDRI-Final application point detailed in Figure 5. The average time to complete the PDRI assessment was approximately 1.5 hours.

In general, the feedback from users was extremely positive. The tool performed very well in identifying critical risk issues during the front end planning process, and spurred important conversations about elements not yet considered by the project team. As one user stated, "Utilization of the PDRI-Small Industrial Projects tool not only provided for a structured process to assess the status of project scope definition and execution readiness, it also assisted the team in bringing newly assigned individuals on the project up to speed on the project scope and status, as well as gaining alignment within the team on the project plan." As another user stated, "My first reaction was – this is going to take a long time… I picked it up and realized it wasn’t complicated at all. I like (the tool) because it’s easy and straight forward."

5 CONCLUSION

Effective front end planning practices can substantially improve project performance if implemented consistently and correctly. The PDRI tools developed by CII are meant to assess how well a project team has planned for an upcoming project, providing guidance to specific elements that should be considered during front end planning to quickly identify project risk factors related to desired outcomes for project cost, schedule, and operating performance. The PDRI elements are weighted to highlight their relative importance to project success. This paper has summarized the development of the newest PDRI tool, which was developed specifically to address small industrial projects, a project type the makes up a substantial portion of industrial projects completed each year. The tool has been used on 12 projects to date, with extremely positive feedback regarding the tool’s effectiveness and ease of use.

Empirical evidence would suggest that small projects are just as prevalent in the building and infrastructure sectors as they are in the industrial sector. The methodology described in this paper along with the Research Report (CII 2015) developed by Research Team 314 could be used in future research to develop PDRI tools specifically for small infrastructure and building projects.

AUTOMATED DIMENSIONAL COMPLIANCE ASSESSMENT WITH INCOMPLETE POINT CLOUD

Thomas Czerniawski¹, Mohammad Nahangi¹, Scott Walbridge¹, and Carl T. Haas¹
¹ The Ralph Haas Infrastructure Sensing and Analysis Laboratory, Civil and Environmental Engineering Department, University of Waterloo, Waterloo, ON, Canada

Abstract: Dimensional compliance assessment of prefabricated assemblies is a critical part of mitigating rework on heavy industrial construction projects. As assemblies become more complex, manual direct contact metrology becomes ineffective at detecting fabrication error and so automated alternatives that offer objective, fast, and continuous data collection must be explored. Nahangi and Haas (2014) developed an automated method for assessing pipe spools through an algorithm that compares as-built laser scans to 3D design files. The tool is capable of automatic and continual monitoring of prefabricated assemblies throughout their lifecycle and enables timely detection and quantification of dimensional non-compliance. In the original publication, the tool was validated using ideal input data. In this paper, the tool is tested for robustness when processing incomplete point cloud input data. Non-ideal input data is a risk associated with unfavorable conditions in the fabrication environment such as random assembly occlusions causing blind spots in sensing setup, budgetary constraints limiting the purchase of sensing equipment/viewpoints, and random hardware or software failures resulting in corrupt data. The tool was found to reliably detect dimensional non-compliance so long as the non-compliance indicator (pipe spool feature distinguishing the non-compliant state from the design state) was not fully occluded. Accuracy of non-compliance quantification was predominantly high, however, loosely proportional to the input point cloud’s coverage of the assembly’s surface area.

1 INTRODUCTION AND BACKGROUND

1.1 Introduction

As the use of modularization and prefabrication becomes more prevalent within industrial construction, the scope of modularization will expand to include a greater diversity of systems and account for a larger portion of constructed facilities (Chandler 2013). As a result, the effective execution of prefabrication will play an increasingly central role in total cost and schedule management on construction projects.

Prefabrication errors and omissions are considered a significant source of rework (Dissanayake et al. 2003), and so have been the focus of many quality control tool development projects (Bosché 2010; Akinci et al. 2006; Kim et al. 2015). In order to achieve successful deployment in the field, these tools need to be subjected to additional rigorous testing for robustness when operating under non-ideal conditions. In this paper, a series of data inputs of varying quality representing an as-built experimental pipe spool are collected and used for analysis using the tool presented in (Nahangi and Haas 2014). The relationship between input data quality and the accuracy of output fabrication error detection and quantification are explored.
1.2 Rework

In the construction literature, rework is the wasteful effort involved in redoing work that has not yet yielded a product adequately conforming to contractual requirements (Love and Li 2000; Hwang et al. 2009). Rework directly and significantly contributes to cost and schedule overruns on construction projects (Love 2002; Hegazy, Said, and Kassab 2011). Specifically, research published by the Construction Industry Institute (CII) states that rework costs between 2 percent and 20 percent of a typical project’s contract amount (Construction Industry Institute (CII) Research Team 252 2011). Using data from 178 construction projects, (Hwang et al. 2009, 187-198) assessed the impact of rework from a contractor’s perspective and concluded that it most greatly influenced cost increases on heavy industrial projects. It has been argued that the cause of rework on such projects is attributable to poor construction techniques and poor construction management policies (O’Connor and Tucker 1986). On a mining expansion megaproject in Alberta, it was discovered that errors and omissions in prefabrication and poor workmanship of prefabricated materials was a significant source of rework (Dissanayake et al. 2003). Systematic quality assessment of construction components during their lifecycle is important to reduce rework on projects (Love and Li 2000) and particular attention must be given to processes within prefabrication facilities to ensure they are meeting project requirements and mitigating field rework. Any automated quality assessment tools used for this purpose would need to have the capability of identifying errors and omissions in a timely and accurate manner, while using the most up-to-date design files as many rework situations occur because field changes are not communicated to the fabricator effectively.

1.3 Laser Scanning and Fabrication Process Control

Designers and QC specialists typically utilize standardized dimensional tolerance guidelines such as the systems published by American Society of Mechanical Engineers (ASME) or the International Organization for Standardization (ISO). Currently, the predominant processes for monitoring the critical dimensions outlined in these standards involve manual assessment by certified QC personnel using direct contact measurement devices such as measuring tapes, calipers, custom gauges, squares, and straightedges. These processes can help fabricators evaluate whether basic assemblies are compliant with design specifications, but their effectiveness deteriorates as the assembly’s geometrical complexity increases because manual measurement is subjective, time-consuming, costly, and discontinuous. There is a need for automated and systematic dimensional compliance control tools that offer objective, fast, and continuous data collection for reliable quality control on heavy industrial construction projects.

Laser detection and ranging (LADAR) is an increasingly important technology from 3D computer vision used for metrology in the AEC industry (Patraucean et al. 2015). Laser scanners are used to collect spatial data about their surrounding in the form of a 3D point cloud. Compared to contact metrology, laser scanning collects data quickly (up to 976,00 data points per second) allowing for comprehensive coverage of large structures, and with millimeter accuracy (error ± 2mm) (FARO 2015). Considering these capabilities, the feasibility of laser scanning technology for dimensional quality control has been studied by several researchers. (Bosché 2010) proposed an automated method for recognizing 3D CAD model objects in laser scanned data for dimensional compliance control of construction assemblies. (Akinci et al. 2006) proposed a general formalism involving the comparison of as-built laser scans with design CAD models for quality control. (Kim et al. 2015) proposed a holistic approach for dimensional and surface quality assessment of precast concrete elements based on comparing BIM and 3D laser scans.

1.4 Automated Dimensional Compliance Checking in Pipe Spool Fabrication

The increasing complexity of off-site fabricated modules necessitates the implementation of automated dimensional compliance feedback tools capable of comprehensive and reliable measurement. (Nahangi and Haas 2014) presented an automated compliance control method for construction modules that reliably detects the presence of dimensional non-compliance and has consistently quantified the deviations with less than 10% error in experimental studies. The method requires two 3D imaging input files: (1) a 3D model of the as-built assembly generated using a 3D reconstruction technique such as LADAR and (2) the tolerance specifications as represented by the 3D CAD design file. The files are input into a three stage algorithm,
1. **Preprocessing**: involves converting the input 3D imaging files into a standard point cloud format and object of interest isolation from the as-built cluttered point cloud.

2. **Registration**: begins by importing the two input point clouds into a common 3D space. Since the input files do not share a common origin, they need to be aligned through a combination of course registration using principal component analysis and fine registration using iterative closest point (Bosché 2012; Besl and McKay 1992).

3. **Dimensional non-compliance detection and quantification**: analyzes the deviations between the superimposed files using a 3D cube local neighborhood-based metric and outputs discrepancies between the two files in a number of different formats (ex. rotation at joints, extensions/contraction of members) depending on user preference.

The experimental study that validated the method within the paper used ideal as-built data with complete surface coverage of the object of interest.

**1.5 Practical Implications of Tool Implementation**

Transferring knowledge and technology from universities to industry is extremely challenging because of the inherent gap between basic research at universities and industrial exploitation (Griffiths and Röhrbein 2013). University-industry collaborations attempt to increase and test the robustness of basic laboratory proven technologies to ensure their suitability for application in complex industrial environments. If applied in a fabrication facility, an automated dimensional compliance checking tool would need to be capable of generating meaningful outputs from non-ideal data inputs. Non-ideal data collection conditions and resulting incomplete point cloud inputs are an unfortunate reality because of: random assembly occlusions causing blind spots in sensing setup, budgetary constraints limiting the purchase of sensing equipment/viewpoints, and random hardware or software failures resulting in corrupt data (Seversky and Yin 2012).

In order to progress the tool presented in (Nahangi and Haas 2014) towards application in industry, its ability to accurately detect and quantify dimensional non-compliance from incomplete point cloud inputs should be evaluated.

**2 METHODOLOGY AND EXPERIMENT**

**2.1 Laboratory Setup and Equipment**

To evaluate the performance of the methodology proposed in (Nahangi 2015) under incomplete point cloud input conditions, a series of experiments were conducted at the University of Waterloo’s Ralph Haas Infrastructure Sensing and Analysis Laboratory. The researchers collected data using a reconfigurable pipe spool (Figure 1), and a FARO LS 840 HE (Table 1). The pipe spool has custom connections that allow controlled displacements and rotations in order to deviate the assembly from its design compliant state.

Two controlled rotations were introduced into the assembly: 2.5 degrees on Branch 1 (B1) and 15 degrees on Branch 2 (B2) (Figure 2). These rotations simulated a state of design non-compliance that was held constant for 7 laser scans. A plan view layout of the locations of the laser scanner for the 7 laser scans can be found in Figure 1.

2.2 Preprocessing

7 laser scans were collected of the pipe spool in its design non-compliant state. The scans were then merged in different combinations to obtain a set of point clouds with varying pipe spool surface coverage. The point clouds were imported into Meshlab (Cignoni et al. 2014), and through surface reconstruction, a surface area of coverage was calculated and compared to total surface area. Surface coverage is used as a metric for point cloud completeness. The mesh generated from scan 1 data points can be seen in Figure 3. The surface area calculated indicates 44% total pipe spool surface area coverage and 30% surface area coverage of the design non-compliance indicators (NCI) (pipe spool features distinguishing non-compliant state from design state).

Results of preprocessing can be found in Table 2. Total surface coverage ranges from 26% to 100% for the set of point clouds. Point cloud 1 was created by modifying scan 2 to simulate a large obstruction such as a welding screen, occluding half of the pipe spool (Figure 4). In point cloud 3, the NCI for B2 was fully occluded.

3 RESULTS

The incomplete as-built point clouds were analysed for dimensional non-compliance using the methodology described in section 2.3. Monitoring both the total surface area coverage and NCI surface area coverage of the pipe pool by the as-built point clouds, the relationship between these factors and the accuracy of the corresponding dimensional compliance assessments was explored. As seen in Figure 5, the detection rate of the controlled rotation in B1 was 100% (i.e. all point cloud instances were able to detect the presence of the rotation). As well, the quantification of the controlled rotation in B1 ranged from 2.41 to 2.53 degrees, representing a maximum error of 4% for point cloud from a single scan, 1.6% from two scans, and 3.2% from three scans (relative to the quantification from Point Cloud 15, 2.51 degrees).

The detection rate of the controlled rotation in B2 was 93%. The point cloud which was unable to detect the rotation had 0% surface area coverage of the B2 NCI and was not included in the quantification stage of the methodology. The quantification of the controlled rotation in B2 ranged from 8.61 to 28.63 degrees representing a maximum error of 90% for point cloud from a single scan, 42.9% from two scans, and 20.9% from three scans (relative to the quantification from Point Cloud 15, 15.08 degrees). All data suggests an inverse correlation between error of non-compliance quantification and surface coverage by point cloud.
Prefabrication errors are a significant source of costly rework on heavy industrial projects. Researchers have developed and validated dimensional compliance control algorithms that have the potential to improve quality control in prefabrication environments by using data from LADAR and concepts from computer vision. However, these tools need to be subjected to additional rigorous testing for robustness to non-ideal data inputs before successful deployment in the field can be achieved. Several scans were collected of an experimental pipe spool, and a surface area of assembly coverage metric was used to gauge the quality of input point clouds. Processing the data using the methodology described in section 2.3, a relationship between input data quality and the accuracy of detection and quantification of dimensional non-compliance was explored.

The result was a 100% dimensional non-compliance detection rate in the experimental study, with the exception of the case in which the NCI (pipe spool feature distinguishing non-compliant state from design state) was fully occluded. Thus, reliable detection of non-compliance is possible from a single scan, but the output is susceptible to false negatives resulting from assembly occlusion. In order to mitigate this risk and improve the methodology's robustness, at least two scan perspectives should be used to ensure dimensional non-compliance detection.

The accuracy of quantifying the detected dimensional non-compliance improved as the input as-built point cloud's coverage of the assembly's surface area increased. The error of quantification for the rotation in B2 (branch 2 of the experimental pipe spool) was greater than the error for B1 (branch 1 of the experimental pipe spool), which could be attributable to the smaller surface area of the NCI. However, the error in B2 was substantially reduced as point cloud surface coverage increased. Thus if accurate
quantification is desired, it can be achieved by using additional scans in the analysis. Quantification in B1 was consistently accurate.

Future work should build on our present understanding of other pertinent variables in the methodology, particularly those involved in the manual portions of the process, in order to better determine the source of error and variability in output accuracy.

DEVELOPMENT OF MECHANISMS BY USING CONCEPTUAL SYSTEM DYNAMICS MODELS TO RESOLVE DELAY IN CONSTRUCTION PROJECTS

Diilip Kumar Das
Central University of Technology, Free State, South Africa
ddas@cut.ac.za

Abstract: A major concern in the construction industry remains with the non understanding of the mechanisms that cause delay in construction. Therefore, the objective of the paper is to evolve mechanisms, which could assist in identifying activities and events, comprehend and foresee the causal feedback relations among the variables that cause delay, and take appropriate actions to resolve the challenges of delay. A survey was conducted among 120 stakeholders from various construction projects in India. Evaluation of the major control parameters were done by using Likert scale. Subsequently, conceptual models were developed by using System Dynamics modelling principles. The important causal feedback relations from the conceptual models were used to evolve mechanisms to understand the events and chain of actions that lead to delay; which could assist in evolving policy/strategic interventions to resolve the challenges. It was observed that most of the client, contractor, consultant and design related variables are the major causes of occurrence of delay. However, policy/strategic interventions based on the four dynamic hypotheses; such as, the causal feedback relationships among (1) communication, decision-making, progress in payment and construction delay; (2) effective planning and scheduling, planning for finance and budget ahead, adoption of construction methods, contingencies in planning for rework and exigencies by the contractor and construction delay; (3) appointment of highly competent consultant and design team, delay in producing the design documents and delay in construction; and (4) provision of effective communication mechanism, conflict resolution and delay in construction, would able to assist in resolving delay in construction.

1 INTRODUCTION

Delay is a major cause of concern in almost all construction projects. The reasons of delay could be generally classified under broad issues related to client/owner, contractor, design, construction, materials, equipment and project management (Alaghbari, Razali, Kadir, Ernawat 2007, Assaf, and Al-Hejji 2006, Chan and KumaraSwamy 1997, Desai and Bhatt 2013; Kaming, Olomolaiye, Holt, Harris 1997, Odeh and Battaineh 2002; Stumpf 2000). However, the main concern remains with the non understanding of the mechanisms and not foreseeing of the unwarranted events by the stakeholders and project management team, which lead to delay. Over the years there are plenty of investigations made regarding to the causes, and various methods of analysis of construction delay. But, investigations relating to development of interventions or mechanisms to resolve the challenges of delay in construction projects are observed to be scarce. Taking into account the significant impacts of delay, there is an argument that development of mechanisms by considering various components and stakeholders would assist to foresee the chain of events that cause delay and to resolve the challenges (Alaghbari et al. 2007, Sweis, Sweis, Hammad, Abu 2008). Therefore, the objective of the paper is to evolve mechanisms, which could assist the project stakeholders to identify the activities and events, comprehend and foresee the causal
feedback relations among the variables that cause delay, and take appropriate actions to resolve the challenges of delay. The investigation was conducted by using a survey research methodology and System Dynamics (SD) modelling approach. A total of 120 stakeholders and professionals from large and medium projects in India, which includes project managers, architects, engineers, skilled technicians, consultants, designers, quantity surveyors, contractors and clients, were surveyed through semi-structured interview method to comprehend the major control variables causing delay in construction projects. Followed by, conceptual models were developed based on the causal feedback relations among the major variables influencing delay by using SD modelling principles. The important causal feedback relations in the conceptual models were used to comprehend the mechanisms that could enable understanding of the events and chain of actions that lead to delay; and to evolve policy/strategic interventions to resolve the challenges. It was observed that variables relating to client, contractor, consultant and design are the major causes of delay. These variables are interlinked with each other and function in causal feedback mechanisms creating a chain of actions, which influence the occurrence of delay. The mechanisms developed based on these causal feedback relations among the variables will act as a tool to assist the stakeholders, such as clients, contractors, consultants and project management team to foresee the challenges of delay ahead at each and every stage of construction projects and take appropriate actions to resolve them.

2 LITERATURE REVIEW

Delay in construction can be defined as the time overruns either beyond the contract date specified in a contract, or beyond the date that the parties agreed upon for delivery of a project. Generally, it is the additional days of work for completion of project/ activity or as a delayed start of an activity (Assaf, Al-Hejji 2006; Stumpf 2000). Since the construction process is subject to many variables and unpredictable factors, delays are found to be inevitable and become integral part of the project’s construction life. Even with the availability of advanced technology, and understanding of the project management techniques, construction projects continue to suffer delays (Stumpf 2000). The sources of delay are varied, which include the performance and involvement of stakeholders, resources availability, environmental conditions, contractual relations, and so on (Alaghbari, Razali, Kadir, Emawat 2007, Kaming, Olomolaiye, Holt, Harris 1997, Odeh and Battaineh 2002, Stumpf 2000). Besides, scholars like Al-Barak (1993), Al-Momani (2000), Chan and Kumaraswamy (1997), Kaming et al. (1997), Kumaraswamy and Chan (1998) and Noulmanee, Wachirathamrojn, Tantichattanont, Sittivijan (1999) have studied the causes of delay in different projects.

From these studies it is found that causes of delay vary with context and project environment. For instance, Chan and Kumaraswamy (1997) found five principal factors: poor risk management and supervision, unforeseen site conditions, slow decision making, client-initiated variations, and work variations. According to Kaming, et al. (1997) two different set of factors influence differently for cost overruns and time overruns. The major factors influencing cost overrun are material cost increase due to inflation, inaccurate material estimation and degree of complexity. For time overrun, the most important factors responsible are design changes, poor labour productivity, inadequate planning, and resource shortages. Some attribute the reason to bias of different industry groups and difference in perception by different groups as to what causes delay (Kumaraswamy and Chan 1998). According to Noulmanee et al. (1999), although delays can be caused by all parties involved in projects, the main causes come from the inadequacy of sub-contractors, organization that lacks sufficient resources, incomplete and unclear drawings, deficiencies of consultants and contractors, and differences between consultants and contractors. Similarly, Al-Momani (2000) observed that delay is related to designer, user changes, weather, site conditions, late deliveries, economic conditions and increase in quantity. Al-Barak (2000) concluded that lack of experience, poor estimation practices, bad decisions in regulating company’s policy, and national slump in the economy are the severe factors, which cause delay. Also, Aswathi and Thomas (2013) observed that contractors, rather than consultants and owners, were the most responsible party for the delays in construction projects (Ndekugri, Braimah and Gameson 2007). However, the role of owners in causing delay is no way meagre. In summary, factors like delay in progress of payments by owner, delay to furnish and deliver the site to the contractor by owner, change orders by owner during construction, late in revising and approving design documents by owner, delay in approving shop

drawings and sample materials, poor communication and coordination by owner and other parties, slowness in decision making process by owner, unavailability of incentives for contractor for finishing ahead of schedule, suspension of work by owner cause delay (Desai, Bhatt 2013, Assaf, Al-Hejji 2006). Similarly, inappropriate design, design changes, mistakes in design, late inspection, late design works, late approval, insufficient inspectors, incapable inspectors could cause delay (Alhomidan 2013, Desai and Bhatt 2013). However, causes like accidents, temporary stoppage, rework, extra work, external factors like weather conditions, unavailability of utilities, government law and regulations, etc., cannot be undermined (Iyer, Chaphalkar, Joshi 2008). Overall, the attributes can be classified into project, owner, contractor, consultant, design, material, equipment, labour and external related factors. Although, it is seen that many of the factors are interlinked and have cause and effect relationships (Assaf and Al-Hejji 2006, Chan and Kumaraswamy 1997, Frimpong et al. 2003, Manavizha and Adhikariib,2002, Odeh and Battaineh 2002, Sambasivan and Soon 2007), studies relating to such aspects are found to be limited. So, scholars like Alaghbari et al. (2007) stressed the importance of early identification of construction delays and development of major delay-reducing remedies (Sweis, Sweis, Hammad, Abu 2008).

A number of methods and techniques have been developed over the years to understand or analyse delay in construction industry (Braimah 2013). Yeats (2007) developed a decision support system (DAS) for delay analysis in construction projects, which could consider factors like equipment, external delay, labour, material, owner, contractor, management, subcontractor and weather (Odeh, Battaineh, 2002). Terry (2003) studied the standard methods currently available for assessing extension of time delays on major projects, and issues around such assessment, and used network causal mapping and system dynamics approach to study the impact of delays on a project. The other methods used are the frequency index (FI), severity index (SI), importance weight (IW), importance index (II), average weight (AW), influence value and activity duration. Some of the investigations have also used Monte Carlo simulation to derive delay reduction interventions (Aswath, Thomas 2013) and Fuzzy logic for delay computations (Pandey, Dandotiya, Trivedi, Bhadoniya, Ramasesh 2012). However, many of these methods do not explicitly consider the causal feedback relationships among the factors, which cause delay.

3 METHODOLOGY

A survey research methodology was employed to collect primary data from the various stakeholders in construction projects in India. A total of 120 questionnaires were administered, of which 102 were returned (approximately 85% response rate). Professionals and stakeholders from large and medium projects in India, which includes project managers, architects, engineers, skilled technicians, consultants, designers, quantity surveyors, contractors and clients/owners, were surveyed through semi-structured interview method. The respondents were asked to provide their opinions on the various parameters that cause delay and to rate the challenges in a scale of 1 to 5 (1= not influential, 2 = less influential, 3 = somewhat influential, 4 = significantly influential and 5 = most influential in causing delay) from the experiences in the projects they were involved in. The simple random sampling technique was used in the selection of samples for the survey.

Quantitative descriptive statistics analysis and Cronbach's alpha test of the data collected were conducted to observe the reliability of the data. Likert scale (Gravetter and Wallnau 2008) was employed to measure the relative influence causing delay through development of a delay index (DI) for the variables; and their general rank and rank under each major factor. Followed by, conceptual models by using SD modelling principles based on the systems thinking process (Von Bertalanffy 1974) were developed. The construction project was considered as the system or environment while developing the model. The influential variables, their positive and negative influences on the related variables and the causal relationships among them were used to develop the conceptual SD models. The causal relationships among the variables within and across the major parameters were developed based on the discussions and experiences of the professionals surveyed. While developing the causal relationships, initially the variables, such as, information, decision and action and environment (system) variables (Olaya 2012) were identified. The variables were then connected with simple one way causality in terms of one way linkages of information – decisions – actions – impact on the environment with their influence (i.e., information assisting in evolving decisions (policy interventions), decisions leading to appropriate
actions, and actions influencing the environment (system)) (El Halabi, Doolan, Cardew-Hall 2012, Veniix1996). Once the one way causalities were established the feedback relationships were checked and established. The constructed causal feedback relations were then discussed with the professional and experts in the field to check the veracity of the causal diagrams and relevant modifications with respect to the variable names, their polarity and causal relations as need be were made. The valid causal feedback diagrams (causal loop diagrams) were then employed to develop the conceptual SD models.

4 RESULTS, CONCEPTUAL SD MODELS AND DISCUSSION

4.1 Major Factors Causing Construction Delay

Table 1 presents the factors and their level of influence in construction delay. The various factors were grouped under project, client/owner, contractor, consultant, design, materials, equipment and labour related factors. However, external factors, such as, weather, availability of basic utilities, regulations, accidents, etc., have been kept out of the scope of the analysis. The acceptable standard deviation (SD) values and high Chronbach α (0.93) value show the reliability and acceptability of the data. The delay index (DI) and their general rankings revealed that majority of the factors belonging to client, contractor and consultant and design aspects of the projects have significantly higher delay indices compared to the factors belonging to materials, equipment and labour aspects. Thus, client/owner, contractor, consultant and design aspects have significant influence on construction delay. Similarly, the ranking in the groups show that delay in progress of payments by owner, slowness in decision making process by owner, change orders by owner during construction, poor communication and coordination by owner and other parties, delay in approving shop drawings and sample materials by the owner are the major client/owner related factors, which cause delay. Factors like delay in furnishing and delivering the site to contractor, suspension of work and lack of incentives to contractors for completion of the work ahead of schedule have lower impact. Similarly, difficulties in financing project by contractor, delay in financing project by contractor, conflicts between contractor and other parties (consultant and owner), rework due to errors during construction, ineffective planning and scheduling of project by contractor are the major contractor related causes of delay. Factors like poor communication and coordination by contractor with other parties, improper construction methods implemented by contractor, and delay in site mobilization also influence delay although to a lesser extent. Under consultant related factors, late in reviewing and approving design documents, delay in performing inspection and testing, delay in approving major changes in the scope of work, poor communication/coordination between consultant and other parties, inflexibility of consultant are the significant causes of delay, whereas delays in producing design documents, complexity of project design, mistakes and discrepancies in design documents, and unclear and inadequate details in drawings are the design related factors, which are the causes of concern. However, despite being relatively less influential delay due to delivery of material and late procurement of material, shortage of equipment, equipment breakdown, shortage of labour and unqualified labour force do cause delay in construction although they can be attributed to contractor or client related factors.

4.2 Conceptual Model and Mechanisms

Considering the influence of the factors as discussed above conceptual SD models have been developed to comprehend the dynamic causal feedback relationships among the factors, which cause delay and develop the possible mechanisms that can assist in reducing the delay. In the model, the causal feedback relations (loops), which essentially balance or disrupts the system (construction projects), and consequently augment delay are identified by balancing loops (B). On the other hand, the causal feedback loops, which reinforce the smooth functioning of the system and consequently assist in reducing or eliminating delay, are identified by reinforcing loops (R). While developing the models, only client, contractor, consultant and design aspects were considered because of their higher influence. Consultant and design related factors were taken together because of their strong inter-linkage and interdependence. The other factors belonging to materials, equipment and labour aspects were integrated to the client, contractor and consultant and design aspects according to their relationship and importance.

4.2.1 Client Related Aspects

As mentioned above delay in progress of payments by owner, slowness in decision making process by owner, change orders by owner during construction, poor communication and coordination by owner and other parties, and delay in approving shop drawings and sample materials by the client are the major client/owner related factors, which cause delay although others factors contributes to lesser extent. It is observed that there exists cause and effect relationships among these factors, and they work through a feedback mechanism. Figure 1 manifests the conceptual SD model based on such causal feedback relationships. As shown in the figure, slowness in decision making leads to delay in progress in payment, which cause delay and disrupts the system through balancing loop OB1. Also, poor communication leads to slowness in decision making and vice versa through another balancing causal feedback sub loop OB1A. So balancing sub loop OB1A aggravates the balancing loop OB1. Besides, factors like change in orders during construction, delay in approving the drawing and materials, late approval of revision of designs and delay in furnishing the site delivery by the client are influenced by slowness in decision making and vice versa. On the other hand, effective communication among stakeholders (which can be enhanced by coordination among them) will assist in decision making that will facilitate timely payment and consequently will assist in reducing the construction delay from client’s side.
However, to achieve this, measures, such as, coordination among stakeholder that would lead to effective communication; availability of requisite information to aid timely decision making, and availability of adequate fund and budget allocation that would allow timely payment are necessary.

Thus, the feedback mechanism involving effective communication, timely decision making and timely payment will reinforce reduction in delay through reinforcing loop OR1. As a result, the disrupting effects of feedback mechanisms (OB1 and OB1A) are balanced or negated by feedback mechanism OR1. So, the causal feedback relationship among communication, decision-making, progress in payment and construction delay is the dynamic hypotheses, which influence delay and need to be attended to alleviate the problem.

4.2.2 Contractor Related Aspects

Contractors form important parts of construction project. They are essentially responsible for the actual construction activities. As evident from this investigation, difficulties in financing project by contractor, delay in financing project by contractor, conflicts between contractor and other parties (consultant and owner), rework due to errors during construction, and ineffective planning and scheduling of project by contractor are the major contractor related causes of delay. However, factors like poor communication and coordination by contractor with other parties, improper construction methods, and delay in site mobilization also influence delay although to a lesser extent. The causal feedback relationships among the factors and delay in the SD model (Figure 2) reveal that ineffective planning and scheduling has a direct linkage with construction delay through a feedback mechanism (balancing loop CB1). While ineffective planning, essentially may happen because of poor communication, it can influence the construction activities through delay in site mobilization, poor management of site and supervision, and rework because of lack of contingencies in time schedule for such occurrences. Similarly, difficulty in financing the project by contractor, which can lead to delay in financing the project will cause construction delay through feedback mechanism (CB2) and disrupts the project. However, adoption of best practices of the industry through (1) planning for finance and budget ahead (CR1A), which can lessen the burden of difficulty in financing; (2) provision of effective communication and coordination, which can reduce ineffective planning and scheduling (CR1B); (3) use of appropriate construction methods (CR1C); and (4) provision for rework and exigencies (CR1D), which can reduce the rework, will enable reduction of delay in construction.

![Figure 2: SD model based on causal feedback relations among the contractor related factors causing delay](image-url)
Therefore, reduction of delay will occur through reinforcing loop CR1 between adoption of best practices and construction delay (through reinforcing sub loops CR1A, CR1B, CR1C, and CR1D). Thus, the disruptive mechanisms through CB1 and CB2 can be balanced or negated by reinforcing mechanism CR1. Therefore, causal feedback mechanism involving effective planning and scheduling, planning for finance and budget ahead, adoption of construction methods, and contingencies in planning for rework and exigencies by the contractor and construction delay is the dynamic hypothesis, which should be considered while developing policy interventions to reduce delay in construction.

4.2.3 Consultant and Design Related Issues

The consultant and design related issues are more or less integrated, and therefore both of them are considered together while developing the conceptual model. As seen from the Table 1, late in reviewing and approving design documents by consultant, delay in performing inspection and testing by consultant, delay in approving major changes in the scope of work by consultant, poor communication/coordination between consultant and other parties, inflexibility (rigidity) of consultant are the significant causes of delay, whereas delay in producing design documents, complexity of project design, mistakes and discrepancies in design documents unclear and inadequate details in drawings are the design related causes, which are responsible for delay in construction. The conceptual SD model is presented in Figure 3. The causal feedback mechanisms manifest that complexity of the project influence the delay in production of the design document by consultant, which essentially cause construction delay through balancing loop DB1. Complexity in design also can lead to mistakes and discrepancies in design document, which can lead to unclear and inadequate detail drawings through balancing sub loop DB1A. Similarly, delay in production of design document is influenced by delay in performing inspection and testing by consultant, delay in approving major changes in the scope of work of the consultant by the client, and late reviewing and approving the document by the consultant. Therefore, complexity of design can disrupt or cause construction delay through balancing feedback mechanism DB1 supported by feedback loop DB1A. However, on the other hand, appointment of highly competent consultant and design team will able to meet the challenges of complex design as well as eliminate the problems of mistakes and errors and enhance clarity in detail drawings through feedback mechanism (sub loop DR1A). Consequently, it will reinforce the reduction of delay by reducing the delay in producing the design documents through feedback mechanism DR1.

![Figure 3: SD model based on causal feedback relations among the consultant and design related factors causing delay](image-url)
Thus, causal feedback mechanism DR1A reinforces causal feedback mechanism DR1. Further, provision of an effective communication mechanism between consultant and other stakeholders will assist in conflict resolution among client, contractor, design team and consultant, and thereby reduces delay through causal feedback mechanism DR2. Besides, DR2 will be further reinforced by feedback mechanism DR2A, as effective communication will eradicate the challenges created by poor communication like misunderstanding of client's requirement leading to reduction in the challenges of complexity of design. Thus, the feedback mechanism DB1 causing construction delay will be balanced or negated by the feedback mechanisms DR1 and DR2. So, the causal feedback mechanisms involving appointment of highly competent consultant and design team, delay in producing the design documents and delay in construction; and provision of effective communication mechanism, conflict resolution and delay in construction are the dynamic hypotheses, which need to consider while developing policy interventions for reducing delay from consultant and design point of view.

5 CONCLUSION

Delay in construction projects is a menace. It leads to both appreciable cost and time overruns, which affect both socially and economically to the society. Although, there were plenty of studies conducted to investigate the causes of the delay, which differ depending on contexts, yet there are several causes which are observed to be common in most of the projects. However, there is scanty literature available regarding the mechanisms, which could aid in developing policy interventions to reduce or eliminate construction delay. This challenge has therefore warranted the investigation. The investigation was conducted by using a survey research methodology. A survey was conducted among the various stakeholders and professionals belonging to medium and major projects in India to understand the various causes, their level of influence and causal relations. Followed by, causal feedback mechanisms and consequent conceptual SD models were developed by using SD modelling principles, which lead to evolving of dynamic hypotheses to resolve the challenges of delay in construction.

It is evident from the results that parameters belonging to client/owner, contractor, consultant and design aspects have major influence on the occurrence delay, whereas material, equipment and labour related issues have lesser significance. However, the causal feedback mechanisms revealed that there are four dynamic hypotheses, which need to be considered while developing policy interventions to resolve the challenges of delay in construction. They are (1) the causal feedback relationship among communication, decision-making, progress in payment and construction delay; (2) the causal feedback mechanism involving effective planning and scheduling, planning for finance and budget ahead, adoption of construction methods, contingencies in planning for rework and exigencies by the contractor and construction delay; (3) the causal feedback mechanisms involving appointment of highly competent consultant and design team, delay in producing the design documents and delay in construction; and (4) the provision of effective communication mechanism, conflict resolution and delay in construction.

The paper has its limitations. The obvious limitation is that the modelling was done conceptually, although the basic premise behind it was to see the challenges of delay in a more critical way. However, there is a need for the quantitative modelling to examine the extent to which construction delay can be reduced or eliminated under different scenarios of strategic/policy interventions based on the dynamic hypotheses, which is the further scope of this research. Despite the limitation, this study can assist construction project managers, leaders and stakeholders to analyse and diagnose construction delay challenges by using the dynamic hypotheses in their projects and derive plausible strategic/policy interventions to reduce or eliminate delay in construction projects.

\(^1\) Department of Building, Civil and Environmental Engineering, University of Concordia, Canada
\(^2\) thikradawood2002@yahoo.ca

Abstract: The Canadian Urban Transit Association (CUTA) estimated that transit infrastructure needed a total of 53 Billion Canadian Dollars in 2013. Subway networks form an essential part of the public transportation infrastructure. Several surface defects may develop on subway infrastructure facilities, of which the most commonly identified are cracks, scaling, spalling, delamination, moisture marks, and efflorescence. These distresses participate not only in degrading the structure aesthetically, but in increasing the deterioration mechanisms of its components, taking into account the severe environmental conditions and continuous heavy loads that the structure is subjected to during its service life. High deterioration rates may cause the closure of subway system, therefore condition assessment of subway networks represents a crucial yet challenging task in the sustainability of a sound concrete infrastructure. Visual inspection techniques are considered the principal methods used in the condition evaluation of civil infrastructure. These methods are time-consuming, expensive, and depend inherently on subjective criteria. Several models have been proposed by previous researchers to assess the condition of subway systems. However, all of the developed methods were dependent on the visual inspection reports, hence they lacked the objectivity in quantifying and estimating the severity of defects. Therefore, a robust model that can detect the distresses and compute their severity needs to be developed. This paper defines the details of the recently introduced procedure based on image processing and assessment techniques. A five phased process is presented for accurate condition assessment of subway networks. The developed methodology utilizes data acquisition tools for collecting images of different elements in subway networks. Multiple algorithms are utilized to detect, interpret and measure surface defects, such as binary transformation, histogram equalization, image dilation, and hole filling. A case study from Montreal subway system was used to exemplify the application of the developed method. The results prove the potential benefits of the proposed methodology in identifying and quantifying surface defects. This research concludes the reliability of image-based data model in terms of accuracy, efficiency, and ease of analysis.

Keywords: Image Processing, Subway System, Inspection, Condition Assessment

1 INTRODUCTION

Public transit infrastructure plays a vital role in the economy, prosperity and the well-being of people. Subway networks form a fundamental constituent of the public infrastructure. Statistics show that the amount of passengers choosing the subway system for their daily travel is on the rise. According to the American Public Transportation Association (APTA) Fourth quarter report (APTA, 2013), in New York
City, 2.7 billion trips took place in 2012, while in the case of Montreal, that number reached around 357 million trips. (APTA 2013).

The increasing demand for underground transportation in addition to other factors will participate in the deterioration of subway systems. These factors include but are not limited to, the aging of infrastructure facilities, harsh environmental conditions, heavy loading, and deferred maintenance and rehabilitation plans. The high deterioration rates and the growing demand on metro systems, make the condition assessment procedure a critical safety issue. Accordingly, a reliable condition assessment method has become a vital task yet a necessity to ensure the sustainability of the structure.

Condition assessment of subway networks provides inputs for planning future maintenance activities. In both Canada and the United States, the main approach to evaluate the condition of subway systems, is based on visual inspection (VI), which is time-consuming, expensive, and depends regularly on subjective criteria. Automating the current practice is expected to provide more objective, accurate, quantitative results which will eventually lead to enormous savings in time and money. Among several damage detection techniques, the use of optical devices such as digital cameras and image processing methods are promising methodologies. One automation aspect is the detection of spall defects which develop on the surfaces of concrete structure. This paper aims at developing an automated assessment model for subway networks based on image processing algorithms and non-destructive evaluation (NDE) technologies. The model performs damage identification and quantification of spalling on the external surface of concrete. It provides a systematic approach for the identification of spall areas through different image enhancement algorithms, such as histogram equalization, image thresholding and mask processing. The output of this research is a decision support tool, expected to assist the infrastructure managers and civil engineers in their future plans and decision making.

2 BACKGROUND AND LITERATURE REVIEW

In the literature review, several efforts have been made to evaluate the condition of subway networks. Semaan (2006) has developed a condition assessment model to diagnose and assess the conditions of subway stations. This model has defined functional criteria and applied the Analytic Hierarchy Process (AHP) to calculate their weights. Then, the Preference Ranking Organization Method of Enrichment Evaluation was used to find the aggregation of weights and scores, and finally Station Diagnosis Index (SDI) was calculated using the Multi-Attribute Utility Theory (MAUT), and a condition scale for the evaluation of each station was proposed. This model was applied later on Montreal Metro stations. Another model was proposed by Semaan (2011). This model was developed to assess the performance of subway network, it has started by the hierarchy identification of subway network. Then, the physical and functional performances of each component in the network were assessed and integrated into one performance index using the AHP and MAUT theory. Performance prediction curves for all the components in the network were constructed using a Weibull reliability function. Moreover, this model has evaluated the performance of various systems, lines and the whole network by the use of the series-parallel system technique and was implemented in the Montreal subway network.

Kepaptsoglou et al. (2012) have developed a model to evaluate the functional condition of subway stations, this model was applied to Athens Metro systems. Several criteria and sub-criteria were allocated to every station. The AHP and Fuzzy AHP were utilized to rank the sub-criteria according to their significance to the station’s operational phase. The sub-criteria were weighted according to their significance to the station’s operational phase and they were evaluated on a scale of 0-5 by Athens transit authority. Then, their scores were aggregated with the use of MAUT to get the Metro’s Condition Index. This model was developed solely for the condition assessment of subway stations. In order to improve the previous model and achieve the interdependencies among its criteria, Gkountis and Zayed (2013) have applied the Analytic Network Process (ANP) and have used the same 0-5 scale. The additive MAUT was implemented to acquire the station’s condition index.

Abu-Mallouh (1999) has developed a “Model for Station Rehabilitation Planning” so called “MSRP” in an effort to improve the “Point Allocation Model” implemented by the MTA NYCT. The MSRP has considered the same functional and social criteria used by New York Transit Authority. The Analytic Hierarchy Process (AHP) technique was applied to obtain weights for the stations. For rehabilitation planning, a
powerful optimization technique (Integer Programming) was used to allocate budget for stations. The weights and budget allocation were later used to prioritize stations for rehabilitation. In fact, the MSRP is a budget allocation model rather than a condition assessment or a deterioration model and it is only limited to the evaluation of stations. Furthermore, it did not use real collected data for the validation process. Faraan (2006) has proposed a model “maintenance and rehabilitation planning for public infrastructure” known as “MRPPI” and implemented in the Montreal subway stations. This methodology has considered the life-cycle cost analysis of the structural elements in the infrastructure. It has applied Markov Chains theory to evaluate the deterioration of the elements and used transition probability matrices as input variables to the model. Consequently, Genetic Algorithm optimization technique was utilized to minimize the life cycle cost after considering a series of intervention actions.

Derrible and Kennedy (2010) have developed a model, the objective of which was to improve the efficiency and ridership of Toronto Metro network by assessing its performance as well as comparing it to other subway networks. The model was developed by computing three major factors including coverage, directness and connectivity. Numerous variables were considered in the computing process, including covered area, ridership, possible transfer options and number of lines. Marzouk and Abdel Aty (2012) have proposed a Building Information Modeling (BIM) framework for the maintenance of subway infrastructure. Various asset management indicators were included in the body of this research, such as structural integrity, mechanical systems, HVAC systems, electrical system and user-related indicators. The model has aimed at offering a solid ground by proposing BIM flowchart that considers the indicators as prepared inputs to a comprehensive BIM/Asset management model.

Abouhamad (2014) has developed a risk-based asset management framework for subway networks. The study has proposed two main models namely; fuzzy risk index model and risk-based budget allocation model. In the first main model, risk was evaluated using three sub models; probability of failure, consequences of failure and criticality index. Probability of failure for several structural components was evaluated based on inspection reports and Weibull reliability function. Consequences of failure were evaluated through seven attributes, such as revenue loss, replacement/repair cost, etc. Consequently, criticality index was computed using seven criteria, such as number of lines, number of exits, etc. And finally, the second main model was proposed which is a budget allocation model. It has delivered recommendations to prioritize stations for rehabilitation action and applied two sets of variables.

In all of the aforementioned studies, the models were subjective and dependent on the visual inspection reports. Therefore, they have lacked the objectivity in quantifying and estimating the severity of defects. As a result, more accurate condition assessment techniques are essential in order to acquire reliable results and improve the quality of inspection in concrete infrastructure. This paper presents an auto inspection system that is capable of accurately detecting, analyzing, and evaluating the condition, as well as reducing the inspection time and cost in subway systems. The frame work of the methodology is based on image processing techniques.

3 RESEARCH METHODOLOGY

The main concept of the imaging data model is to acquire digital images of surface defects in subway network, and apply different image processing techniques to make these defects more distinguishable and suitable for computing purposes. Figure 1 presents the model architecture which is based on applying different image processing algorithms.
Figure 1: Image data analysis and assessment model
Step 1
Images of the components of subway system were obtained using a digital camera. The images contained different visible defects on the structure’s surface, such as cracks, moisture marks, scaling, spall ...etc. as shown in Figure 2. A digital camera (Canon EOS Rebel XS, 10.1-magapixel) with a high resolution of 2592x3888 pixels was employed to acquire images for concrete surfaces. Afterwards they were transferred to the computer to be processed. This research takes spall defects that are visible on subway concrete surfaces as an example for the proposed methodology.

![Images showing different surface defects](image1.png)

(a) Cracks on lower slab  (b) Moisture marks on upper slab

(c) Scaling on upper slab  (d) Spall on lower slab

Figure 2: Different surface defects in subway networks

Step 2
The term “image” could be defined as a two dimensional (2D) function $f(x, y)$, where $f$ denotes the gray-level or intensity of the image at spatial coordinate point $(x, y)$ which corresponds to each pixel in the image (Gonzalez and Woods 2008). A digital image could be represented as a matrix which includes a large number of elements called pixels. Generally, the images are either gray-level images or color images. A gray-level image is a black-and-white image which has one matrix only, and the elements of the matrix represent pixels’ intensity values. Normally, matrix values in a digital image range from 0 to 255. A color image is an RGB image which is formed of three planes; red, green, and blue as depicted in Figure 3. It is necessary to split the RGB image into three planes in order to choose the plane which demonstrates the best visualization and to facilitate image enhancement and detection processes. The acquired images in this research were RGB images, they have been split into the three planes and the red plane was selected so that it can be processed later.

![RGB image planes](image2.png)

Red Plane  Green Plane  Blue Plane

Figure 3: The three planes of RGB image
Step 3

One of the most significant methods is thresholding the image through segmentation. Thresholding is the method of separating the object of interest from the background of the image. It is a binary transformation of the gray-level into either black or white intensity levels. Accordingly, matrix elements of a binary image have either zero or one value. Figure 4 shows a binary transformation of an image.

![Figure 4: Binary transformation of the image](image)

The selection of the best threshold value of a gray-level image is correlated to plotting its histogram. Therefore, the position of best threshold value will be specified. Figure 5 illustrates a histogram of a gray-level image. The horizontal axis represents the intensity of gray-level and the vertical axis is the frequency of occurrence of a pixel value in the image.

![Figure 5: Gray-level image and its histogram](image)

Step 4

It is quite useful to apply some morphological algorithms on the binary image, especially for the detection of boundaries. There are other techniques and filters which can be used concurrently with these algorithms, such as hole filling, thinning, thickening, etc. One of the basic algorithms which is used for filling holes in the image is developed on incorporating dilation, complementation, and intersection. Dilation is the process of thickening the boundaries of an object in a binary image (Gonzalez and Woods 2008), hence the object will be clearly visualized. Figure 6 depicts the processed image after using different morphological operations on the binary image including thinning, dilation, and hole fillings.
Before evaluating the condition of any element using image analysis, the images should be calibrated by setting the appropriate scale. A commercially available software ImageJ was used for processing and scaling the images. Prior to uploading, processing and scaling the images by the software, the length of spall (object) has been measured in situ so that it can be set as an entry data in the software. Thereby pixel values will correlate with actual measurements allowing all possible measurement to be done on the image. Subsequent to scaling the image, the defect has been selected, hence it is possible to obtain feature attributes such as area, percentage area, perimeter, width, lengths of major and minor axes, mean, standard deviation, etc. Figure 7 illustrates scaling the image and selecting the defect using the analysis software. For the purpose of evaluating the condition of a component in this research, only the spall area and its percentage in that component were taken into consideration.

**4 RESULTS FROM MODEL**

The proposed imaging data model was applied on a station in Montreal’s subway network. A total of 50 images were acquired for the upper and lower slab surfaces of the station for the objective of quantifying and measuring the defect (spalls). Table 1 summarizes the assessment results for a sample of 10 images acquired for the station slabs. These images targeted spall distress which is visible on the components'
surfaces. The defect (spall) area and spall percentage in each image were calculated using the proposed model. For example, from table 1, image number 6 which has been used in the image processing of this research, was processed by the model and demonstrated the largest area of 224 cm$^2$, thereby acquiring 57% of the whole slab area and considered a severe defect. Whereas, image number 3 showed the smallest area of 6.88 cm$^2$, thus acquiring 1% of the whole slab area and considered as a minor defect. The proposed assessment methodology was validated by taking actual measurements for the spall defects in Montreal subway station. Then area and spall percentage calculations were performed on each defect and compared to the calculations obtained from the model. The results showed that image-based model had an accuracy of 98% in detecting, measuring and evaluating surface defects in subway infrastructure.

5 SUMMARY AND CONCLUSION

This paper presented a framework which applies image processing techniques for the detection and quantification of surface defects in subway networks. The imaging data model was realized by following five steps, each step comprised the utilization of several algorithms. In the first step, images for different surface defects have been acquired by a digital camera, then they were transferred to the computer to be processed. Step two included exploring the color space and extracting three planes for the purpose of selecting the best visualized plane to be further processed. Thresholding the gray-scale image and plotting its histogram was the approach applied in the third step to be followed by using some morphological operations such as image thinning, dilation and hole filling in the fourth step. And finally, the image has been calibrated and feature vectors such as area, percentage area, width, etc. were obtained. The proposed methodology was applied on segments of Montreal's subway system. The case study results were compared to the results taken from ground measurements, thus demonstrated a high accuracy of 98% in assessing the severity of defects. This proves the robustness of the proposed model in enhancing the quality and consistency of condition assessment, as well as, reducing the cost and time required to inspect subway networks.

FACTORS IMPACTING SELECTION OF CONSTRUCTION SUBCONTRACTORS

Maryam Ghaffari Dolama1,2 and Farnaz Sadeghpour1
1 Department of Civil Engineering, University of Calgary, Calgary, Canada
2 maryam.ghaffaridolam@ucalgary.ca

Abstract: A considerable portion of the work in construction projects is carried out by subcontractors. The current lowest bid practice, in which the main contractor offers a subcontract to the bidder who submits the lowest price, is considered to leave subcontractors with very low profit margins, and with a lack of motivation to provide high quality work. Selecting appropriate subcontractors is consequently seen as contributing significantly to a project's success. Although subcontractors are mainly selected by the main contractor, as one of the influential contributors to the project, the choice of subcontractor will also affect other project stakeholders such as owners and consultants. The goal of this study is to identify the factors that different project stakeholders consider important when selecting subcontractors, and the extent to which their professional background affects the way they view selection factors used for subcontractors. To this end a questionnaire was designed and distributed among construction industry experts in Alberta, Canada, from three groups of general contractors, owners, and consultants with various professional backgrounds. The survey results verified that the factors identified in the survey were in fact those that were considered in the selection of subcontractors. Based on statistical analysis of the survey results in most cases, respondents from the contractor group associated a different degree of importance to each selection factor compared with consultants and clients. The level of importance associated to each selection factor was found to be more similar among the latter two groups. Interestingly the lowest bid price was not necessarily ranked highest by professionals within all background groups.

1 INTRODUCTION

A considerable portion of the work in construction projects is carried out by subcontractors. Consequently, selecting appropriate subcontractors contributes to a project's success (Hartmann et al. 2009). The literature around selection criteria has been mostly focused on choosing main contractors. These studies mainly focused on the selecting based on the low bidding price versus considering multi-criteria selection method.

A research study conducted in Singapore examined the relative importance of different factors in selecting a subcontractor by the main contractor. A survey was conducted to ask contractors which of the four factors of price, technical know-how, quality, and cooperation would affect their decision in selecting a subcontractor. Professionals from 221 construction firms in Singapore responded to the survey. In order to find out if these criteria play an important role in selecting subcontractors, contractors were asked to rank the level of importance they associated to the four selection factors. Based on the survey results, contractors perceived all four factors important in selecting subcontractors. They were then asked to do a discrete choice experiment and express their preference based on a number of hypothetical scenarios.
Interestingly, the discrete choice survey results showed that price is a predominant basis for the choice decision. While low bidding price accounted for 50% of the contractor’s decision, a subcontractor’s attractiveness could be increased by the other three factors of quality of the work, its cooperation and technical know-how respectively. In addition, it was shown that under equal conditions, previous relationship with the main contractors could work to subcontractor’s advantage (Hartmann et al. 2009).

A study in Pakistan examined the overall contractors’ satisfaction with the quality of services provided by subcontractors (Choudhry et al. 2012). A survey was conducted to investigate the extent and involvement of construction firms in subcontracting, reasons for subcontracting, and the selection criteria of subcontractors. The study found that the most widely used method for selecting a subcontractor was using a preference list that individual contractors prepared, generally based on the previous working experience with subcontractors. The second most common method was negotiation, while open bidding was the least preferred method. This study also found that out of five selection factors of price, quality, ability to complete work on time, subcontractors’ resources, and personal relationship, the most important criterion was the bid price, followed by the ability to complete the work on time and the quality of the work, respectively. Moreover, the study identified a high level of consistency in the opinions of the three groups (clients, consultants, and contractors) on the selection criteria of subcontractors (Choudhry et al. 2012). The objective of this study is to identify the factors that are deemed important in selecting subcontractors in Canada. The study will examine these factors not only from contractors’ perspective, but also from the perspective of experts from client and consultant organizations. This will enable a comparison of how experts at different roles in the industry view these selection factors.

2 METHODOLOGY

With the objective of the study in mind, a survey questionnaire was designed, consisting of two parts: The first part of the questionnaire contained general questions to identify the respondents’ professional background, including the relevant industry sector and segment, and level of experience. This part included seven questions which were considered independent variables in the consequent statistical analysis. The second section consisted of the proposed subcontractors’ selection factors. Twelve factors were surveyed in this section. Respondents were requested to rank them on a scale of 1 to 5 as shown in Table 1 below. These factors were treated as dependent variables.

</tbody>
</table>

The questionnaire was used to survey different professionals involved at various roles in the construction industry in Alberta, and the collected data was then statistically analyzed. A total number of 137 professionals from different walks of industry were surveyed. The participants were contacted through three modes of communications: in person (34.3% of responses), by email (62% of responses), and by regular mail (3.6% of responses). The following two sections provide summary of the survey results for the two parts of the questionnaire.

3 SURVEY SUMMARY: DESCRIPTIVE STATISTICS

3.1 Part I: Professional Background

In the first part of the survey, participants were asked seven questions regarding their professional background. Below is the summary of their responses:

**Industry sector [P1]:** 32.8% of the respondents were from the public sector and the remaining 67.2% from the private sector.
Role of the organization [P2]: 31.4% of the respondents worked for a client (owner) organization, 49.6% for contractors and 19% were from consulting firms.

Construction segment [P3]: 13.9% of the participants were involved in projects related to the residential construction 18.3% in non-Residential construction, 26.3% in heavy infrastructure construction, and 65% in industrial construction. As it can be inferred from the distributions, some participants were active in more than one section.

Years of experience in the construction industry [P4]: 29.9% of the participants had less than 5 years of experience in the construction industry; 31.4% had between 5 to 10 years of experience and the remaining 38.7% had more than 10 years of experience.

Years of experience in Alberta [P5]: 44.5% of the participants had less than 5 years of experience in Alberta’s construction industry; 32.8% had 5 to 10 years and 22.6% had more than 10 years of experience. A comparison of these percentages with those of the previous question can reflect the share of participants with larger years of experience in construction (more than 5 years) who have moved to Alberta.

Involvement in selecting subcontractors in projects [P6]: About 60% of the respondents were involved in selecting subcontractors in less than 10 projects and the remaining 40% in more than 10 projects.

Direct experience in working with subcontractors [P7]: 78.8% of the participants had experienced directly working with a subcontractor, and the remaining 21.2% lacked such experience.

3.2 Part II: Subcontractor Selection Criteria

In the second part of the survey, the respondents were asked to rank the importance of twelve factors in the selection of subcontractors on a scale of 1 to 5 as shown in Table 1. Below are the results of the second part of the survey:

Subcontractor’s experience in similar projects (F1): 0.7% ranked this factor very unimportant, 2.9% good to have, 38.7% important and 57.7% very important.

Subcontractor’s familiarity with the local market (F2): 0.7% ranked this factor very unimportant, 9.5% unimportant, and 42.3% good to have, 34.3% important and 13.1% very important.

Subcontractor bidding for the lowest price (F3): 10.2% considered this factor unimportant, 35.8% good to have, 24.1% important, and 29.9% very important.

Compliance of the subcontractor’s submitted schedule with the project’s overall schedule (F4): 1.5% considered this factor very unimportant, 22.6% unimportant, 11.7% good to have, 33.6% important, and 30.7% very important.

Subcontractor’s financial strength (F5): 23.4% ranked this factor very unimportant, 5.1% unimportant, 18.2% good to have, 36.5% important, and 16.8% very important.

Subcontractor’s available resources (F6): 1.5% ranked this factor very unimportant, 2.9% unimportant, 8% good to have, 54% important, and 33.6% very important.

Subcontractor’s reputation in the construction industry (F7): 2.9% considered it unimportant, 38% good to have, 39.4% important, and 19.7% very important.

Presentation of a solid execution plan in subcontractor’s proposal (F8): 3.6% ranked this factor very unimportant, 15.3% unimportant, 29.9% good to have, 34.4% important, and 19.7% very important.

Subcontractor having a well-defined quality assurance and quality control (QA/QC) program (F9): 1.5% categorized this factor as very unimportant, 1.5% unimportant, 31.4% good to have, 41.6% important, and 24.1% very important.
Subcontractor’s past safety record and having a health and safety program (F10): 2.2% ranked this factor very unimportant in their selection, 7.3% unimportant, 27% good to have, 23.4% important, and 40.1% very important.

Qualification of the key project personnel (F11): 5.1% ranked this factor very unimportant, 8% unimportant, 16.15% good to have, 45.3% important and 25.5% very important.

Previous positive business relation with the subcontractor in other projects (F12): 3.6% considered it very unimportant, 15.3% unimportant, 33.6% good to have, 33.6% important and 13.9% very important. Figure 1 shows the mean score of rankings for the above twelve factors. It is interesting to note that the mean score for all the questioned criteria ranges from 3 to 4.5. This shows that the participants found all the identified factors relevant to the selection of subcontractors, and therefore, provide an indication that they were selected appropriately.

![Figure 1: Mean score of factors impacting the selection of subcontractors](image)

4 ANALYSIS OF THE SURVEYED DATA

In order to examine the existence of significant relationships between the respondents’ professional background and how they ranked factors that affect the selection of subcontractors, a cross tabulated analysis of the survey data was carried out. Depending on the number of choices available to answer a question related to an independent variable, either t-test or ANOVA test were used. Whenever the number of choices in answering a question related to the professional background (independent variables) was limited to two mutually exclusive groups (e.g. P1-Industry Sector: Public or Private), t-test was applied to identify whether the difference in the answers of these two groups were statistically significant. For example, the average score that professionals from the two groups of Public and Private sectors (P1) gave to the importance of subcontractor’s experience on similar projects (F1) was 4.53 and 4.52, respectively. Therefore t-test was used to see if the 0.1 difference in their average scores is statistically meaningful or it was created by randomness. However, when the independent variable was composed of more than two mutually exclusive groups, (e.g. Role of respondent’s organization (P2): owners, contractors, or consultants), ANOVA test was applied to examine statistically significant difference between their opinions on a specific selection factor. If the result of the ANOVA test proved that there is significant difference, then the groups’ responses were compared two by two using the t-test to
find out which group’s opinion was significantly different than the others. The statistical analysis was conducted using the statistical package for social science (SPSS).

In total, 142 tests were conducted to examine the existence of significant relationships between the independent and dependent variables in the survey. At a 95% confidence level, 69 of the examined relationships were statistically significant. In other words, 5% possibility of type I error was accepted in this study which is what is commonly accepted in the similar studies (Winer 1971). Table 2 summarizes those relationships with P values less than 0.05. This section provides a brief explanation of the significant relationships organized based on the independent variables.

4.1 Industry Sector [P1]

As it can be inferred from Table 3, the public and private sectors had different opinions about the importance of the most of factors influencing the selection of subcontractors. The mean values in Table 3 indicate that professionals from the public sector ranked schedule compliance (F4), financial strength (F5), execution plan (F8), QA/QC plan (F9), safety record (F10), qualification of the key project personnel (F11), and previous business relationship with subcontractor (F12) higher than those professionals from the private sector. On the other hand, professionals from the private sector put higher importance for the low bidding price (F3) than their counterparts in the public sector.

4.2 Role of the Organization [P2]

As shown in Table 4, this study could not find a correlation between the type of organization that the respondents worked and their ranking for the importance of subcontractors’ experience in similar projects (F1), available resources (F6), and safety reputation (F9). Professionals working in contractor organizations ranked the importance of lowest bid price higher (μ= 4.2) than those from clients and consultant organizations (μ= 3.28, μ=3.19, respectively). Those from owner organizations associated a higher importance to compliance to the schedule (F4), safety record of the subcontractor (F10), and qualification of the subcontractor personnel. Interestingly, professionals from the consultant firms associated a higher value to all the factors except for the lowest bidding price. In general, it appears that professionals from consultant and owner organizations associated closer importance to most of the factors compared to those from contractor organization (see average values in Table 4).

4.3 Construction Industry Segment [P3]

Since respondents could be involved in projects that belonged to more than one construction segment (Residential buildings, Non-residential buildings, Infrastructure, and Industrial projects), they could select more than one answer for this question (i.e. answers were not mutually exclusive). Therefore four separate t-tests were carried out to identify possible relationships between the involvement in each
industry segments and the ranking of the factors (Tables 5). Professionals from the residential segment associated a high importance to almost all factors except for familiarity with the location market (F2) and lowest bid price (F3). Those involved in non-residential building construction found compliance of the subcontractor’s schedule with the project schedule (F4) and subcontractor’s execution plan (F8) were the most important factors. Professionals from heavy construction segment also found compliance to project schedule (F4) an important factor, along with subcontractor’s safety record (F10), and qualification of the personnel (F11). Those from industrial construction projects considered all factors as good to have.

</table>
4.4 Years of Experience in the Construction Industry [P4]

An interesting split was observed when studying the effect of years of experience on ranking the factors considered in selecting the subcontractors. As it can be seen in Table 6, respondents with low experience (less than 5 years) and those with high experience (more than 10 years) had a more similar opinion than those with medium experience (5 to 10 years). The latter group ranked the lowest bidding price (F3) higher than their counterparts with higher and lower years of experience (µ= 4.19 versus 3.43 and 3.66). Conversely, respondents with both less (less than 5 years) and higher experience (more than 10 years) associated higher level of importance on a good number of factors including the subcontractor’s familiarity.

with the local market (F2), schedule compliance (F4), financial strength (F5), reputation in the industry (F7), safety record (F10), previous business relationship (F12). The less experience professionals ranked having a well defined execution plan (F8) higher than those with more experience. The rest of the factors had the same level of importance for the surveyed professionals regardless their years of experience.

4.5 Years of Experience in Alberta [P5]

Similar to the years of experience in previous section, statistical analysis, as summarized in Table 7, revealed that respondents with less (less than 5 years) and those with higher experience (more than 10 years) in Alberta had a more similar opinion about the importance of factors than those with medium experience (5 to 10 years). The first two groups ranked subcontractor’s schedule compliance (F4), financial strength (F5), and previous relationship (F12) higher than professionals with medium experience in Alberta (5 to 10 years). Similar to previous section, the latter group ranked the lowest bidding price higher than their counterparts with less and more experience in Alberta. Subcontractor’s execution plan (F8) was more important to respondents with less than 5 years experience in Alberta and the remaining selection factors had equal degree of importance for respondents from all three groups. Therefore, in general it appears that the experience in Alberta will not significantly change the ranking of factors compared to experience from other parts of the world.

4.6 Involvement in Selecting Subcontractors [P6]

Professionals who were involved in selecting subcontractors in more than 10 projects ranked the importance of lowest bid price (F3) slightly higher (µ= 3.98) than those involved in selection of subcontractors in less than 10 projects (µ= 3.57). However, the rest of the factors received a higher score from professionals with less involvement in selecting subcontractors. Particularly in cases of compliance of schedule (F4) and financial strength (F5), the gap of opinions was considerable (Table 8).

4.7 Direct Experience in Working with Subcontractors [P7]

Respondents’ without direct experience in working with a subcontractor put more importance on the subcontractor’s familiarity with the local market (F2), financial strength (F5), having a solid execution plan (F8) and a positive relationship than those with direct experience in working with subcontractor (Table 9).
Those with direct experience in working with subcontractors ranked the lowest bidding price (F3) higher. However, both groups had the same idea on the importance of the remaining selection factors.

5 SUMMARY AND CONCLUDING REMARKS

This study presented a survey of the factors that are deemed important when selecting subcontractors for construction projects. 137 construction industry professionals were surveyed. About two-thirds (67%) of the participants were from the private sector and the remaining from the public sector. The majority of participants were from contractor organizations, accounting for almost half of the population, followed by those from the owner organizations. Most of the participants were active in the industrial construction segments (64%), followed by the heavy infrastructure. While more than two thirds (70%) of the participants had above 5 years of experience in the construction industry, only slightly over half of the participants (55%) had more than five years of experience in Alberta. This gap can be reflective of the percentage of immigration of experienced professionals to this province. Around 40% of respondents were involved in selecting subcontractor in more than 10 projects and about 80% had direct experience in working with subcontractors, which may support the reliability of their responses.

Based on the survey result, the lowest bid price was the most important selection factor for participants from construction contractors and professionals with medium range (5-10 years) of experience in the construction industry in Alberta, those involved in selecting a subcontractor in more than 10 projects and with direct experience in working with subcontractors. Experience in similar projects was most important to professionals from residential segment. Familiarity with the local market was deemed most important by those from the consultant firms. Compliance to the project schedule was seen important by professionals from public sector, those from owner and consultant firms, those involved in residential segment, less than 5 years of experience in construction industry and involved in selecting subcontractors in less than 10 projects. Financial strength and reputation of subcontractor was scored highest by professionals from consultant firms and those involved in residential segment. Professionals from public sector, those with owner and consultant firms, those involved in residential segment, those with little experience in selecting subcontractors found the quality assurance program of subcontractors an important factor. Safety records and qualification of the personnel was scored highest by public sector, owner and consultant firms, residential and heavy segment, and those with little experience in selecting subcontractors. Interestingly, the consultants were the only group that associated a high important to the previous relationship with the subcontractor.

A STATISTICAL SAFETY CONTROL MODEL FOR CONSTRUCTION SITES USING LOCATION SYSTEMS

Tsah Edrei\textsuperscript{1}, Shabtai Isaac\textsuperscript{1,2}

\textsuperscript{2} corresponding_author_isaacsh@bgu.ac.il

Abstract: A statistical safety control model is presented that utilizes data from a Real Time Location System of relatively low accuracy, to alert of unsafe situations at construction sites. Based on the Statistical Process Control methodology, predefined statistical rules are used to detect trends of increasing exposure to hazards, and provide proactive alerts before a critical exposure takes place. An initial verification of the performance of the model was carried out through extensive laboratory tests.

1 INTRODUCTION

Various studies indicate that the incidence rate of fatal workplace accidents in the building industry, with an estimated 60,000 fatal casualties a year around the world, is higher than in any other industrial sector (Aires et al. 2010). The most common cause for fatal accidents on construction sites is usually falling from heights (Aneziris et al. 2012; Wu et al. 2010). In recent years, a number of studies have been dedicated to the improvement of safety on construction sites through the application of a Real Time Location System (RTLS) in order to track the movement of workers and prevent accidents from occurring (e.g. Nattichia et al. 2013; Maalek and Sadeghpour 2013). The main purpose of the RTLS is to facilitate an alert when a worker enters an area that has been defined as being of "high risk". Such an approach can be considered deterministic, and requires a highly accurate tracking system in order to be able to detect in real-time when a worker moves from a low risk area to a high risk area.

Highly accurate indoor tracking systems such as Ultra Wide Band (UWB) (i.e. systems that, unlike standard GPS, can be used inside buildings that are under construction) are relatively expensive technologies that require significant time and effort to deploy (Khoury and Kamat 2009). Other, less expensive technologies such as WLAN-based tracking systems are economical but provide a much lower accuracy (i.e. 1.5 to 2 m, as opposed to centimeter level positioning accuracy for UWB). Such a low accuracy is not compatible with a deterministic approach, in which any penetration into a high risk area needs to be immediately identified.

An additional factor that needs to be taken into account, in the application of a RTLS to improve worker safety on construction sites, is the high uncertainty that typically exists regarding expected worker locations. This uncertainty stems from the fact that the project plan often does not reflect in real time decisions on changes that are made by the project management team (Isaac and Navon 2013). In addition to that, even an accurate and up-to-date project plan cannot fully reflect the complexity and unpredictability of worker movements, which often deviate from expected work envelopes (Isaac and Navon 2013).
The use of a RTLS on construction sites can therefore enhance worker safety. However, the economic rationale for using a cheap but inaccurate RTLS, and the uncertainty regarding actual worker behavior onsite, means that one might not be able to rely solely on the definition of safe work areas with clear-cut boundaries, and deterministic alerts in case these boundaries are crossed. In fact, the uncertainty regarding worker behavior may imply that improving the accuracy of real-time location measurements is likely to be less beneficial than is often assumed. Transgressions on the site are likely to be frequent, due to both workers entering dangerous areas, and the location of those areas changing in ways that differ from the project plan. One solution could be to compensate for the expected inaccuracy and uncertainty by significantly enlarging the areas defined as being of high risk, and therefore off-limits for most workers on site. However, this would reduce the efficiency of the construction processes.

An additional limitation of the current deterministic approach for applying RTLS systems to enhance construction worker safety is the fact that for some safety risks, the temporal dimension is of importance. In other words, the duration of risk exposure has to be taken into account. For example, in case of a hazardous noise exposure, the duration of exposure is an essential factor. The current deterministic approach for using a RTLS for safety control on construction sites therefore has three main limitations:

1. It requires highly accurate and expensive tracking systems
2. It is not fully compatible with the highly uncertain nature of construction projects
3. It does not take into account the duration of risk exposure, which is of importance for certain hazards.

In order to provide an answer to these limitations, the present research is based on a statistical approach that complements the existing deterministic methods. Specifically, this research deals with the development of a statistical safety control model that utilizes data from a RTLS, with the objective to alert of unsafe situations at construction sites of multistory buildings. An unsafe situation is defined here as one that causes workers to be exposed to hazards which were initially created by other teams of workers. While there are many methods and models available to assess the risks that the workers’ own activities pose to themselves, few studies have dealt with the hazards derived from the concurrent activities of other workers on site to which workers are also frequently exposed (Hallowell et al. 2011).

2 THE PROPOSED STATISTICAL SAFETY CONTROL MODEL

The proposed model is implemented in four modules, as follows:

1. Identification of hazards which are related to the execution of an activity;
2. Risk assessment according to a structured method (though sufficiently flexible to accommodate different types of hazards);
3. Division of the site into risk areas according to predefined parameters of injury level and distance from hazard;
4. Definition of safety zones using a statistical methodology.

In the first module, an identification of potential hazards, based on the construction site layout and the project's schedule, is required before carrying out an activity. The related hazards are those to which other teams might be exposed. This stage contains several sub-stages. Preliminary Hazards Analysis breaks down the activity into a chain of actions. This list of actions makes it easier to detect the hazards. Following this, the required work area is analyzed in terms of the type of space, and the expected worker movement patterns. This is done in order to identify the potential teams that might be exposed to the related hazards.

In the second module, a risk assessment of the identified hazards is carried out. The assessment is defined by 2 parameters: 1) the level of the potential injury when an accident occurs, based on the classification of the Israel Institute for Occupational Safety and Hygiene; 2) The distance from the
hazards, taking into account different factors such as the RTLS accuracy, the movement velocity of the workers, data processing by the RTLS, worker reaction time to alerts, etc.

In the third module, the construction site is divided into risk areas. This division is a product of the risk assessment. The combination of assessments regarding injury level and distance from hazards creates a matrix which defines the risk level at a certain location. There are several risk area categories, as follows: very high, high, medium and low risk. The main applicable difference between those areas is the level of hazard exposure to which non-authorized teams are allowed. In fact, the risk area classification defines the level of tolerance towards the presence of non-authorized workers in a certain risk area. Therefore, each worker must be familiar with the risk area classification.

In the fourth module, statistical safety zones are defined. This stage is related to the statistical operation. Therefore, statistical alerts rely on this division. The main impact of the division is the definition of a “medium risk” area, where the proposed statistical model can provide benefits not provided by deterministic models. The medium risk area may appear to be "free" of hazards, since the risk is not defined there as critical or immediate. However, a continuous exposure to a certain hazard may harm a worker, or might increase the probability that that worker will penetrate into the high risk area. Therefore, the model contains several statistical rules that detect an increasing exposure to a hazard, and that provide alerts before a critical exposure occurs.

The remainder of this paper will focus on the fourth module, which is based on an existing methodology of process management, called Statistical Process Control (SPC).

3 STATISTICAL PROCESS CONTROL (SPC)

SPC is a statistical methodology for process management, which has been mainly used for quality control in manufacturing. SPC uses statistical tools to observe specific characteristics of the manufactured product, and identify significant variations in those characteristics. Instead of defining deterministic rules for rejecting a product that does not meet certain specifications, SPC assumes that some variation in the process is to be expected, and that only a statistically significant variation needs to be addressed, and the factors causing it identified. The assumption in SPC is that the measured characteristic of a specific object has a normal distribution, which distributes symmetrically around the Mean ($\mu$), with three zones defined according to the Standard Deviation ($\sigma$):

1. Zone1: ~68% of population, which defined as: $\mu \pm \sigma$;
2. Zone2: ~95% of population, which defined as: $\mu \pm 2\sigma$;
3. Zone3: ~99% of population, which defined as: $\mu \pm 3\sigma$;

An application of the SPC methodology for safety control on construction sites, instead of for quality control in manufacturing, obviously requires significant adjustments. Firstly, it is assumed, based on the Central Limit Theorem, that the distribution of the movements of workers will be normal relative to the main “work” location. Secondly, the division into zones is based on safety aspects. Thus, Zone1 is related to a low risk area, Zone2 and Zone3 are related to a medium risk area, and all locations above Zone3 are related to a high risk area. The hypothesis of the present research is that a statistical model can deal with issues such as the relatively low-level accuracy (2m) of a cost effective RTLS and the high uncertainty regarding workers’ movements, by providing alerts based on a statistical analysis of locations within medium risk areas, in addition to the existing deterministic alert when a worker enters a high risk area. In practice, such medium risk areas would constitute buffers between planned work areas and areas identified as being of high risk to the workers.

The application of SPC for quality control is based on certain statistical rules. The rules that are nowadays commonly used in the manufacturing industry were defined in the middle of the 20th century by an American company called Western Electric Company (Western Electric Co. 1958). These rules can be used to detect statistical trends relative to the desired mean, based on the expected normal distribution.
For example: measurements that fall within Zone3 have a low probability (under 1%), and are therefore considered abnormal. Other rules are based on sequential measurements related to the predefined zones and their probabilities. For example: the probability of four out of five consecutive measurements being in Zone2 or Zone3 is about 3%, and therefore considered to be statistically significant.

An advantage of the statistical approach is thus the ability to detect trends of increasing exposure to hazards by calculating sampling rates, either for a single worker or an entire crew. This supports proactive actions in the form of alerts, which are received before a critical exposure takes place. As will be demonstrated, the model can ensure that alerts will not be ignored, by using such statistical rules to avoid an excessive number of alerts, and by discerning who should be the client of an alert. We can thus increase both safety and efficiency (in terms of multiple teams working simultaneously on site). This, on contrast to the present situation, in which areas with moderate risk exposure levels are either ignored (therefore increasing safety risks), or included in deterministic no-entry zones (therefore reducing the efficiency of the construction processes).

4 IMPLEMENTATION OF THE MODEL

The implementation and initial verification of the model was based on laboratory tests that were carried out at the Structural Engineering Department at Ben-Gurion University of the Negev, Israel. Simulated movements of workers were monitored in the department using a Wi-Fi-based RTLS that was installed for this purpose. The RTLS included Access Points, Low Frequency tags and a software platform. The accuracy of the RTLS was 2 meters, and it was chosen due its low cost, which is expected to increase the likelihood that it will be used in actual construction projects. In fact, this type of RTLS is based on a regular Wi-Fi network that is installed in any case in most buildings. The only extra costs would therefore be those of the tags, which can be reused from one project to another. It was assumed that the implementation of a statistical model would make it possible to overcome the relatively low accuracy of the RTLS.

For the tests, one floor of the department was divided into three different zones and a high risk area. The location of those zones changed in the tests according to different scenarios of construction activities that were defined. The definition of the zones according to one such scenario is shown in Figure 1. Zone1 (related to a low risk area) is shown in green, Zone2 and Zone3 (related to a medium risk area) are shown in yellow, and the high risk area is shown in red. During the tests, teams of participants carrying tags moved around the department and their locations were tracked. These locations were then converted into their distance from a simulated hazard location, according to the scenario.

Using the model, different types of alerts were provided. These included alerts related to a penetration into a high risk zone, as well as statistical alerts according to the predefined rules. The model was used to track movements and provide statistical alerts at 3 different levels:

- At the level of a single worker (Figure 2);
- At the level of a team of workers (Figure 3);
- At the project level (Figure 4).
The trend charts in Figures 2-4 present the locations of the tags that were tracked in tests, relative to the statistical zones. The horizontal axis is the time axis, whereas the vertical axis presents the location of a tag relative to the predefined statistical zones. Black marks indicate locations for which statistical alerts were provided. These alerts depend on the definition of the statistical zones, which depend, in turn, on the structured risk assessment that was carried out. The alerts can be related to a single worker (when the location of that worker deviates from the safe work area), to an entire team (for example, when the team starts working in a medium risk area), or to all the teams (when a certain event or management decision puts them in danger). Accordingly, the clients of such alerts can be the worker, a site manager, or the company administration.

![Trend chart of employee #4 in one of the tests](image1)

**Figure 2: Trend chart of employee #4 in one of the tests**

![Trend chart of Team #2 in one of the tests](image2)

**Figure 3: Trend chart of Team #2 in one of the tests**

![Trend chart of all the Teams](image3)

**Figure 4: Trend chart of all the Teams**

The verification criteria for the testing of the statistical model were based on a comparison of the alerts provided by the model, with a manual measurement of the duration for which participants were located in
a certain zone. The results of this comparison reveal that about 7% of the samples in the medium risk area were mistakenly identified as being in a high risk area (i.e. a false alert) (Table 1). In addition, about 12% of the samples in the high risk area were mistakenly identified as being in a medium risk area. One might assume that in those cases in which the second type of error occurred, the risk potential was high, since there wasn’t any deterministic alert of the participant entering a high risk area. However, all of those cases were in fact detected through the statistical rules in the model, and statistical alerts were accordingly provided. Therefore, all of the events in which a worker would have been exposed to a high risk, were either warned of through a deterministic alert of a penetration into a high risk area (~88% of the events), or through a statistical alert that was provided according to the predefined rules in the model (the remaining ~12% of the events). Nevertheless, it should be noted that an implementation of the model in a real project, would of course include an adjustment of the model’s parameters in order to improve its accuracy.

5 CONCLUSIONS

A statistical model was developed in this research, with the objective to alert of unsafe situations on construction sites. The model utilizes data from a cost-efficient, yet relatively low-accuracy RTLS, to prevent workers from being exposed to hazards which were initially created by other teams of workers. The statistical approach complements existing deterministic models by detecting trends of increasing exposure over time to hazards, and providing proactive alerts that are received before a critical exposure takes place. This enables it to deal with issues such as a high uncertainty regarding workers’ movements on construction sites, which is usually not observed in other types of industry.

The results of the laboratory tests show that the model has the ability to overcome the medium accuracy of the RTLS, based on the division of the site into statistical zones. In addition, it was found that the percentage of errors in zone identification is about 10%. Nevertheless, the statistical rules were found to be efficient, since all the critical zone detection errors that were related to a penetration into a high risk area would have been prevented by alerts provided according to the predefined statistical rules, and this in turn would have prevented the entrance of workers into a high risk area. Obviously, these results still have to be confirmed through an implementation in a real construction project.

Abstract: As highways deteriorate over time, it is necessary to execute preventive interventions to ensure that they continue to provide an adequate level of service. As the execution of interventions on highways almost invariably results in the interruption to traffic flow, it is often beneficial to group interventions. By grouping interventions into workzones, there is, for example, less lane changing required by vehicles traveling on the highway and, therefore, perhaps fewer accidents. The objects included in the optimal workzones depend on many factors, such as the condition/performance of the objects, the length of the workzone, the traffic configuration within the workzone, the length of time required to execute the interventions, and the budget available. Recent research by Hajdin & Lindenmann (2007) and Lethanh et al. (2014) has been focused on the development of optimization models to solve such problems. One difficulty with them though is the construction of the set of possible combinations, which was done manually. Once large networks are to be analyzed this is no longer possible. In this paper, a routing algorithm is presented that can be used together with these optimization models to automatically establish the combination matrix, taking into consideration constraints on the length of the workzone and the distance between workzones. The algorithm is developed in Matlab and empirically tested on a real world road network, with 671 km of roads and 567 objects including bridges, tunnels, and road sections. The state of each object is classified on a discrete scale of 5, with 1 being the best and 5 being the worst. Several scenarios based on setting constraints on maximum workzone length, and minimum distance between two adjacent workzones are used to verify the robustness of the algorithm. It is found that the algorithm is both efficient and fast for all scenarios investigated. The development potential, in particular with respect to integration in GISs, is discussed.

1 INTRODUCTION

Road networks are comprised of different types of objects, such as road sections, bridges, and tunnels. These objects are subjected to deterioration and, therefore, interventions (e.g. repair, rehabilitation, replacement) need to be executed to ensure that they continue to provide adequate levels of service. When an intervention is executed on an object, a workzone has to be set up to ensure that the intervention can be executed. When there are more than one object on which interventions are to be executed there is the possibility of grouping multiple objects within one work zone. Whether or not they are included, however, depends on their closeness to each other, the benefits of grouping them together as opposed to establishing separate work zones and constraints, such as the amount of funding
available, the maximum allowed length of a work zone, and the minimum allowed distance between workzones. An infrastructure manager is, of course, interested in determining the set of workzones.

The importance of having an optimal set of workzones can be simply explained with the following fictive road link consisting of 2 lanes comprised of five objects (Figure 1). Object 1, 3, and 5 are in states in which interventions are required while object 2 and 4 are in states in which no interventions are required.

![Figure 1: Possible sets of workzones (WZ) for a road link of five objects](image)

With 3 objects on which interventions are to be executed, there are 9 possible sets of workzones. The sets of workzones from 1 to 4 are possible when there is sufficient amount of budget. Whilst, in the sets from 5 to 9, a workzone might not include objects that require intervention due to limitation in the amount of budget. It is assumed that within a workzone, one lane is closed while the other lane is opened with a restriction on speed. In workzone set 1, there are 3 workzones. However, in workzone set 2, there are 2 workzones and one of the workzone includes objects 1, 2, and 3. In this workzone, there is no intervention on object 2 because it is still in good state. However, restriction on speed limit of vehicles is still applied. This is because it is not feasible with regard to the capacity of traffic control to allow 2 lanes of traffic flows in opposite directions in a short distance. Evidently, the impacts on stakeholders are different for each set of workzone, e.g. with workzone set 1, the owner of the road would have higher setup costs than with workzone set 2, where the users if the road could have higher additional travel time costs.

The problem of determination of optimal workzones undoubtedly becomes challenging when: 1) there is no longer a road link of only a few objects but a network of hundreds or thousands objects; 2) objects are not homogeneous sets but they are a mix of many different types of objects; 3) there are more than one intervention type or traffic configuration to be considered for each object (e.g. traffic flows for a road section of 4 lanes can be formed with more than one configuration).

Recently, research work focused on solving this problem has been conducted, but there are still improvements to be made before implementation is possible. One of the pioneer research was the work of Hajdin & Lindenmann (2007) and Hajdin & Adey (2005), which presented a linear optimization model to determine a single workzone, but not multiple workzones. In setting up the model, it is a must to construct two matrices: the continuity matrix and the combination matrix. These two matrices have to be setup so that input parameters (e.g. intervention cost, long-term benefits) related to each object and to any possible workzone can be estimated when the optimization model runs. In Hajdin & Lindenmann (2007), the authors verified the robustness of the model with a simple example of a road link with 36 objects. They setup the two matrices manually and thus it was possible with the size of the example. However, it is a tedious process and thus not possible if the size of the link becomes a network of hundreds or thousands objects and with a network having looping structure. This was done similarly in Hajdin & Adey (2005).

\footnote{a set of workzones can either be a single workzone or a group of multiple workzones}
The approach emphasized in these two papers was extended from one work zone to multiple work zones in the work presented by Lethanh et al. (2014), using a mixed-integer linear model. This also involved the introduction of maximum length of a workzone and minimum distance between two adjacent workzones constraints. This work was, however, also done by setting up the continuity and combination matrices manually.

In order to overcome the limitation of having to do this, it is necessary to develop a routing algorithm that allows a computer program to generate the two matrices giving only initial information such as the numbers of objects, numbers of nodes, maximum workzones length, and minimum distance between two adjacent workzones. The goal of the work presented in this paper was to develop such an algorithm.

The remainder of the paper is set-up as follows. The optimization model of Lethanh et al. (2014), which is the model that this work is based on, is described in the following section. Section 3 contains the developed routing algorithm. An example on a road network with 567 objects is shown in Section 4. The last section concludes the paper with highlighted points and elaborates recommendations for future extension of the work.

2 THE MODEL

The objective function is

\[ \text{Maximize } Z = \sum_{n=1}^{N} \sum_{k=1}^{K} \delta_{n,k} \cdot (B_{n,k} - C_{n,k}) \]

where \( \delta_{n,k} \) is a binary variable, which has a value of 1 if an intervention of type \( k \) is executed on road segment \( n \) and 0 otherwise. \( B_{n,k} \) and \( C_{n,k} \) are the long term benefit and cost of executing an intervention of type \( k \) on object \( n \), respectively.

Subject to the following constraints:

Continuity

\[ \sum_{n=1}^{N} \sum_{k=1}^{K} \delta_{n,k} = 1 \]

This constraint enforces the model to select only one intervention of \( k \) on object \( n \).

Budget

\[ \sum_{n=1}^{N} \sum_{k=1}^{K} \delta_{n,k} \cdot C_{n,k} \leq \Omega \]

The budget for executing interventions on the network is in general limited. The total cost of all interventions on the network cannot exceed a certain threshold \( \Omega \) for a given planning period.

Maximum workzone length

\[ \sum_{l=a_l^w}^{e_l^w} \sum_{n=a_n^w}^{e_n^w} \lambda_{l,n} \leq \Lambda_{\text{MAX}} \forall w \]

where \( \lambda_{l,n} \) is the length of the object \( [l,n] \); \( a_l^w \) \((l=a_l^w, n=a_n^w)\) is the first object of the workzone \( w = (1,...,W) \), and object; \( e_l^w \) \((l=e_l^w, n=e_n^w)\) is the last object in the workzone. \( \Lambda_{\text{MAX}} \) is the maximum length of the workzone.
Minimum distance

\[ \sum_{l=1}^{d_l} \sum_{m=1}^{d_m} \lambda_{l,m} \geq \Lambda^{MIN} \quad \forall d \]

where \( a^d \left( l = a^d_i, n = a^d_n \right) \) is the first object the default section \( d \); \( e^d \left( l = e^d_i, n = e^d_n \right) \) is the last object of the default section \( d \); \( \Lambda^{MIN} \) is minimum distance between two workzones.

Combination of maximum workzone length and minimum distance

The maximum workzone length and the minimum distance between workzones constraint is merged into one constraint by defining a combination matrix of objects within the network that cannot be subjected to an intervention simultaneously.

\[ \sum_{n=1}^{N} \sum_{k=1}^{K} \delta_{n,k} \cdot \gamma_{n,k,i} \leq 1 \quad \forall i \]

\( \gamma_{n,k,i} \) is a 1-by-J matrix, with I is the total number of rows and each row contains an object combination that cannot be selected simultaneously.

3 THE ROUTING ALGORITHM

The algorithm was described in this section using an example of a network comprised of 45 objects and 31 nodes with an equal length of 5 km per object (Figure 2). The maximum length of any workzone and the minimum distance between two adjacent workzones are 15 km.

In Figure 2, objects and nodes are indicated by numbers with no circles and numbers with circles, respectively. This network is different from the examples used in Hajdin & Adey (2005); Hajdin & Lindenmann (2007); and Lethanh et al. (2014) in that it has loops. The looping structure of the network becomes an obstacle when having to construct the combination and continuity matrices, which represent all possible ways to form a workzone starting from the first object in the workzone. The main task of the proposed algorithm is to calculate all the possible paths in the network taking into consideration both maximum workzone length and minimum distance between two adjacent workzones. Matlab code for each step is publicly available at Github repository\(^2\).

3.1 Maximum workzone length

For a given object \( n \) in the network, the algorithm calculates all paths starting with this object (max-paths). The lengths of these paths are defined as the sum of the lengths of the objects. The paths are then stored

\(^2\) https://github.com/namkyodai/workzone-routing-algorithm
in a matrix format. For example, with object 1, there are in total 6 paths that can be formed (solid thick lines in Figure 3 and combination of objects in Table 1).

### 3.2 Minimum distance between two adjacent workzones

The algorithm calculates, for a given object \( n \), all paths starting with this object (min-paths). Objects are added to a min-path as long as the min-path's length is smaller than the minimum distance between workzones. The length of a min-path is defined as the sum of the lengths of its objects minus the length of the first object in the path. Thus the number of objects in the paths for the minimum distance is defined as the sum of the lengths of its objects minus the length of the first object in the path. The total number of paths starting with an object for the minimum distance constraint is significantly larger than the total number of paths starting with that object for the maximum work zone length. The following figure and table illustrate the matrix formation for the minimum distance constraint.

<td></td>
</tr>
</tbody>
</table>

![Figure 4: All paths starting after object 1](image)
It can be seen that a min-path has its total length greater than the maximum workzone path. For example, path 10 is comprised of objects 3, 6 and 8 with its total length of 15 km. Then if the object 1 is selected to be in a workzone, the other workzone can only be formed after object 8.

3.3 Impossible object combinations

After all max-paths and min-paths for all objects in the network have been identified, the algorithm searches for a set of impossible object combinations. Impossible object combinations are pairs of network objects that violate the maximum workzone length constraint if they are to have interventions simultaneously. For example, if object 1 is part of a workzone, impossible object combinations are objects that are too far away to be part of the same workzone as object 1, but too close to be part of an adjacent workzone (they are objects 8, 11, 12, 15, and 18 (Table 3)).

Table 3: Impossible object’s combination starting from object 1

</tr>
<tr>
<td>Invalid combination</td>
<td>- - - - - - 8 - 11 12 15 18</td>
</tr>
</tbody>
</table>

3.4 The combination matrix

The combination matrix is a m-by-n matrix where m is the number of constraints and n is the sum product of all the objects in the network and the number of intervention. The number of impossible object combinations and thus the number of constraints depends on the difference between the thresholds for the minimum distance between work zones and the maximum work zone length constraints. With increasing difference between these two thresholds, the number of impossible object combinations grows greatly with the number of constraints. Below is an example of the formulation of linear constraints for the impossible combinations with respect to object 1.

Table 4: Combination matrix starting from object 1

| Objects 1 1 2 2 3 3 4 4 5 5 6 6 7 7 8 8 9 9 10 10 11 11 12 12 12 |
|---------------------------|---------|
| Interventions 0 1 0 1 0 1 2 0 1 2 0 1 2 0 1 2 0 1 2 0 1 2 0 1 2 |
| Binary 0 1 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1 0 1 |

| WZs 1-8 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 0 0 0 0 0 |
| WZs 1-11 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 1 0 0 |
| WZs 1-12 0 1 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 0 1 1 |

In Table 4, the interventions to be executed on multiple objects can be seen. There are 2 types of interventions for objects 1, 2, denoted 0 and 1, and 3 types of intervention for objects 7, 8, 10, 11, and 12, denoted 0, 1 and 2. Interventions denoted as "0" are the “do-nothing” interventions, i.e. there is no physical intervention executed and there is no change to the traffic configuration. Interventions denoted 1 and 2 are combinations of a physical intervention type and a traffic configuration. If intervention 1 or intervention 2 is selected, then the object is included in the workzone. Otherwise it is not. The binary values appeared in the combination matrix (refer to Eq. [6]) become 1 when it is impossible to form two workzones adjacent to each other. This binary value will be multiplied with the binary in the upper part of the table to give a possible workzone. This means that in Table 4, objects 1 are in a work zones, and objects 8, 11 and 12 are not in a work zone.

3.5 The continuity matrix

The continuity matrix ensures that exactly one intervention is selected for every object in the network. The continuity matrix is a p-by-n matrix where p is the number of objects in the network and n is the sum product of all the objects in the network and the number of intervention.
Table 5: Continuity matrix

| Interventions | 0 | 1 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 | 0 | 1 | 2 |
| Binary        | 1 | 0 | 1 | 0 | 0 | 1 | 0 | 1 | 0 | 1 | 0 | 0 | 1 | 1 | 0 | 0 | 1 | 0 | 0 | 0 | 1 | 0 | 0 | 1 | 0 | 0 | 1 | 0 | 0 | 1 | 0 | 0 |

The right hand side of the continuity matrix shows the number of connections for every object. For example, object 1 is connected to two adjacent objects and object 2 is connected to four adjacent objects.

3.6 Example results

The optimal set of workzones for the simplified example is illustrated in Figure 5. Workzones (shown with thick lines) have been identified and all constraints have been satisfied.

![Figure 5: Result of the simplified example](image)

4 Example

To demonstrate the robustness and efficiency of the routing algorithm, it was used to determine optimal work zones for a road network comprised of 567 objects with a total length of 671 km was tested.

For every object, three types of interventions can be executed: 1) Intervention type 0: Do nothing; 2) Intervention type 1: Low benefit intervention; 2) Intervention type 2: High benefit intervention. All objects are considered to be in one of five discrete states, with worsening physical condition from state 1 to state 5. Executing interventions on objects in state 1 yield low benefits whereas intervening on objects in state 5 yield high benefits. The exact values are given in Table 6. States for objects were randomly generated, but once determined, they were used for all investigated scenarios.

4.2 Scenarios and results

Four different scenarios were investigated by means of changes in the budget, the maximum workzone length and the minimum distance between workzones. The optimal sets of workzones were obtained by running the optimization model for these scenarios (Table 7).

<td>6'108</td>
</tr>
</tbody>
</table>

In scenario 1, the budget is restricted to 50 mus, the maximum workzone length and the minimum distance between workzones are set to 5'000 m. For this scenario, the final version of the optimization model contains a total of 2'911 constraints, and once run the interventions to be executed in the optimal work zones are determined to provide a benefit of 483.3 mus.

In scenario 2, the budget and the maximum workzone length remain unchanged (with respect to scenario 1), whereas the minimum distance between workzones is increased to 8'000 m. Due to this increase, the gap between the minimum distance between workzones and the maximum workzone length increases. The larger gap (3'000 m) between those two workzone constraints causes the number of combination constraints to rise and the total number of constraints reaches 6'109. The number of continuity constraints remains the same for all four scenarios. A slight drop in the value of the objective function is observed from 483.3 to 456.2.

In scenario 3, the minimum distance between workzones remains constant (with respect to scenario 2). The budget is lowered to 40 mus and the maximum workzone length is increased to 6'000 m. This increase reduces the gap between both work zone constraints from 3'000 to 2'000 m and thus the number of impossible object combinations drops again. Scenario 3 has a total of 5'196 constraints. The decrease in the value of the objective function is caused by the reduction in the available budget.

In scenario 4, both workzone length constraints are equal to scenario 2, whereas the budget constraint is lifted. The total number of constraints decreases from 6'109 to 6'108 (no budget constraint).

A strong increase in the total number of objects to have an intervention from 29 to 176 is observed due to the unlimited budget. However, the value of the objective function rises only by a factor of 2. This is because, in the first three scenarios, the objects to have an intervention are mainly in condition states 4 and 5. In scenario 4, a lot of objects in good condition states and thus lower benefits are subject to interventions because of the unrestricted budget.

In all scenarios, computational time was less than 5 minutes on a normal lap top computer (32 bits, 4 GB RAM, Dual-Core Intel 2.53 GHz). This infers the power of computation and robustness of the model with

\(^3\) mus stands for monetary units
respect to the size of network, especially when comparing with the manual setup, which might not be feasible with such a network.

4.3 Graphical representation of optimal workzones

Figure 6 illustrates parts of the optimal sets of workzones for the four scenarios. The nodes represent interventions and they are notated in the format of xx.yy, with xx being the object number and yy being the intervention. Workzones are highlighted in rectangular boxes. It can be seen how the optimal workzones changes with the changes mentioned in the previous section.

![Graphical representation of optimal workzones](image)

Figure 6: Sets of workzones under 4 different scenarios

5 CONCLUSION

In this paper an efficient routing algorithm to be used to formulate two matrices (the continuity and combination matrices) for a mixed-integer linear optimization models is presented. Such an algorithm is

---

4 Intervention includes physical intervention types and traffic configuration
beneficial if models developed to solve network problems, such as those developed by Hajdin & Adey (2005); Hajdin & Lindenmann (2007); and Lethanh et al. (2014) are to be expanded to large networks and networks that contain loops. Setting up the combination and continuity matrices, if done manually, is not possible when there are hundreds and thousands of objects in a road network. However, with the developed algorithm (coded in Matlab), they can be generated with ease. In addition, the algorithm allows construction of these two matrices taking into consideration looping structures of a road network.

The algorithm was verified with examples of two simplified road networks: one with a small size network with only 45 objects to describe the algorithm step by step; the other with a large scale network of 567 objects to demonstrate the robustness and efficiency of the algorithm.

With the development of this algorithm a substantial barrier to the implementation of these types of optimisation models has been removed, in the effort to automate the determination of optimal work programs, which are made of work zones, for large road networks. Further work will be focused on testing this algorithm and much larger networks and integrating it into geographical information systems.

Abstract: Natural disasters leave the impacted regions with financial burdens both on the individual and governmental levels. Thus, the goal of the associated stakeholders is to maximize the host communities' welfare through minimizing their post-disaster financial burdens. Accordingly, this paper attempts to find a post-disaster insurance plans equilibrium so as to mitigate the financial impacts associated with the natural disasters. Utilizing an evolutionary game theory approach, the equilibrium is investigated between three different players including: resident families purchasing insurance plans; insurance companies offering different insurance plans; and the government agency that implements post disaster relief financial plans. The authors determined a set of decision actions as well as utility functions for the aforementioned stakeholders. Moreover, the authors created a hypothetical sample of 1,000 heterogeneous income level resident families, three insurance companies offering three unique and different insurance plans per company and two post disaster financial relief plans to be utilized by the government agency. The proposed model was implemented on NetBeans IDE 7.4 platform using JAVA programming language on the hypothetical case study simulating resident family evolutionary learning process in reaching an equilibrium. The results indicate that: (1) resident families tend to prefer insurance plans with the least premium value and coverage; (2) insurance plans with the most comprehensive coverage received the least demand; and (3) the evolutionary stable strategy path oscillates between chosen plans and insurers over time as a result of the stochastic and dynamics nature of the factors associated with disaster management. Currently, the authors are working to develop the model further to better account for simultaneous actions by all stakeholders (not only resident families), population growth and changes in financial and income standards. Ultimately, this evolutionary game theory model will be tested on real post natural disasters data representing physical damages in coastal Mississippi Counties post Katrina, so as to determine the significant increase in the host community welfare.

1 INTRODUCTION

Mitigation of the financial impacts associated with natural catastrophes is becoming a focal issue at both the national and international levels as the rate and magnitude of natural disasters are increasing. According to Climatic Change Science Program (2008) and the National Association of Insurance
Commissioners (2005), recent examples in the United States include (1) Hurricane Andrew in 1992 which caused $20.9 billion in insured losses; (2) the Northridge earthquake in 1994 which resulted in insured losses of $15.9 billion; (3) the four Hurricanes Charlie, Ivan, Frances and Jeanne in 2004 which caused $21.9 billion in insured losses; (4) Hurricane Wilma and Rita in 2005 which resulted in insurance losses of $11.9 billion; (5) the devastating Hurricane Katrina in 2005 which caused economic losses approaching $125 billion; (6) Hurricane Ike in 2008 that resulted in $19.3 billion in property damages; and (7) Hurricane Sandy in 2012 which incurred damages more than $68 billion.

Disaster insurance plays a significant role in the mitigation and preparedness phases of the emergency management. However, there are important gaps in the knowledge-base for emergency management and financial disaster mitigation. Past studies have primarily addressed the challenge of disaster risk management by segregation of the problem without concern of the integration of how these parts fit into a decision making tool that integrates the goals, objectives, perceptions, and beliefs of multiple agents in determining a set of social optimum strategies to mitigate the financial impact of future disaster damage.

2 GOALS AND OBJECTIVES

Using an evolutionary game theory approach, this paper aims to find an equilibrium profile of post-disaster insurance plans purchased by resident families, sold by insurance companies, and ex post disaster relief implemented by a government agency. This should identify the optimal balance between: (1) number of plans offered by insurance companies; (2) types of plans that should be selected by each type of resident family based on their income level; and (3) compensation ratio that the government will pay for each resident family to offset the post-disaster damages. This dynamic integrated assessment minimizes the total losses for the three aforementioned associated stakeholders, thus maximizing welfare within natural disaster host community systems.

3 BACKGROUND INFORMATION

Natural hazards damages have reached a record level causing around 800,000 fatalities last decade as well as damages in the infrastructure of over a trillion dollars (Economics of Climate Adaptation Working Group 2009; Stern 2006). Decision makers nationwide, in both public and private sectors, are concerned about the vulnerability of their economy to natural hazards. They face investment choices in a stochastic environment with overlapping risk factors. These risk factors consist of wind, flooding, fire, and earthquakes, as well as climate change and their effects on investments. Also, as population and economies continue to grow, the total value at risk from natural hazards will increase (Climatic Change Science Program 2008). Research has been conducted by governmental, private, non-profit and academic organizations and institutions to study, assess, and solve problems associated with disaster financial mitigation. Most of these valuable efforts generally fall into three main streams including loss estimation models, computational engineering approaches, and risk management using insurance.

3.1 Loss Estimation Models

Since the 1980s, a number of major impact assessment models have been developed to support disaster preparedness and recovery efforts. For example, HAZUS-MH is a hazard prediction software program developed by the Federal Emergency Management Agency under a contract with the National Institute of Building Sciences to estimate potential losses from earthquakes, hurricane winds, and floods (HAZUS-MH 2007; Pradhan et al. 2007). Loss estimation models provide increasingly comprehensive estimates of regional risk, but offer little guidance about how to use that information to make damage mitigation resource allocation decisions (Dodo et al. 2005). These models can estimate losses in relation to structural damage, contents damage, time-based impacts, and only a small set of predefined mitigation alternatives can be considered (Grossi and Kunreuther 2006). However, they are not able to account for the stakeholders’ side including costs of the alternatives, the budget, and the specific objectives and priorities of each stakeholder (Federal Emergency Management Agency 2003; Dodo et al. 2005).
3.2 Computational Engineering Approaches

Computational engineering approaches have been used extensively for studying and mitigating the financial impacts from natural catastrophes including:

- **Deterministic Net Present Value (NPV):** Altay et al. (2002); and Kuwata and Takada (2003) calculated the avoided loss as the difference between the losses estimated with and without implementation of the mitigation alternatives.

- **Stochastic NPV:** Englehardt and Peng (1996) estimated probability distribution of the benefits associated with revising hurricane requirements and compared it with the cost of implementing the revision. Werner et al. (2002) compared various levels of proposed seismic design or upgrade on both means and standard deviations of losses.

- **Optimization Models:** Augusti et al. (1994) used dynamic programming to select structural mitigation alternatives. Researchers at the International Institute for Applied Systems Analysis (IIASA) developed a spatial-dynamic stochastic optimization model to select the insurance policy design that maximizes profits and minimizes risk of insolvency for insurance companies (Ermoliev et al. 2000; Ermolieva et al. 2001; Brouwers et al. 2001). Dodo et al. (2005) developed linear program for resource allocation in earthquakes that incorporates spatial correlation among a set of mitigation alternatives, associated probabilities, and decision timing.

3.3 Risk Management Using Insurance

Insurance is utilized to spread the financial risk of loss resulting from low frequency-high consequence disastrous events (Kunreuther and Michel-Kerjan 2007). Insurance companies have made significant changes in their approaches to provide coverage for natural hazards (Muller 2008; Mills 2007). Capital market participants developed catastrophe bonds, which are a type of securities that can be purchased by institutional investors to cover certain insurer risks (Cardenas 2006). Proposals have been made to Congress and regulatory agencies to take additional steps in changing the U.S. tax laws and accounting standards to allow insurers to set aside funds on a tax deductible basis and establish reserves for hazards (Smetters and Torregosa 2008; Cardenas 2006). However, these reserves lower federal tax receipts and do not necessarily bring about a meaningful increase in the capacity of the insurance industry. This is because insurers may substitute their reserves for other types of capacity (Shear 2005).

More analytically, Picard (2008) investigated the equity-efficiency trade-off faced by policy makers under imperfect information about individual prevention costs. His research highlighted the complementary relationship between individual incentives tax cuts and collective incentives grants to the local jurisdictions where natural hazard insurance plans are enforced. Chen et al. (2008) studied the determinants for the short-run position resulting from ex-ante insufficient premium and the long-run position resulting from ex-post insurance supply reductions. Greiving et al. (2006) studied the spatial limitations of the Natural Hazard Index for Mega Cities as well as the Total Place Vulnerability Index, and developed an integrated hazards map that combines regional hazards and vulnerability. Also, research revealed that while catastrophe insurance is more price elastic than non-catastrophe insurance in cities like New York, responsiveness to price is inelastic in the coastal areas because price increases only with mandatory purchase by mortgage borrowers (Grace et al. 2004; Kriesel and Landry 2004).

The aforementioned research illustrate several models that asses disaster damages and how to financially mitigate the impacts of disasters on the existing environment and host community. However, few to none discuss the social and individual decision process for selecting an insurance company given their preference for different disaster insurance plans. To this end, this research aims to utilize Evolutionary game theory to simulate residences’ post disaster learning to better guide the disaster...
insurance plans selection. This research will also guide insurers on how to determine an optimal array of plan premiums and coverages that will eventually be accepted by the community over time.

4 METHODOLOGY

In order to attain the aforementioned goal and objectives, the authors utilized the following three-step research methodology: (1) determined the set of possible actions and utility functions that govern the strategy profiles of the associated stakeholders including resident families, insurance companies, and government; (2) utilized the evolutionary stable strategy profile amongst the aforementioned players using game theory; and (3) applied the proposed model to a hypothetical dataset as a proof of concept.

5 ASSOCIATED STAKEHOLDERS: ACTIONS AND UTILITY FUNCTIONS

As previously mentioned, the stakeholders are resident families, insurance companies, and the government. The resident families and insurance companies will be represented by a population of players while the government is represented as a single player. Thus, it is worth noting that selecting a specific insurance plan will affect the resident family player through determining the amount of money spent on the premiums and the compensation obtained from insures in case of an occurrence of a natural disaster. This will also affect the insurer in term of earned revenue (i.e. the amount of premiums collected) and the amount of compensation paid out in case of a natural disaster event occurrence. Moreover, after calculating the post disaster damages for the residential sector, and taking into account the compensation by the insurer, the government compensation can be likewise calculated.

5.1 Resident Families

Each property owner player has a set of actions to choose from, \( A = \{a_{(n,i)}\} \), where \( A \) is the set of possible actions, and \( a \) is the chosen insurance coverage plan \( n \) offered by the associated company \( i \). In selecting a plan at each iterative step \( t \), each resident considers their current wealth, the indemnity received from the insurance company if a natural hazard causes damages to the residence building, the amount of tax paid and the compensation paid by the government post disaster as shown in Eq. (1).

\[
W_p(t) = W_p(t+1) - P(n,i) - T - D(t) + C(n,i) + G
\]

Where \( W_p(t+1) \) is the amount of wealth of a property owner \( p \) at time \( t+1 \), \( P(n,i) \) is the insurance premium paid by a property owner to insurance company \( i \) using plan \( n \), \( T \) is the taxes paid to the government, \( D \) is the damage cost by natural disaster at time \( t \), \( C(n,i) \) is the compensation paid by the insurance company \( i \) if the property owner is using plan \( n \), and \( G \) is the compensation paid by the government. Also, it is worth noting that utility does not govern actions. Generally speaking, players maximize their utility by choosing their optimal actions subject to their beliefs of the actions taken by their rivals. In evolutionary games, the players observe the payoffs of others and mimic those with superior outcomes.

5.2 Insurance Companies

A successful strategy for post disaster damage mitigation should decide on the type of coverage provided by the insurer and the premium structure (Jaffee et al. 2008). However, there are two main concepts that may negatively affect the optimum strategy profile. First, adverse selection as the pool will contain mostly high risk resident families and so the insurance company will keep the premium at a fair rate (Janssen and Karamychev 2005). It is noted though that insurers can change rates to overcome the problem of adverse selection. Second, moral hazard as losses will always be not in the favor of the insured pool and thus the insurance will not change the situation or mitigate the damage for the insured party (Lee and Ligon 2001; Breuer 2005; Doherty and Smetters 2005). This emphasizes the need of an optimum post-disaster insurance plan strategy profile where a selective value of premiums and coverage values should be determined as well. These issues can be handled by allowing the insurer to be myopic in their product offerings and learn from their rivals given the distribution of population types per contract. A decision for
each company is to determine the distribution and pricing of plans to offer the population of resident families. Accordingly, the insurer utility function is shown in Eq. (2).

\[ W_i(t+1) = W_i(t) + \sum R \]

Where, \( W_i(t+1) \) is the insurance company \( i \) wealth at time \( t + 1 \). \( R \) is the aggregate monetary utility gained by an insurance company by calculating the difference between the sum of the premiums paid by the residents and the sum of the indemnities paid to the residents when a natural hazard event occurs. Thus, \( R \) is equal to the \( P(n,i) - C(n,i) \) for every resident that purchased the insurance plan \( n \) from company \( i \).

5.3 Government

State protectionism is essential for a post natural disaster relief. This can be achieved by subsidizing the insurance costs on families or financially aiding families in reconstructing their damaged homes and reconstructing the state damaged infrastructure during the disaster event. The government action will determine the financial compensation for damaged houses post a natural disaster event. The government utility function is simplified to the difference between its current wealth, obtained through tax payments, and compensation paid to the families as showed in Eq. (3).

\[ W_G(t+1) = W_G(t) + \sum (T_p - G_p) \]

6 EVOLUTIONARY GAME THEORY

Game theory is the study of the ways in which strategic interactions among economic agents produce outcomes with respect to the preferences (or utilities) of those agents, where the outcomes in question might have been intended by none of the agents (Samuelson 1997). Since Von-Neumann and Morgenstern (1944), game theory has been used in many different research areas (i.e. economics, biology, engineering, political science, computer science, and philosophy) because of its advantage of a natural and plausible representation of strategic interaction between individuals, organizations, and countries (Son and Rojas 2011). In evolutionary games, a large population of individuals, each having their own actions and strategies, meet in an environment to determine their optimum strategy profiles depending on their payoffs (Samuelson 1997). In other words, evolutionary game theory allows imperfect players to learn from observations. The dynamics are based on the assumption that each strategy is played by a certain fraction of individuals at each moment of the game (Turocy et al. 2001). Inspired by Darwin theory of survival of the fittest, stakeholders having better than average payoff will be more successful and more likely to survive in the next round. Those players who chose strategies that result in less than average payoffs update their strategic choices to mimic (replicate) those making above average payoffs (Samuelson 1997). The replicator dynamics govern the law of motion for the game, and are unique to each stakeholder group. Thus, one would not expect a resident final payoff to equal that of the insurance company or government. A basic requirement in evolutionary games is that a set of strategies is evolutionary stable if for any mutant strategy (perturbation) in the game; the non-mutates must result in a higher payoff than the mutant strategy (Weibull 1995; Smith and Price 1973). Evolutionary game theory has been applied in Economics (Cressman 1995, Friedman 1998), and explored by mathematicians (Hofbauer and Sigmund 2003). However, as far as the authors’ knowledge, there is no implementation for the Evolutionary game theory in the construction management research.

7 PROPOSED MODEL: SOLUTION PROCESSES

The solution processes for the proposed model consider: (1) the post-disaster insurance plans selected by each resident family from the different insurance companies, (2) the premium value charged as per the distribution of contract types offered by each insurer for each plan, and finally (3) the government post-disaster damage compensation ratio. At this stage, as an initial step, the data associated with the three main stakeholders is entered into the model. For resident families, the model requires the population size, the ratio between different income families (i.e. poor, medium, and high), income and current wealth, and a random initial set of selected plans and insurance companies. For the insurance companies data about
the number of associated insurers, different plans offered, premiums, compensation ratios, and wealth of the insurance companies including relationship with reinsurance companies. For the government, the tax rate should also be set as well as an initial percentage of the collected tax amount to be dedicated to post natural disaster mitigation plan. Last, the nature, as a Pseudo player, should also be set in this step including determination of type of hazard accompanied with its characteristic parameter such as severity, frequency, and return period. This information will help the model to create an initial random population of players that have their own actions, and measuring their utility function after the disastrous event, and choose the fittest parents of the population for future evolution.

7.1 Updating Utility Functions for Associated Players

This step depends firstly on the occurrence of disaster or not, and the damage rate for each family residence. Determining that, the model can estimate the loss and calculate the associated compensation ratio by the insurers and the government. The total change of any player's utility will be equal to the difference of the utility function prior and after the disaster occurrence as shown in Eq. (4-6):

[4] For resident families: \[ \Delta W_p = W_p(t+1) - W_p(t) \]
[5] For the insurance companies: \[ \Delta W_i = W_i(t+1) - W_i(t) \]
[6] For the local government: \[ \Delta W_G = W_G(t+1) - W_G(t) \]

Through Eq. (4-6), the relative fitness of each player for every stakeholder can be calculated as shown in Eq. (7) & (8): This is carried out by dividing the player’s (resident family or insurer) change in the utility function’s value by the total change in the utility values for all the players of the same type. Thus, the players with higher positive changes in the utility values will have higher relative fitness values, so as other (lower relative fitness value) players will chose to mimic them – via replicator dynamics – by duplicating their actions and decisions in the next time steps. It is worth noting that there is no relative fitness for the local government as there is only one government player in the game.

[7] For resident families: \[ \text{Relative Fitness}_p = \frac{\Delta W_p}{\sum (\Delta W_p)} \]
[8] For the insurance companies: \[ \text{Relative Fitness}_i = \frac{\Delta W_i}{\sum (\Delta W_i)} \]

8 MODEL IMPLEMENTATION

The authors created a hypothetical sample including: (1) 1,000 resident families taking into account the different level of income; (2) three insurance companies with three different insurance plans available per company, each with different premium percentage to the family house value and different compensation ratio; and (3) two different type of government compensation plans for post disaster damage mitigation. Realizing how complex the evolutionary game theory model between the three associated stakeholders can be, and in order to focus more on the foundational and fundamental steps associated with the model development, the authors treated the resident families as the principal controller of the game’s environment and that insurance companies and the government are supportive players for analysis. The model was implemented on NetBeans IDE 7.4 platform using JAVA programming language.

To this effect, the resident family population is randomly created with 20% under poverty level, 60% of average income and 20% of high income level. The initial insurance plan and insurance company are created randomly for each family, where the three generated insurance companies’ premiums percentages as well as the coverage compensation ratios are given in Table 1. In addition, the government offers plan (A) of compensation percentages of 10%, 15% and 20% or plan (B) of a compensation percentage 15%, 20% and 25% of the damages to the property for the high, medium and poor level income families, respectively. Also, for the sake of simplicity for this model, the probability of windstorm occurrence per time period in the implementation process is set to 95% with damages
accounting for a minimum 10% of the house value up to totally damaged (100%). In addition, convergence was checked every 10 years as to find a similarly steady state when the number of families changing their plans does not exceed 15% of the total family number. The presence of a complete steady state is not practical as nature’s changing weather continuous to plagues the model’s attempts to converge into one.

9 RESULTS AND ANALYSIS

The proposed model output for each of the three player types was extracted from the computer model and analyzed to determine the evolutionary stable strategy profile. As an overview, Figure 1 illustrates the evolution process of the families in their choices over the three insurers. To this end, it was clear that families tend to avoid the costly premium of insurer # 3 even though it gives the highest coverage rates to even a full coverage. Figures 2-4 illustrate the changes in selection of the insurers for each family level.

Figure 1 (left): Overall Families Choices of Insurance. Figure 2 (right): Insurers and Poor Income Families

Figure 3 (left): Insurers and Medium Income Families. Figure 4 (right): Insurers and High Level Families

Reviewing the results illustrated in Figures 2-4, it is obvious that both poor and medium income level families tend over time to avoid Insurer # 3 and prefer more Insurer # 1 than # 2, this is due to the high premium costs of insurer # 3’s plans that doesn’t pay off as well as the low ones by insurers #1 and #2. On the other hand, high income level families are found to be indifferent between the three insurers as the premium costs (high or low) cut only a small portion of their income and would all pay off similarly. Figures 5-7 illustrate the resident families’ choices of the different plans by each insurer. Through these
results, it is observed that insurance plans with the most comprehensive coverage received the least demand. Table 2 presents the targeted percentage of each resident type for each insurer company.

![Graphs showing population over time for different plans](image)

</table>

The aforementioned results illustrated the choices of the three income level family types over the insurance companies’ proposed insurance plans. The results make it advisable for the insurance companies to propose more of the least premium plans to both poor and medium level income families to increase their sales as they are the most demanded ones, as shown in Figure 5-7. As for the government, the choice between plan A and plan B varied through the first two thirds of the time period and settled on plan B as the evolutionary stable strategy profile, which is more or less the same period when the families players are getting deterministic on their plans.

### 10 CONCLUSION AND FUTURE WORK

Natural disaster damages have reached record levels and decision makers nationwide are concerned about the vulnerability of their economy to natural hazards. Their situation is extremely difficult as they are faced with making investment choices in an ever changing stochastic environment with overlapping risk factors. This study utilized evolutionary game theory to identify the optimal balance between: (1) number of plans offered by insurance companies; (2) types of plans that should be selected by each type of resident family based on their income level; and (3) compensation ratio that the government will pay for
each resident family to offset the post-disaster damages. To this end, the authors developed a computer model on NetBeans IDE 7.4 platform using JAVA programming language, and applied it to a hypothetical case study that involves resident families, insurance companies, and the government. Realizing how complex the evolutionary game between the three associated stakeholders can be, and in order to focus more on the foundational and fundamental steps associated with the model development, the authors treated the resident families as the principal controller of the game’s environment and that insurance companies and the government are supportive players for analysis. This proof-of-concept analysis revealed that: (1) resident families tend to prefer insurance plans with the least premium value and coverage; (2) insurance plans with the most comprehensive coverage received the least demand; and (3) the evolutionary stable strategy path oscillates between chosen plans and insurers over time as a result of the stochastic and dynamics nature of the factors associated with disaster management. Based on the results of the hypothetical case study, the authors will develop the model further to take into account simultaneous actions by all stakeholders as well as changes in the social parameters. Furthermore, more investigation will be carried out on the stakeholders' preferences and how they approach risk. Also, an effort will be directed towards integrating input from existing natural hazard prediction software systems (for example, HAZUS-MH) with the new evolutionary game theory model for a more precise simulation of the hazard characteristics. Moreover, based on the positive results associated with the model implementation, the authors are currently working to apply their model to data associated with Hancock County, Mississippi for a way more comprehensive analysis.

3 oh.elanwar@cu.edu.eg

Abstract: Executing construction projects in densely populated areas can have significant impacts on the residents’ quality of life during the construction phase. The social and economic impacts of dense-urban construction are reported for projects undertaken in planned areas as well as unplanned areas (such as slums and squatters). These impacts include residents’ relocation, roads closure, loss of businesses’ income, high noise levels, and temporary disruptions to essential services. On the other hand, socioeconomic disruptions resulting from poorly planned projects in densely populated areas generate resistance among residents to the executed projects, which in turn affects the success of the these projects. The objective of this paper is to present an assessment model capable of estimating and quantifying the level of socioeconomic disruptions expected to be experienced by residents of densely populated areas. This assessment model utilized GIS capabilities and can evaluate candidate construction plans in order to support decision makers in planning for such challenging projects. To this end, this model incorporates four newly developed socioeconomic metrics that are designed to assess (1) the travel delays due to roads closure and detours; (2) number of relocated residents during construction; (3) loss of income due to businesses closure or reduced accessibility; and (4) inconvenience due to high noise levels. In order to demonstrate the model capabilities, its assumptions, and underlying computations, a case study of an upgrading project in a densely populated area in Giza, Egypt is presented.

1 INTRODUCTION

There is a continuous increase in the population density in urban areas, which in turn imposes new construction management requirements for urban construction (Maas and Gassel 2005; Guglielmetti et al. 2008). Nowadays, a significant number of construction projects take place in congested urban sites (Gilchrist et al. 2002), which result in affecting the social and economic welfare of the local residents during the construction phase. For instance, highway construction and repair projects are reported to cause traffic congestions in the surrounding areas leading to travel delays (Tighe et al. 1999; Gilchrist and Allouche 2005). Furthermore, the population density around construction sites introduces a series of socioeconomic challenges that impact the project success, which include the disruptions due to cutting services, road closures, businesses loss of income, and residents’ relocation (El-Anwar and Abdel Aziz 2014). Another challenge associated with construction operations and activities is the increasing levels of the ambient noise that have severe impacts on the nearby residents (Weixiong 2008).

Slums upgrading projects (as a major example for dense urban construction) is investigated in several previous studies (Abiko et al. 2007; The Cities Alliance 2008; and Viratkapan and Perera 2006). These
studies reported a number of social, economic, construction and logistics challenges in and around slums upgrading projects, which makes them quite distinct and complex than development projects in formal-sector urban areas. Abdel Aziz and El-Anwar (2010) and El-Anwar and Abdel Aziz (2011) proposed the use of multi-objective optimization methodologies to achieve three main objectives for slums upgrading projects, including (1) maximizing the project benefits; (2) minimizing the total project costs and durations; and (3) minimizing the social and economic disruptions for resident families. The practical use of these optimization methodologies is dependent on developing social and economic assessment models to alternative construction plans.

Recent research studies focused on the advances of social impact assessment as a means to address these challenges. Burdge and Vanclay (1996), Becker (2001), Burdge (2003), and Becker and Vanclay (2003) discussed the emergence and development of social impact assessment. Other studies aimed at minimizing the social and economic disruptions experienced by resident families and local businesses during construction. In a notable study, Gilchrist and Allouche (2005) proposed a socioeconomic impact costing system based on measuring the disruption caused by construction on (1) traffic; (2) economic activities; (3) pollution; and (3) ecological, social and health conditions. This costing process utilizes mathematical equations to valuate a number of disruption indicators, which include travel delay, loss of income, productivity reduction, health cost, etc. The later research used some valuation methods as measuring loss of productivity, human capital, replacement cost, and user delay cost. However, these valuation methods require significant amounts of data, which might not be readily available in the project planning phase. In a relevant research field, El-Anwar and El-Rayes (2007), El-Anwar et al. (2010) and El-Anwar and Chen (2013) proposed metrics to support minimizing the socioeconomic disruptions for relocated families after natural disasters. These metrics focused on measuring the quality of the new housing locations in terms of employment and educational opportunities, housing quality, displacement distance, accessibility to important facilities and services, and housing delivery time. Similar efforts are needed to quantify the socioeconomic impacts of dense urban construction projects given their unique nature and challenges.

Although most contributions managed to identify the sources and indicators of socioeconomic disruption, there exist limited attempts to assess and quantify socioeconomic disruptions imposed by candidate construction plans. For example, Tsunokawa and Hoban (1997) addressed the difficulty of valuating the losses associated with temporary or permanent loss of houses and businesses. As a result, there exist a need for a practical and comprehensive methodology capable of assessing and quantifying the level of socioeconomic disruption experienced by residents in proximity of dense urban construction projects. This research is a first step to fill this gap using a novel socioeconomic assessment model. The following sections present the proposed model formulation and implementation, and demonstrate the model capabilities using an application example from a current project.

2 MODEL FORMULATION

In this research, the proposed model processes basic data about the urban area and the construction project to evaluate the socioeconomic condition of the area during construction. The model utilizes four main socioeconomic disruption indicators, addressing (1) travel distance delay; (2) resident relocation; (3) business loss; and (4) noise inconvenience. Each indicator is calculated by adding the values of disruption experienced by each resident or business vulnerable to such type of disruption, where the disruption value for each resident or business can range from 0 (indicating no disruption) to 1 (indicating maximum disruption). Furthermore, the effect of the disruption duration is incorporated using an exponential function reflecting the effect of prolonged duration of disruption.

2.1 Travel delay indicator (Dd)

This indicator measures the increase in distance travelled by a dweller from his/her home to a certain service. This increase of distance originates from road closure and detours as a result of construction operations. It is common to estimate the disruption caused by the increased distance using the ratio of the increased distance (∆S) to the original distance travelled (S0) to a certain type of service. However, using this calculation results in an infinite range of results (as the value of increased distance is not...
limited and might exceed the original distance multiple times). Thus, and for the sake of normalizing the ratio to the range from 0 to 1, the formula is modified to calculate the ratio between the increased travel distance ($\Delta S$) to the final travelled distance ($S$) to a certain service. This modified ratio, however, will never reach a value of 1 (where this only occurs when $\Delta S$ approaches infinity, because $\Delta S$ is always smaller than the final distance $S$). As such, the model formulation enables decision makers to define a maximum distance ($S_{\text{max}}$) that if reached the resident is assumed to experience a maximum disruption value of 1. To this end, decision makers define a percentage ($\%s$), which is multiplied by the final distance ($S$) to reduce the upper bound of the travel distance from $S$ to $S_{\text{max}}$, as shown in Figure 1.

Furthermore, the model formulation enables decision makers to define a minimum domain ($\Delta S_{\text{min}}$), below which the increased travel distance has a negligible impact on residents (i.e. the ratio value is set to zero). For example, an increased distance of 100 metres may not produce any disruption. The proposed indicator can be calculated using Equations 1 and 2.

\begin{equation}
[D_{d,i}] = \begin{cases} 
0 & , 0 \leq \Delta S < \Delta S_{\text{min}} \\
\left(\frac{\Delta S - \Delta S_{\text{min}}}{S_{\text{max}} - \Delta S_{\text{min}}}\right)^k & , \Delta S_{\text{min}} \leq \Delta S < S_{\text{max}} \\
1 & , \Delta S \geq S_{\text{max}}
\end{cases}
\end{equation}

\begin{equation}
[S_{\text{max}}] = (\%s) \times S
\end{equation}

\[\text{Figure 1: Impact of the user-defined percentage ($\%s$) to reduce the domain upper bound from } S \text{ to } S_{\text{max}}\]

Where, $D_{d,i}$ is the value of disruption experienced by a dweller ($i$) due to travel delay to a certain type of service, $\Delta S$ is the increased travel distance measured for each resident dweller, $S_{\text{max}}$ is the imposed upper bound to the travel distance, $\%s$ is the percentage of the final distance ($S$) travelled by a dweller after disruption which results in a maximum disruption value of 1, the final distance ($S$) is calculated by adding the increased distance ($\Delta S$) to the original distance travelled before disruption ($S_0$), $S_{\text{min}}$ is the defined increase in travel distance that results in negligible disruption, and $k$ is a constant defining the incremental shape of the disruption function (i.e. $k = 1$ generates a linear function, $k < 1$ generates an exponential function, and $k > 1$ generates a logarithmic function).

Finally, the travel delay indicator ($D_d$) calculates the total value of travel delay disruption for all residents, as shown in Equation 3.

\begin{equation}
[D_d] = \sum_{i=1}^{n} D_{d,i}
\end{equation}
2.2 Resident relocation indicator \((D_r)\)

Various factors might require relocating residents during construction, such as road closure, houses entrance blockage, and houses structural instability. The residents relocation indicator \((D_{r,i})\) computes the number of residents who will be affected by the temporary displacement and its associated socioeconomic disruptions, as shown in Equation 4.

\[
D_r = \sum_{i=1}^{P} d_{r,i}
\]

Where, \(P\) is the original number of dwellers before construction, and \(d_{r,i}\) is a binary variable that equals 1 if resident \((i)\) is temporary relocated and equals 0 otherwise.

2.3 Business loss indicator \((D_l)\)

Local businesses suffer two types of impact. The first type is function in the number of reduced customers \((\Delta C)\), which is incurred due to dwellers relocation away from the business location or as a result of road detours (where some dwellers might choose the second nearest business offering the same service), as shown in Equations 5 and 6.

\[
D_{l,i} = \begin{cases} 
0 & , \ 0 \leq \Delta C < \Delta C_{\text{min}} \\
\left( \frac{\Delta C - \Delta C_{\text{min}}}{C_{\text{max}} - \Delta C_{\text{min}}} \right)^k & , \ \Delta C_{\text{min}} \leq \Delta C < C_{\text{max}} \\
1 & , \ \Delta C \geq C_{\text{max}}
\end{cases}
\]

\[
C_{\text{max}} = (\%c) \times C_0
\]

Where, \(D_{l,i}\) is the value of economic disruption suffered by a certain business \((i)\) as a result of customers reduction, \(\Delta C\) is the number of reduced customers measured for each business, \(C_{\text{max}}\) is the upper bound of reduced customers resulting in a maximum disruption value of 1 and calculated as a percentage \((\%c)\) of the original number of customers \((C_0)\) before disruption, \(\Delta C_{\text{min}}\) is the reduction in the number of customers that results in negligible disruption, and \(k\) is a constant defining the shape of the disruption function.

The second type of loss is function in the number of closed businesses resulting from business inaccessibility due to road closure. In this case, a closed business \((i)\) will have a maximum disruption value \((D_{l,i})\) of 1.

\[
D_l = \sum_{i=1}^{P} d_{l,i}
\]

Where, \(B\) is the original number of businesses before construction.

2.4 Noise inconvenience indicator \((D_n)\)

Although there are many adverse health issues associated with construction activities, noise has always been a major source of complaints among urban construction projects (Hanson et al. 2006). The value of noise disruption is proportional to the number of residents living in the zones within harmful noise levels.

To measure the intensity of noise at a certain distance from the noise source, sound attenuation has to be considered. Sound attenuation depends on a number of factors, including the distance to the noise source, noise directivity, average air temperature, average atmospheric humidity, presence of obstructions and sound reflection (Harris 1966; Piercy et al. 1977).
Neglecting the minor effect of noise directivity, noise obstruction and reflection, which will be difficult to
determine, the level of noise \((N_i)\) affecting a certain dweller \((i)\) as a result of a noise sources \((j)\) can be
calculated using Equation 8 (Lamancusa 2000). In the proposed model, dwellers subjected to the harmful
noise levels will have a noise disruption value \((H_i)\) equals to 1, while other unharmed dwellers take a
disruption value of 0. Accordingly, the noise inconvenience indicator \((D_n)\) is calculated using Equation 9.

\[
N_i = 10 \times \log \left( \frac{L_j \times 10^{-20 \log r_{ij} - 11 - A_{abs}}}{11} \right)
\]

\[
D_n = \sum_{i=1}^{R} H_i
\]

Where, \(L_j\) is the noise level in dB resulting from a source \((j)\), \(NS\) is the total number of active noise
sources, \(r_{ij}\) is the distance from noise source \((j)\) to dweller \((i)\) location in metres, \(A_{abs}\) is the atmospheric
absorption in dB which is function in source frequency and average atmospheric temperature and
humidity (Lamancusa 2000), \(H_i\) is the noise disruption value for each resident dweller \((i)\) and \(R\) is the total
number of residents in the impacted area.

2.5 Total socioeconomic disruption indicator \((D_T)\)

The total value of socioeconomic disruption \((D_T)\) is computed as the weighted average of the
aforementioned normalized indicators multiplied by a factor accounting for the time duration of disruption.
As such, the total value of socioeconomic disruption is given by Equation 10.

\[
D_T = (W_d \times D_d + W_r \times D_r + W_l \times D_l + W_n \times D_n) \times T^z
\]

Where, \(W_d, W_r, W_l\) and \(W_n\) are the relative weights of the four socioeconomic disruption indicators, and
the effect of disruption duration is incorporated using \(T^z\), which is the exponent of the disruption duration,
and \(z\) should be set to a value greater than 1 to indicate the exponential effect of prolonged
socioeconomic disruption.

To enable the practical use of the proposed assessment methodology, an automated model is developed
as described in the following section.

3 MODEL IMPLEMENTATION

The proposed model is implemented in three main steps, as shown in Figure 2.

3.1 Define Project Characteristics

The first step in the automated socioeconomic assessment model is to define the main characteristics of
the project and its surrounding area. GIS is used to plot road networks, residential buildings locations,
services locations and noise sources locations. A map layer is used to draft the area features, where
each road in the network is defined as a vector having a start point and an end point. Buildings are
defined as nodes each having a specific location. Services are also represented as nodes; but in addition
to the location attributes, the type of service is also defined. Finally, noise sources are defined as nodes
each having a location and noise source attributes.

A graphical user interface (GUI) is used to define additional variables, such as the total number of
residents, average daily number of visits for each service type, average atmospheric temperature, and
humidity. Moreover, the user defines construction-related data, including construction phasing, phases’
durations, road closure plan, and noise levels associated with different construction resources and
operations.
3.2 Input Socioeconomic Disruption Sources

The model studies the effect of two main socioeconomic disruption sources; (1) road closure, and (2) construction noise. Road closure has a direct effect on travel distances to services, the number of relocated residents, and businesses closure. Road closure has also an indirect effect on business loss through reduction in the number of customers due to their relocation away from the business location. Construction noise directly results in increasing the number of people exposed to harmful noise levels.

3.3 Measure Socioeconomic Disruption Value

Hoogendoorn (2003) shows that pedestrian’s route choice has an infinite number of paths options, but a certain pedestrian will mainly choose a path with minimum travel time or minimum travel distance to his target location. To this end, the model manipulates the GIS data, where the road vectors are first converted into road segments linked together using intersection nodes, as shown in Figure 3. Dijkstra’s Algorithm is used to calculate the shortest path travelled by a dweller to the nearest instance of each service type.

An initial (pre-construction) state is first generated to be compared to the different states corresponding to the candidate construction plans. In the initial state, each dweller node is associated with the ID of the nearest instance of each service type along with the travel distance. A backward calculation is then implemented using this data so that each service instance is associated with the initial number of customers (dwellers) visiting that service.
3.3.1 Measuring travel delay

To compute travel delay, the initial state is compared with the road closure scenario results. The significance of a certain travel pattern is inferred from the amount of its repetition due to the need to frequently visit a target service. The need to frequently visit services can be defined by the average number of monthly visits input for each type of service. For example, some services have higher rate of visits, such as groceries and bus stops, while others have limited number of visits.

3.3.2 Computing the number of relocated residents

A resident is assumed relocated if the road segment within which the resident’s home is located is completely closed for construction reasons. The GIS model is used to identify the buildings whose roads are closed, and accordingly the number of relocated residents is calculated. Currently, the model assumes an average number of residents in each building, which can be modified in future developments to allow for specific buildings occupancy data.

3.3.3 Measuring businesses loss

The GUI allows the user to define each service type in the area either as a business or a public service. The expected number of customers measured after a road closure scenario is compared to the initial business state. For each construction plan, the number of closed businesses is first computed by identifying road closures. Secondly, the change in the number of customers is computed for the remaining businesses taking into account route changes and detours because of the construction operations.

3.3.4 Measuring noise inconvenience

Noise received at each dweller’s location as a result of construction operations is calculated using the distances between the dweller’s location and noise sources. This data is obtained from the GIS model. The noise inconvenience indicator is then measured by counting the number of dwellers subjected to harmful noise levels.

4 APPLICATION EXAMPLE

The proposed socioeconomic assessment model is applied to a dense urban construction project in Giza, Egypt. A main sewage pipe was broken at a depth of about 7.5 metres under Imam El-Ghazaly Street in the District of Imbaba, where the leakage of soil into the pipe led to critical settlements in the surrounding buildings. Auger piles were used as side supports for the required excavation depth in the narrow streets. Imbaba is a highly populated area in Greater Cairo. Moreover, Imam El-Ghazaly Street is considered a main street in the area with high concentration of residents and services.

The area under consideration is about 33,000 m² with a simple road network of narrow streets and high buildings density. There are about 188 buildings distributed over the residential zone. The construction operations required the closure of some road segments, as shown in Figure 4. The services in the area are mostly of a basic nature, including two bus stops, eight groceries, two pharmacies, three retail shops, two bakeries, four household appliances shops, four restaurants, and four workshops. All the previously mentioned services are considered for business disruption calculation except for the bus stops; thus the total number of disrupted businesses in the area is 27. The average temperature in the area is 30°C and average humidity is 75%, and the harmful noise level is set to 85 dB. Two main sources of noise are present; the first is a fixed generator producing 80 dB at 1100 Hz, while the second is a moving bored pile rig producing a noise of 75 dB at 950 Hz. The contractor has only one piling rig which makes the piling activity critical.

There are three studied construction scenarios. In the first scenario, construction will be executed in two phases, as shown in Figure 4. The two phases will be executed in series, where the road segment of phase 2 will be closed only after opening the road segments closed during phase 1. Noise resulting from
the pile rig is assumed to occur at the midpoint of the closed road segment. The duration of executing each phase is about 6 months, where the site preparation and mobilization takes place in the first month of each construction phase. Accordingly, the total project duration is 12 months. The second scenario assumes that construction of the second phase will start one month before the end of phase one so that the mobilization and preparation period will overlap with the execution period of phase one. This will lead to a total project duration of 11 months. The third scenario assumes that construction will be executed in one phase by closing all the road segments for about 11 months. In this case, mobilization and site preparation will only occur once at the start of the project.

The variables of the travel distance delay function are assumed to have a minimum domain ($\Delta S_{\min}$) of 200 metres, a maximum domain of 95% of the final traveled distance (i.e. $S_{\max} = 95\% \times S$) and a logarithmic curvature (k) value of 2. The function of business loss is assumed to have a minimum domain of 0 customers, a maximum domain of 80% of the initial number of business customers (i.e. $C_{\max} = 80\% \times C$) and an exponential curvature (k) value of 0.8. The duration is very critical, so it is assumed to have an exponential value of (k) equals to 2. Moreover, the relative weights of the indicators are assumed to be 0.3 for dwellers relocation, 0.4 for business loss, 0.1 for travel distance delay and 0.2 for noise inconvenience indicators. The model enables the users to set the values of all these variables before running the socioeconomic analysis.

The model results show that the socioeconomic disruption indicators of the first and the second scenarios have near results which are much lower than those of the third scenario, as shown in Figure 5. The best scenario in this case is the second scenario which has the lowest total socioeconomic disruption indicator. The results also show that the highest impacts of this project are on noise inconvenience.

Figure 4: GIS Model of the project area showing the location of different types of services on the road network and the project phases
5 CONCLUSION

This paper presents a socioeconomic assessment model capable of quantifying the socioeconomic disruption experienced by residents in proximity to construction projects in dense urban settings. The model incorporates four important socioeconomic indicators; namely (1) Travel Distance Delay, (2) Residents Relocation, (3) Business Loss, and (4) Noise Inconvenience. The model enables decision makers to assign a relative weight to each of these four indicators and accounts for the impact of prolonged socioeconomic disruption when computing the total impact of any construction scenario.

![Bar chart showing SEDI values for different scenarios]

Figure 5: Model results

In order to ensure the practicality of the proposed model and its ease of use, the model computations are automated using a GIS-based system integrated with a VBA user interface. The automated system allows decision makers to break down the construction project into phases and define different scenarios for possible construction plans. The model then assesses the socioeconomic impact of each plan in order to support reaching an informed decision that accounts for the welfare of nearby residents. The main challenge to using the developed system is the need for users to set the values of different variables (such as the minimum travel distance $S_{min}$ that results in social disruption, etc.). Future research will address this limitation using sensitivity analysis to identify the significance of these variables.

Abstract: Productivity is one of the most important elements to manage construction projects especially with regards to the prediction of the activities’ durations. Uncertainty is an entrenched characteristic of most construction projects. Most research works in simulating construction productivity have focused predominantly on modeling and have neglected to study the effect of subjective variables on productivity of construction process. The unique nature of construction projects and uncertainty of the construction processes lead to a need of new generation of models that utilizes the historical data. The presented research develops, using Fuzzy approach, a model to utilize, analyze, extract and find the hidden patterns of the project data sets to predict the construction process productivity. The engine depends on finding the relation between quantitative and qualitative variables, which affect the construction processes, and productivity. The methodology of this research consists of six steps: (1) Investigate the factors affecting the productivity (2) select the critical factors that affect the productivity; (3) build Fuzzy sets; (4) generate Fuzzy rules and models; (5) build Fuzzy knowledge base; and (6) validate the effectiveness of the built model to predict the construction process productivity. The developed model is validated and verified using case study with sound and satisfactory results, 90.65 % average validity percent. The developed research/engine benefits both researchers and practitioners because it provides robust model for construction processes and a tool to predict the productivity of construction processes.

1 INTRODUCTION

Productivity is one of the most important elements to manage construction projects especially with regards to the prediction of the activities’ durations. Productivity is defined as “the ratio of output of required quality to the inputs” for a specific construction process (Al-Zwainy, et. al. 2013). Several studies applied many statistical methods in the construction management; regression, probability functions, stochastic techniques, and mathematical learning curves for simulation and/or optimization (Bee Hua, 2008).

Raw (i.e. dirty) data can cause confusion for the mining and modeling procedure that leads to unreliable output (Han and Kamber 2006). If users believe the data are dirty, they are unlikely to trust the results of any data mining that has been applied to it. Most research works in simulating construction processes have focused predominantly on modeling and neglected to prepare the data before mining process. Before dealing with the system building, the data problem should be identified. There are major two problems of data, which are missing data and outliers. The simple way that most research works deal with
is to remove incomplete data set and outliers. Knowledge Discovery in Database (KDD) is the nontrivial process of identifying valid, novel, potentially useful, and ultimately understandable patterns in data (Fayyad et. al 1996). Data mining is used to extract hidden knowledge from a data set that is not obtained by traditional methods as statistical analysis. The KDD is an interdisciplinary field involving concepts from machine learning, database query, statistics, mathematics and visualization (Anand et al. 1998). Most modern KDD tools have focused almost exclusively on building models (Cox and Wills 1997). A 60% of time goes into preparing data for mining; however, actual mining step typically constitutes about 10% of the overall effort (Cabena et al. 1998). Knowledge discovery in databases (KDD) and data mining consist of a series of steps including domain and data understanding, data preparation, data mining, and finally, pattern evaluation and deployment (Chapman et al. 1999). The KDD has been applied in the area of construction and facility management in recent research in response to the explosive growth of computerized historical databases (Buchheit et al. 2000; Soibelman and Kim, 2002). Chau et al. (2002) developed an application of data warehouse and decision support system to provide the information about and insight of existing data.

The previous studies show a lack of using the historical data and experts to build models/knowledge bases that help to predict the construction productivity.

2 RESEARCH OBJECTIVES

The overall objective of this research is to build a construction productivity model. To achieve this objective, the following sub-objectives are as follow:

1. Develop a data mining engine to utilize, analyze, extract, and model the hidden patterns from the project data.
2. Integrate the enormous amount of historical data and knowledge base design in order to predict construction productivity.
3. Verify and validate the proposed framework using a case study.

3 BACKGROUND

Construction management research used the fuzzy set theory, fuzzy logic, and hybrid fuzzy techniques (Chan, Chan, & Yeung, 2009). Therefore, many studies went through to combine the fuzzy set theory/ fuzzy logic with artificial intelligence systems as well as Gas, Ann, and PSO in order to create a hybrid model to implement model parameter optimization (Bee Hua, 2008). Several studies investigated the factors that affect the construction labors productivity variations; the National Electrical Contractors Association (NECA) studied the effects of humidity and temperature on labor productivity (Sonmez & Rowings, 1998). Another study developed a model using a methodology based on the regression and neural network modeling techniques to evaluate many factors on productivity for concrete pouring, formwork, and concrete finishing tasks from task to task (Sonmez & Rowings, 1998).

The theory behind learning curve models revealed that as the production quantity of any product doubles, the unit or average cost (hours, man-hours, dollars, etc.) will decreases by a fixed percentage of the previous unit or average rate (Thomas, et. al., 1986). A number of mathematical models were used to describe and predict the learning curve, including the straight line power model, cubic power model exponential model, and piecewise model (Thomas, Mathews, and Ward, 1986). Straight line power model is the most commonly used model in construction productivity, moreover, it provides the most reliable prediction of future performance (Everett and Farghal, 1994). Hildreth (2012) presented a case study of his construction students where they participated in virtual construction operation. The experiment resulted in excellent knowledge regarding learning curve theory and its application within construction industry.

Malyusz and Pem (2014) used mathematical algorithms to evaluate the predictive capabilities of various learning curve models and data presentation methods for labor intensive construction operations. The algorithms gave sequential predictions for future performance of construction activities.
Situation-based simulation models is a recently developed technique that is used to model the triggering situations in construction to predict productivity. Choy and Ruwanpura (2006) developed an application model that uses “root causes of productivity loss” as the situations. This model allows users to develop models based on the interactions of various situations and work types. A study by (Al-Zwainy et al., 2013) developed a model using Multivariable Linear Regression technique (MLR) to estimate construction productivity for marble finishing works of floors.

4 RESEARCH METHODOLOGY

This research consists of five phases that provides detailed explanation of the research methodology. A comprehensive literature review phase has been conducted that includes the state of the art review of construction productivity, data mining and knowledge discovery, as well as fuzzy knowledge base building and Design. The second section pertains to system development and implementation procedures that includes the following three stages: Variable Selection, Fuzzy Sets, Fuzzy Rule Induction, and Fuzzy Knowledge Base. The third phase focuses on data collection, which includes a case study to verify and validate the developed system. The fourth phase denotes verification and validation of the developed system using a case study. The final phase of this research propounds conclusions and recommendations for future work. What follows is a detailed explanation of the aforementioned five-study section and their sub sections.

5 PRODUCTIVITY DATA MINING ENGINE DEVELOPMENT

The productivity Data mining engine make the variable selection to build the knowledge base through Fazzification and fuzzy induction rules. The productivity data mining engine consists of five steps as follows:

5.1 Variables selection

In this step, the variables that affect the task productivity rate are selected using Fuzzy average method. The fuzzy curve will be built using Equation 1 and the variables will be ranked using equation 2.

I. Build the Fuzzy curve

For every input and output points \((X_i, Y_j)\) the equation 1 will be applied (Lin and Cunningham III 1995). If there is a completely random relationship between the input(s) and output(s), then, the fuzzy curve is flat and vice versa.

\[
C_i(x_i) = \frac{\sum_{j=1}^{n} y_j \mu_{ij}(x_i)}{\sum_{j=1}^{n} \mu_{ij}(x_i)}
\]  

(1)

Where:

- \(C_i(x_i)\): Curve points

II. Ranking the variables

Mean Square Error (MSE) will be used to rank the variables using Equation 2. The MSE value shows the significant; if the value is small that mean a high significance and vice versa.

\[
MSE_i = \frac{1}{M} \sum_{k=1}^{M} (c_i(x_i,k) - y_k)^2
\]  

(2)
5.2 Fuzzy sets (Fuzzification)

Crisp quantities are converted into fuzzy sets in this step using the Artificial Neural Network (ANN) technique. The ANN will be built from modeling data sets of the selected variables. The training will simulate the relationship between the coordinate locations and membership values. After the net is trained, its validity and efficiency can be checked using the testing data. Then it is ready and can be used to determine the membership value of input data set in the different regions.

5.3 Fuzzy rules induction

Rule induction creates a knowledge base of fuzzy if-then rules by modeling the embedded patterns in the data. This is a supervised knowledge discovery that use Fuzzy rule induction algorithm. The functional relationships between the independent and dependent variables are expressed as a set of fuzzy if-then rules. The inputs of this step are Fuzzy sets that will be isolated to data point mapping with the highest membership degree that could happen if there are two data sets in the same Fuzzy set, the higher degree would be selected. The final rules are selected from a pool of data pairs. The degree of effectiveness (E) for each rule will be computed. It selects the most effective rules amongst the candidate rules using Equation 3 (Cox, 2005).

\[ E(r_i) = \mu_x(v_1) \times \mu_y(v_2) \times \mu_z(v_3) \]  

(3)

5.4 Fuzzy knowledge base (FKB)

The collection of all the previous steps are forming Fuzzy knowledge base, which includes variables, fuzzy sets, and fuzzy rules. This collection of FKBs may form a solution to a complex system. FKBs are containers where they store the data definitions (variables) and the required rules to solve a set of outcomes associated with the system.

5.5 Validation

Prediction effectiveness of the developed engine will tested in this step using a mathematical validation. The average invalidity percent (AIP) and the Average validity Percent (AVP) will be calculated using Equation 4 and 5 respectively. If the AIP value is closer to 0.0, the model is sound and a value closer to 100 shows that the model is not appropriate to predict the productivity (Zayed and Halpin, 2005). Similarly, the Root Mean Square Error (RMSE) is estimated using Equation 6. If the value of the RMSE is close to 0, the model is sound and vice versa. In addition, the Mean Absolute Error (MAE) is defined as shown in Equation 7. The MAE value varies from 0 to infinity. However, the MAE should be close to zero for sound results (Dikmen et al. 2005).

\[ AIP = \left( \frac{1}{n} \sum_{i=1}^{n} \left| 1 - \left( \frac{E_i}{C_i} \right) \right| \right) \times 100/n \]  

(4)

\[ AVP = 100 - AIP \]  

(5)

\[ RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^{n} (C_i - E_i)^2} \]  

(6)
6 ANALYSIS OF DATA MINING ENGINE IMPLEMENTATION TO A CASE STUDY

In this study, data were collected through both on-site observation and digital camera monitoring system for Engineering, Computer Science and Visual Arts complex of Concordia University (Khan, 2005). The implementation to a case study will concern the productivity of concrete pouring operation. The factors that affect the productivity are shown in Table 1. A sample of case study data is shown in Table 2.

Variables selection

In this step, the variables that affect output variable (work task productivity) are selected. Two methods are used to select the variables that affect the productivity. The first is sorting factors according to Mean Square Error (MSE) as shown in Table 3. The second method is using Fuzzy curve. As shown in Figure 1 and Figure 2. The MSE method will be used to validate the Fuzzy curve method and how it selects and ranks critical variables. The ANN method is used to compare the ranking and selection efficiency using the selected variables as shown in the following sections.

Variables selection using the ANN method

The ANN method is used to validate the Fuzzy Average method of selecting and ranking critical variables. Ranking of input variables is required in order to determine the relative importance of each variable and those that have the most effect on the task duration. The contribution percentages are derived from analysis of weights of the trained neural network. The higher the number, the more that variable is contributing to the classification and/or prediction. Obviously, if a certain variable is highly correlated, the variable will have a high contribution percentage. Table 4 shows the contribution percentage (relative significance) of eight variables. By comparing the results of Fuzzy Average Method and ANN methods, it is clear that four out of eight variables are similar in the top of each ranking and the other variables have different ranking.

**Fuzzy sets**

The Fuzzy clustered points are used to train and build the Neural Network. As shown in Table 5, a sample of Fuzzy membership values for data shown in Table 2. The ANN is used to predict and form the Fuzzy sets. The Fuzzification process involves assigning membership values for the given crisp quantities. Membership’s values are assigned using the Neural Network technique in order to model the relation between the fuzzy membership functions and productivity.

Fuzzy rule induction

Rule induction creates a knowledge base of fuzzy if-then rules by modeling the embedded patterns in the data. This step aims at finding the functional relationships between variables and task duration defined as a set of “if-then” rules. Fuzzy Rule Induction Algorithm is used. A sample of Fuzzy rules is shown in Table 6. As the final rules are selected using only the highest degree of effectiveness (E).

Fuzzy knowledge base

Fuzzy knowledge base includes all the previous steps, i.e. the selected variables, fuzzy sets, and fuzzy rules. The FKB is a representation of a particular model of each process that means the FKB of concrete pouring process is separate from the loading process.

Fuzzy knowledge base validation

The goal of this step is to test the engine prediction effectiveness. To test the effectiveness of the engine’s prediction, a validation data set is embedded into the developed engine to compare its results with actual data. As shown in Equation 4 and 5, the average validity percent (AVP) and the average invalidity percent (AIP) are used. The developed Knowledge base is validated by comparing the predicted results with the actual values for productivity using the validation data set. The results show that the average validity percent is 90.65 %, the RMSE is 1.5, and the MAE is 3. Therefore, the developed fuzzy knowledge base is acceptable and robust to predict the productivity of the work task.

7 CONCLUSIONS

The current research presents a construction productivity data mining engine to prepare, utilize, analyze and extract the hidden patterns from the project data to predict the work task productivity. The engine depends on preparing the historical data to be modeled and finding the relation between quantitative and qualitative variables, which affect the construction processes, and work task productivity. The developed data mining engine consists of the following steps: (1) select the factors that affect the construction process; (2) generate Fuzzy sets; (3) define Fuzzy rule and models; (4) build Fuzzy knowledge base; and (5) validate the effectiveness of the built knowledge base to predict the work task durations. The presented research shows the significant effect of qualitative and quantitative variables on the task durations. It shows the efficiency of Fuzzy approach to model the hidden patterns of construction project data. The developed engine is validated and verified using case study with sound and satisfactory results, 90.65 % average validity percent. The developed research/engine benefits both researchers and practitioners because it provides robust knowledge base for construction processes and a tool to predict the related task productivity for construction activities.

Abstract: Overall schedule optimization, considering all temporal, spatial and precedence constraints is a difficult task due to the complexity which is inherent in construction projects. The difficulties associated with modeling all aspects combined become more considerable when optimizing linear type of projects with high activities’ inter-relations. The progress of these projects highly depends on the productivity achieved from their resources which is directly dependent upon the space and time available to these resources. As a result, in order to practically optimize linear schedules, not only their achieved productivities need to be managed well, but also the spatio-temporal flexibilities and constraints are to be integrated into the optimization process. This paper aims to fill the gap in the current literature by proposing a practical approach for modeling and optimization of linear schedules while taking into account all the project-dependent constraints. For this purpose, the methodology is built on the new concept of Space-Time float for explicit consideration of spatio-temporal constraints of activities. The developed method uses constraint-satisfaction optimization approach to minimize duration of the generated schedules. As such, by having Space-Time floats for different activities’ resources and using such constraints, the schedule is optimized to get the minimum achievable duration for the total project. A numerical example is analyzed to present the proposed and developed method as well as its added benefits.

Key words: Schedule optimization; Spatio-temporal constraints; Constraint programming; Linear projects; Space-time float.

1 INTRODUCTION

Having accurate and up-to-date information of each activity and its respective resources has a large impact on effective project scheduling and control of linear construction projects (Roofigari Esfahan and Razavi, 2013, Roofigari Esfahan and Razavi, 2012, Andersson et al., 2007, Roofigari Esfahan et al., 2014). This is due to the fact that, in this class of projects, construction crews are often required to repeat the same work in various locations and therefore, move from one location to another. As a result, the spatio-temporal constraints of such movements need to be considered when scheduling each and any of the linear activities. As such, the schedule developed for these projects should first be enhanced taking into account all the logical precedence constraints of activities as well as spatio-temporal constraints on movement of resources (Hegazy, 2005, Moselhi and Hassanein, 2003, Polat et al., 2009, Yang and Chi-Yi, 2005, Song et al., 2009).
The current scheduling methods for linear projects do not consider spatio-temporal constraints for movement of activities' resources and the flexibility in their movement to enhance and improve the schedules. This subsequently causes them to overlook other possible whole range of productivity rates that can be achieved without delaying activities.

The limitations stated can be tackled by the new concept of Space-Time float prisms to generate and optimize schedules of linear projects. The scheduling framework presented here integrates location of construction resources through an innovative modification of Linear Scheduling Method LSM by adding the spatio-temporal constraints to the traditional LSM productivity. Using such constraints, the schedule is then optimized to get the minimum achievable duration for the total project.

The optimization phase of the proposed method takes a constraint-satisfaction approach to find the optimum productivity rates for activities that will lead to minimum achievable duration for the project. To achieve this goal, the objective of the optimization process is set as duration minimization, and the decision variables include the start date and productivity rates of linear activities. All the project precedence, and spatio-temporal constraints identified through using Space-Time float prisms are then used to limit the search space into practical solutions. The output of the optimization phase, i.e. the optimum schedule for the project and the optimum productivity rates of activities, are then used to visualize and track the progress of the project schedule.

The remaining of the paper is organized as follows: first, an overview of the current state of scheduling linear projects is presented. Subsequently, the new concept of Space-Time float prisms previously published by the authors (Roofigari Esfahan et al., 2014) is briefly introduced and the modification to traditional linear scheduling method using Space-Time float prisms is then described. In the next step, the optimization framework used to optimize the duration of the generated schedule is presented followed by the details of tracking and control of such schedules. Finally a numerical example is analyzed using the proposed framework to present the method as well as its added benefits.

2 BACKGROUND

Due consideration to space and time constraints and requirements should be given when it comes to scheduling linear construction projects. This is because the dynamic resources on sites of linear projects are more likely to interact with each other in a complex spatial-temporal manner. Current available network techniques and linear scheduling methods mainly consider technological constraints and resource requirements in generating schedules for repetitive and linear works. Such techniques and methods overlook the requirements of activities for the requisite work space for material storage and movement of manpower and equipment. The literature on scheduling and planning linear projects is rich. A number of methods including Linear Scheduling Method (LSM), Repetitive Scheduling Method (RSM), and Line of Balance (LOB) are presented in the literature to plan, schedule and control linear projects; e.g. ((O’Brien, 1975, Stradal and Cacha, 1982, Harmelink, 2001, Harmelink and Rowings, 1998, Harris and Ioannou, 1998, Johnston, 1981, Cosma, 2003). Much research also has been performed to predict the production rate of linear projects based on simulation, probability, or regression analysis (e.g.(Duffy et al., 2011, Watkins et al., 2009, O’Connor and Huh, 2005, Woldeisenbet et al., 2012, Jiang and Wu, 2007, Kuo, 2004).

The methods presented in the literature to optimize schedules of linear projects can be divided into four main categories: 1) the methods whose purpose is to minimize resource fluctuation of these projects (e.g. (Georgy, 2008, Mattila and Abraham, 1998, Tang et al., 2014a, Tang et al., 2014b, Shu-Shun and Chang-Jung, 2007); 2) methods that tend to minimize resource idle times (Vanhoucke, 2006, Gonzalez et al., 2013); 3) Methods that optimize project schedule considering minimization of project cost as objective (e.g. (Handa and Barcia, 1986, Senouci and Eldin, 1996, Hegazy and Wassef, 2001, Moselhi and Hassanein, 2003, Ezeldin and Soliman, 2009, Ipsilandis, 2007, Menesi et al., 2013); and 4) the methods which reduce the duration of the linear projects (Russell and Caselton, 1988, Fan and Lin, 2007, Bakry et al., 2013, Bakry et al., 2014, Cho et al., 2013).
There are also methods that attempted to visualize linear schedules, using 4D CAD (Staub-French et al., 2008) and MS-Excel (Lluch, 2009) as well as methods that consider variable productivity rates for linear activities; e.g., (Lucko, 2008, Lucko et al., 2014, Duffy et al., 2011). Yamin (Yamin, 2001) developed an approach to analyze the cumulative effect of productivity rate variability (CEPRV) on linear activities in highway projects. The focus of that study was to advance the risk analysis capabilities of linear scheduling to allow managers to forecast the probability of project delay. Duffy, et al.’s method (2011) divided linear schedules to areas of time and location for which unique production variables, called working windows can be assigned. Working windows display when and where production variables may change along the linear project’s timeline. Similarly, (Lucko et al., 2014) models linear schedules using singularity functions to model changes in productivity along the execution time of each activity. In a recent attempt, (Shah, 2014) aimed to provide the precise scheduling information of working locations, allocation of resources, and identification of time–space conflict on a weekly, particularly in the earthwork operations of road and railway construction projects.

However, none of these methods optimizes the schedule with due consideration to the whole range of possible production rates that are available to each activity at each point in time and space. The existing methods mainly focus on minimizing day to day resource usage fluctuations, not taking into account the range of achievable productivity rates of resources. As a result, they overlook possible production rates that can lead to minimum duration schedules. Furthermore, none of these methods considers the space available to the activities’ resources throughout their execution. This is a limitation that can be tackled by using Space-Time float, as introduced in the authors’ previous work (Roofgari Esfahan et al., 2014). As a continuation to the previous work, this paper proposes a constraint-satisfaction approach to optimize project duration of linear projects using space-time floats. The details of the method are presented in next section.

3 BACKGROUND

The methodology developed in the present study is based on: 1) the Linear Scheduling Method (LSM) (Harmelink and Rowings, 1998) as a resource-driven technique suitable for repetitive tasks; 2) explicit consideration of spatio-temporal constraints of activities; and 3) constraint-satisfaction integer optimization approach to minimize duration of the generated schedules.

The method integrates all the above mentioned tools in one framework and generates, optimizes, and visualizes linear project schedules. The system presented here has three essential integrated modules, namely: scheduling, optimization and visualization modules. Figure 1 shows the different modules of the proposed method.

![Scheduling and Optimization Framework](image)

Figure 1: Framework of the proposed method
3.1 Scheduling Module: Scheduling Linear Projects using Space-Time Float Prisms

The Linear Scheduling Method (LSM) is used to schedule linear projects in this study. For this purpose, the Space-Time float is considered in this study to take into account the movement constraints of the resources in scheduling linear activities. Space-Time float is an envelope for all possible movement patterns that an activity or its associated resources can take considering the time and space constraints of that activity (Roofigari-Esfahan et al., 2014). Movement of resources can be classified as actual and potential. Actual movement is represented by a space-time path, that is, the set of space-time coordinates where a resource entity is actually taken. Potential movement is represented by a Space-Time float prism, which consists of the set of space-time coordinates representing the activity-related constraints. Each spatially dispersed activity has association with spatial anchors, i.e. pre-determined locations at which an activity must take place. Such activities are not only associated with a duration, but also with locations, showing where they start and/or finish. These activities’ start and end locations are assumed as the anchor points of Space-Time float prisms (see Figure 2).

![Figure 2: Realization of a) 2D and b) 3D Space-Time Float Prism](image)

Traditionally, productivity has been defined as the ratio of input/output, e.g. the ratio of the input of an associated resource (usually, but not necessarily, expressed in person per hours (p-hrs)) to its real output (in creating economic value). To restate this definition for use in the construction industry it can be said that labor productivity is the physical progress achieved per p-hrs (Dozzi & AbouRizk, 1993). Converting this definition to Space-Time float and path, the slope of the space-time paths in each time interval can be used as an indicator of crew productivity within that interval. Vertical paths accordingly demonstrate idle times in an activity when no productive work is actually executed. The optimum path can also be identified. This is the path for which the slopes of the line at each time interval are equal to the planned productivity for that activity at the corresponding time interval (see Figure 2(a))

In order to draw respective Space-Time float prisms for all possible productivity rates for each activity, prism boundaries are also needed in addition to its anchor points. These boundaries in the construction concept can be considered as maximum and minimum allowable productivity rates for resources. As can be seen in Figure 2(b), the minimum productivity rate can be zero, meaning that the activity can be stopped for some time. This, as known, is consistent with the definition of activity floats in construction scheduling. Subsequently, based on the maximum and minimum acceptable productivity rates for activities, the respective Space-Time float prism is constructed. The prism is an envelope which comprises all the possible productivity rates for an activity at each time interval (see Figure 2(b)). Further, scheduling the project through the generation of a Space-Time float for each activity also provides a better understanding and realization of Space-Time flexibilities that are available for each activity.

Identifying spatial conflicts between activities and their respective resources in construction sites provides a potential to minimize delays caused by such conflicts. Because deviation from planned production rates
in linear projects’ activities may result in spatial conflicts between their respective resources, the generation of Space-Time Float prisms is important to help detect such conflicts. Through the use of Space-Time float, the schedule can adapt to variable production rates at each time interval and subsequently the system can potentially identify and forecast potential space-time conflicts (i.e. congestion). It should be noted that identification, quantification, and optimization of space-time conflicts are not within the scope of this paper.

After scheduling the linear activities and visualizing this initial-non optimum schedule using Space-Time Float prisms, the method proceeds to the next module to optimize the generated schedule. The optimization method presented in this paper aims at generating optimized schedules for linear schedules, taking into account all logical and spatio-temporal constraints of linear activities as described in the next section.

3.2 Schedule Optimization Module using Constraint-based integer programming

The optimization phase of the proposed scheduling and control model is a Constraint Satisfaction -based integer optimization model. This module can automatically establish linear schedules with minimum achievable schedule duration. Optimal or near-optimal schedules can be obtained in a relatively short period of time using Constraint Programming (CP) techniques. It should be noted that Constraint Satisfaction Problems are defined by a set of variables, X1;X2; … ;Xn, and a set of constraints, C1;C2; … ;Cm. Each variable Xi has a non-empty domain Di of possible values. Each constraint Ci involves some subset of the variables and specifies the allowable combinations of values for that subset. A state of the problem is defined by an assignment of values to some or all of the variables. An assignment that does not violate any constraints is called a consistent assignment. A complete assignment is one in which every variable is mentioned, and a solution to a CSP is a complete assignment that satisfies all the constraints.

Constraint programming is a programming paradigm being used for solving Constraint Satisfaction Problems (CSPs) through using a combination of mathematics, artificial intelligence, and operations research techniques (Chan and Hu 2002; Liu and Wang 2012; Tang et al. 2014b). It has been successfully used to solve complex combinatorial problems in a wide variety of domains. Its Selection of appropriate variables and values through heuristics reduces the required computational effort and improves the search ability (Liu and Wang 2007; Russell and Norvig 2009).

Apart from being an effective tool in solving a variety of problems, CP has particular advantages in solving scheduling problems (Menesi et al. 2013; Chan and Hu 2002; Heipcke 1999) due to: (1) its efficient solution search mechanism, (2) flexibility to consider a variety of constraint types, and (3) convenience of model formulation. In other words, the highly constrained problems associated with project scheduling can be best modeled and optimized using CP because of its flexibility in description of constraints as well as its capacity to naturally incorporate constraints into the problem description (Chan and Hu 2002) and in processing complex and special constraints (Tang et al., 2014a). When solving an optimization problem in CP, the objective function in the problem is treated as a constraint and this additional constraint forces the new feasible schedule to have a better objective value than the current schedule. The upper or lower bounds of the constraint are replaced as soon as a better objective function value is found. The propagation mechanism narrows the domains of decision variables to reduce the size of the search space while recording the current best schedule. The search terminates when no more feasible schedule is found and the last feasible schedule is the optimal schedule (Pinedo 2008; Liu and Wang 2008).

For the proposed model in this study, the objective and variables were determined in the problem specification stage. In the research reported in this paper, the objective was considered as duration minimization, and the decision variables include the start date and productivity rates of linear activities. To facilitate the use of CP algorithms in scheduling problems, a powerful optimization package, termed ILOG CPLEX Optimization Studio (Beck et al. 2011), was developed incorporating a CP optimizer engine that offers features specially for solving scheduling problems. ILOG CPLEX Optimization Studio was used and the ILOG OPL language was adopted as the model formulation language.
To optimize the schedule with the objective of minimizing duration for the initial schedule, spatial and temporal availabilities to each activity are considered as constraints applied in the optimization process. To do so, all the productivity rates in the feasible productivity interval for each activity (i.e. within prism boundaries) are translated into integer feasible durations for that activity. The search engine then explore these options and finds the productivity rate for each activity that optimizes the overall project duration. The following variables, constraints, and objectives were adopted in the construction of the CSP-based model:

**Constants:**
- SLi  Start location of activity i;
- ELi  End location of activity i;
- \( P_{\text{mini}} \)  Minimum productivity rate of activity i;
- \( P_{\text{maxi}} \)  Maximum productivity rate of activity i;
- \( B_{ij} \)  Required time buffer between activity i and activity j;
- \( D \)  Project deadline

**Decision variables:**
- \( \text{OptPro}_i \)  Optimum resource production rate of activity i;
- \( \text{OptPro}_i \in [P_{\text{mini}}, P_{\text{maxi}}] \)
- \( \text{ST}_i \)  Start time of activity i;
- \( \text{ST}_i \in [0 , D] \)

**Decision expressions:**
- \( \text{ET}_i \)  End time of activity i;
- \( \text{ET}_i = \text{ST}_i + (\text{EL}_i - \text{SL}_i)/ \text{OptPro}_i \)

**Constraints:**

The precedence relationships between activities are considered as the main constraints applied to the optimization model. In this study, all kinds of precedence relations are taken into account, namely: Finish to Start (FT), Start to Finish (SF), Finish to Finish (FF) and Start to Start (SS). The required time buffers between activities are also considered when considering the precedence relationships between succeeding activities.

There are also fixed constraints applied to the model. These fixed constraints are as follows:

- \( \text{ST}_i \geq 0 \)
- \( \text{ET}_i \leq D \)
- \( \text{ET}(\text{fa(last activity)}) \leq D \)
- \( \text{ET}(\text{fa(first activity)}) = 0 \)  (or the start time assigned to the project)

The output of this Module is the best option of each activity i.e. optimum productivity rates for each activity which will minimize the project duration. These rates along with maximum and minimum productivity rates of each activity are then used to visualize the generated optimum schedule.

**4 CASE STUDY**

The method presented here was applied to a case study previously presented in the literature (Mattila and Abraham, 1998, Tang et al., 2014a). The minimum and maximum productivities are calculated from the minimum and maximum resources available in the original example. In the real-world examples also project management teams are requested to enter general information about the project and respective activities. The project network consists of 9 activities. The project included widening of a segment of U.S. Route 41, located in northern Michigan. Major activities consist of removal of existing concrete paving, ditch excavation, embankment, sub-base, gravel, and bituminous paving. This highway construction project was used for verifying the scheduling and optimization capabilities of the proposed model. The
finish date presented in the literature for this example is 38 days. The description of each activity as well as inputs and outputs of the optimization process are included in Table 1.

As it is shown in Table 1, the input data of the optimization process include Activity IDs, their start and end location, successors, and their minimum and maximum achievable productivity rates. It should be noted that these boundaries were calculated using minimum and maximum available resources used. The optimization engine used this information to search for the minimum duration for the project considering all logical and spatio-temporal (productivity) constraints for each activity. As shown in that Table, the project deadline, and project start day are other constraints inputted to the optimization process. If some activities are required to start or finish at a certain day, this information will also be included as constraints. The output of this process includes optimum productivity rate and the duration associated with this productivity rate, as well as start and end times of all the activities, considering precedence relationships. The optimum duration for each activity is also calculated from the optimum productivities attained in the optimization process. It should be noted that in case of non-repetitive activities, the start time is calculated based on the precedence relationships with their predecessors and successors.

The optimum duration for the project was calculated to be 36 days in the optimization module which is 2 days shorter than the other methods (Mattila and Abraham, 1998, Tang et al., 2014a) (see Table 3). The optimum productivity rates achieved in the optimization process, which creates the duration of 36 days, are listed in Table 2 for all activities. It should be noted that because integer approach has been used, the conversion errors persist to exist, causing some values to be located near the assigned interval. Table 2 also shows the comparison of the activity durations and optimum productivities of the initial schedule with the optimized schedule obtained through the optimization process.

Table 3 shows the durations achieved previously for this example versus the results of this study. By considering the whole range of possible productivity rates of each activity, the current method is able to relax some activities, causing less required resources per day. This consequently reduces the potential congestion in the job site while still not passing the project deadline. It should be noted that in relaxing of activities, daily fluctuation of the resource usage is also taken into account.

Furthermore, generating schedules with due consideration of the Space-Time floats for each activity instead of only the optimum path helps in better management and control of these projects. This simple example demonstrates the ability of the proposed method to derive alternative plans in order to meet project deadlines. The optimized generated schedule demonstrates that by considering flexibility of movement in addition to all activity constraints, the best duration for the project can be achieved that can be shorter than the estimated duration. Summary and concluding remarks
This study proposed a scheduling and control system for linear projects. The proposed method aims to address the limitation of the current scheduling and control methods for linear projects by taking into consideration the spatio-temporal as well as logical constraints of linear activities. For this purpose, the new concept of Space-Time float and constraint satisfaction problem approach were incorporated. As such, by having Space-Time floats for different activities’ resources and using such constraints, the schedule is optimized to get the minimum achievable duration for the total project. Furthermore, knowing the exact or near exact location of required resources for each activity (or set of activities) and visually integrating such information with the project schedule and space-time constraints, leads not only to an optimized and more practical, updated, and executable schedules, but also to more efficient project control. Consequently, management decisions and corrective actions can be made to prevent/treat the identified issues.

To demonstrate the use of the proposed method and to illustrate its capabilities, a numerical example was analyzed. This example shows the benefits of considering space-time flexibilities and constraints when optimizing schedules of linear projects. As the results of the numerical example illustrates, the optimized schedule saves 2 days in overall duration of the project. Also, despite other methods whose objective is to minimize the daily fluctuation in resource usage linear projects, considering number of resources as variable, here the productivity rate are considered which is a more meaningful factor showing progress of activities over time. Furthermore, the spatio-temporal constraints considered in the optimization process not only facilitate the search for the optimum solution by narrowing down the search space but also leads to having more practical schedules this way, the scheduling optimization method presented in this paper provides an efficient tool for scheduling of linear projects. The method can help the manager teams of liner projects to plan their activities in the most efficient way, while also decrease delays to their minimum, and accordingly prevent cost overruns.

5 SUMMARY AND CONCLUDING REMARKS

This study proposed a scheduling and control system for linear projects. The proposed method aims to address the limitation of the current scheduling and control methods for linear projects by taking into consideration the spatio-temporal as well as logical constraints of linear activities. For this purpose, the new concept of Space-Time float and constraint satisfaction problem approach was used. As such, by
having Space-Time floats for different activities’ resources and using such constraints, the schedule is optimized to get the minimum achievable duration for the total project. Furthermore, knowing the exact or near exact location of required resources for each activity (or set of activities) and visually integrating such information with the project schedule and space-time constraints, leads not only to optimized and more practical, updated, and executable schedules, but also to more efficient project control.

Consequently, management decisions and corrective actions can be made to prevent/treat the identified issues. To demonstrate the use of the proposed method and to illustrate its capabilities, a numerical example has been analyzed. This example shows the benefits of considering space-time flexibilities and constraints when optimizing schedules of linear projects. By bringing all the necessary elements of a successful control system, i.e. timely schedule, tacking all the spatio-temporal and logical constraints of activities in the optimization phase, the method provides an efficient tool in scheduling and control of linear projects. Such a control system can also decrease delays to their minimum, and accordingly prevent cost overruns.

Abstract: Space is a strictly limited resource on a construction site. For linear type of construction projects, the importance of effectively managing space is crucial as their schedules is generated with due consideration to both time and space. As a result, spatio-temporal congestions between activities of these projects could substantially hinder the performance of interfering activities and cause deviations from planned schedules. The existence of such congestions decreases work productivity, and causes accidents to occur. The current literature focuses on minimizing the workspace conflicts in order to perform efficient work and increase productivity. However, the other side of this problem, i.e. the changes in productivities which give rise to such spatio-temporal congestions is overlooked. To tackle this limitation, this paper proposes a constraint satisfaction approach to quantify and minimize potential space-time congestions in the schedules of linear projects using space-time floats. The method is able to detect not only potential conflicts between each activity with its immediate successors, but also any possible conflict between resources of any activity with all other project activities throughout the lifecycle of the project. In order to optimize the potentially congested schedules in the planning stage, either the range of productivities available to activities are narrowed down, or the overlapped activities are rescheduled to minimize the conflict. A numerical example is analyzed to demonstrate the added benefits of the proposed method.

1 INTRODUCTION

Workspaces associated with construction activities and materials continuously go through variations in space and time throughout the lifecycle of a project. Selecting construction methods, scheduling activities, and planning the use of site space over time have been known to be the key to constructing a construction project efficiently (Zouein and Tommelein, 2001). Construction planning, scheduling and control need to be studied and employed not only on temporally but also spatially.

Integrating spatial information of project resources and activities into project scheduling and control has long been studied. However, compared to the available methods for sequencing tasks, provided by critical path analysis and its derivatives, still relatively lower attention is paid to the allocation of tasks to spaces (Winch and North, 2006).

The space planning problem in construction has been studied in two different domains: the space scheduling problem, which focuses on planning of task execution spaces (e.g. (Thabet and Beliveau, 1997, Dawood and Mallasi, 2006, Koo et al., 2013, Choi et al., 2014)) and the site layout problem which
focuses on the location of temporary facilities of various kinds (e.g. (Zhou et al., 2009, Andayesh and Sadeghpour, 2014, Pradhananga and Teizer, 2014, Karan and Ardeshir, 2008)).

Acknowledging activity work space requirements and integrating this requirement as a constraint in the scheduling process provides a number of benefits such as: improved safety, decreased conflicts among workers, reduced crew waiting and idling, improved efficiency, increased productivity, better quality, and reduced project delays (Thabet and Beliveau, 1994, Su and Cai, 2013). Among all, the main purpose of such integration of spatial information into schedules is to prevent available and/or potential space-time conflicts and congestions in the construction site. Existence of congestions in construction site not only decreases resource productivity, but also impacts safety, and may lengthen project durations.

Linear projects such as highways, bridges, pipelines and railways not only aren’t exception to this rule, but also need more careful considerations in terms of spaces allocated to the movement of their resources. This is due to the fact that, this class of project is characterized by a series of repetitive activities; where construction crews are often required to repeat the same work in various locations and therefore, move from one location to another. This frequent movement of resources makes it important to continuously integrate the location and movement of resources into the schedules of these projects (Roofigari-Esfahan et al., 2015). As a result, the progress of these projects highly depends on the productivities achieved from their resources. In other words, activity production rates derive the development and accuracy of linear schedules (Duffy et al., 2011). The productivities achieved in these projects are dependent upon the space paved by resources allocated to activities over time. Congestion on construction sites often leads to lowered efficiency and productivity of resources (Watkins et al., 2009). Consequently, a reasonable and resource-leveled schedule that allows for adjustments for unforeseen circumstances and minimizes possible congestions during construction is critical for managing linear construction projects.

The spaces considered by some methods are the spaces associated with construction objects and not the ones required for the movement of resources. Also, the current linear scheduling methods still do not consider the whole range of possible production rates that are available to each activity at each point in time and space. Also, As a result, they disregard all other possible production rates that can be achieved without delaying activities. This is a limitation that can be tackled by using Space-Time float, as explained in authors’ previous work (Roofigari-Esfahan et al., 2015).

As a continuation of the previous work, this paper proposes a constraint satisfaction approach to quantify and minimize potential space-time congestions in the schedules of linear projects using space-time floats. The space-time congestion in this research specifically means the workspace interference when two activities have both spatial and temporal overlaps. The method is able to detect not only conflicts between each activity with its immediate successors, but also any possible conflict between resources of any activity with all other project activities, throughout the life cycle of the project.

2 RELEVANT LITERATURE

Early research studies in construction site planning have recognized the importance of space as a construction resource and have subsequently incorporated it as an integral part of planning constraints (Winch and North, 2006, Hildum and Smith, 2007). Watkins et al. (Watkins et al., 2009) proposed an agent-based modeling method to represent the construction site as a system of complex interactions and explore whether labor efficiency can be treated as an emergent property resulting from individual and crew interactions in space with positive results.

Zouein and Tommelein (Zouein and Tommelein, 2001) noted that construction sequences were often constrained by the sequential occupation of workspaces. The utilization of space associated with these sequences is then analyzed from a comparison of space supply and demand. Winch and North (Winch and North, 2006) further refined this idea by defining and analyzing the criticality of space in a manner analogous to critical-path method. Akinci et al. (Akinci et al., 2002) introduced a taxonomy of space conflicts which correctly defines conflict as a high-level knowledge construct, encompassing various forms
including congestion, unavailability of access, safety hazards, damage of finished products, and design conflict.

Guo (Guo, 2002) analyzed spatial conflict and temporal conflict separately, introducing two independent interference indicators called the interference space percentage and the interference duration percentage. Additionally, the spatial requirements of movement paths (space for moving workers, equipment, and materials on-site) have not been adequately modeled. Other research used graphical methods to explain potential congestions in collided areas and detection of interferences among trades (e.g. (Chua et al., 2010, Koo et al., 2013). Riley and Sanvido (1995) argued that abstracting workspaces in “solid” CAD models was not truly representative of on-site construction. Four-dimensional 4D computer-aided design CAD overcomes this difficulty by incorporating the temporal element in three-dimensional 3D models. Many construction practitioners and researchers have developed four-dimensional (4D) models by linking the three-dimensional (3D) components of buildings with the network activities of a project schedule (Wang et al., 2014, Mallasi, 2006, Moon et al., 2014). However, these methods mainly model the space required for objects in the construction site. They do not consider the space that is occupied throughout execution of the project only as a result of movement of its resources. This way, the space floats that are available to each resource at each point during activity execution is not taken into account while dealing with unforeseen events.

As mentioned in the introduction section, due consideration to space requirements becomes more important when it comes to scheduling linear type of construction projects. This is because the dynamic resources on sites of linear projects are more likely to interact with each other in a complex spatial-temporal manner. Currently available network techniques and linear scheduling methods mainly consider technological constraints and resource requirements in the generation of schedules. Such techniques and methods overlook the requirements of activities for the requisite work space for material storage and movement of manpower and equipment.

There are methods that attempted to visualize linear schedules, using 4D CAD (Staub-French et al., 2008) and MS-Excel (Lluch, 2009) as well as methods that consider variable productivity rates for linear activities; e.g. (Lucko, 2008, Duffy et al., 2011). Yamin (2001) developed an approach to analyze the cumulative effect of productivity rate variability (CEPRV) on linear activities in highway projects. The focus of the research was to advance the risk analysis capabilities of linear scheduling to allow managers to forecast the probability of project delay. Duffy, et al.’s method (2011) divided linear schedules to areas of time and location for which unique production variables, called working windows can be assigned. Working windows display when and where production variables may change along the linear project. Similarly, (Lucko et al., 2014) models linear schedules using singularity functions to model changes in productivity along the execution time of each activity.

However, none of these methods considers the space available to the activities’ resources throughout their execution. As such, the potential space-time conflicts that can happen as a result of variation in planned productivity rates cannot be detected. This is a limitation that can be tackled by using Space-Time float, as introduced in authors’ previous work (Rofigari-Esfahan et al., 2015). As a continuation of the previous work, this paper proposes a constraint satisfaction approach to quantify and minimize potential space-time congestions in the schedules of linear projects using space-time floats. The space-time congestion in this research specifically means the workspace interference when two activities have both spatial and temporal overlaps. The method is able to detect not only conflicts between each activity with its immediate successors, but also any possible conflict between resources of any activity with all other project activities, throughout the life cycle of the project. The details of the method are presented in next section.

3 RESEARCH METHOD

The optimization method presented in this paper aims at generating minimized-congestion schedules for linear schedules. The method utilizes the output of the duration optimization method presented by the authors (Rofigari-Esfahan and razavi 2015) to identify and quantify the potential congestions and and re-
optimizes the schedule by minimizing them. This is done in two different inter-related phases as described in following sections and shown in Figure 1.

3.1 Congestion Detection and Quantification

As stated earlier, the optimized schedule generated from (Roofigari-Esfahan and Razavi 2015) is used as the input to the congestion minimization framework presented here. In this schedule, optimum project duration and optimum productivity rates for each activity are defined. However, there exist potential congestions in the generated schedule that are to be minimized to ensure successful implementation of the planned schedule. The focus of this study is to detect and quantify potential congestions in the generated schedule. These potential congestion areas are those that might be happening as a result of changes in planned productivities. It should be noted that congestion in this paper is defined as areas in space and time where the possibility of interaction between resources of subsequent activities exists. Such congestions will actually happen if the progress rate of activities deviates from what planned for them, which is a common case in execution of linear activities. This way, the congestions can also be predicted even before the execution phase starts. Such changes in productivity will, therefore, be identified before they cause project delays as shown in Figure 2. The locations and times where such congestion would potentially happen are also identified (Figure 2). The figure also shows the comparison of the generic linear schedule generated versus the schedule generated with due consideration to space time constraints of different activities; through use of Space-Time Float Prisms.

![Congestion Minimization Framework](image)

Such potential congestion areas cannot be detected using the traditional linear models which present only optimum productivities. Considering a range of possible productivity rates, i.e. through consideration of space-time prisms/polygons for each activity, helps in identification of Space-Time floats simultaneously. This consequently helps in detection and prevention of potential congestions between succeeding activities. It should be noted that simultaneous consideration of space and time floats makes it possible to trade-off one for the other which consequently allows planning for potential delays before the actual execution commences (Roofigari-Esfahan and Razavi 2015).

This phase is modeled in MATLAB environment. In order to transfer the data generated in the previous study, a spreadsheet interface is used between the two environments. The data transferred include number of project activities, activity id’s and the information required to generate space-time polygons for each activity. This information includes start and end locations and times of the activity, minimum and
maximum achievable resource productivity rates (polygon boundaries) and activity’s optimum productivity rate.

As it can be seen in Figure 2, the intersection between polygons, i.e. potential congestion between activities, are automatically detected. Subsequently, a matrix is generated in which the exact areas of the congestions are calculated. In that matrix, if the element $a_{ij}$ is filled with a number, it means there would exist potential congestion between activities $i$ and $j$. Essentially, the element $a_{ij}$ will be equal to zero if no potential congestion exist between the two activities $i$ and $j$. It is important to note that in the generation of congestion matrix, these congestions are considered for any two activities within project network. This helps detect not only potential congestions between each activity with its immediate successors, but also will detect any potential congestion in the construction job site. The schedule is then revised in the next phase to minimize the detected congestions. Further, as shown in that figure, the time and space that these congestions would potentially happen are also identified.

Figure 2: a) Generated Linear Schedule b) Realization of Potential Space-Time Congestions with Due Consideration to Space-Time Float prisms

3.2 Congestion Minimization

The optimization framework proposed here is a Constraint Satisfaction Problems CSP-based optimization model. Constraint programming (CP) is a programming paradigm being used for solving Constraint Satisfaction Problems (CSPs) through using a combination of mathematics, artificial intelligence, and operations research techniques (Chan and Hu 2002; Liu and Wang 2012 (Tang et al., 2014b). It has been successfully used to solve complex combinatorial problems in a wide variety of domains. To improve the computational efficiency of solving problems, CP provides users with different consistency techniques such as node, arc, and path consistency for variable domain reduction. Constraint programming provides different search strategies such as generate and test (GT), backtracking (BT), and forward checking (Liu and Wang 2008; Marriott and Stucky 1998). Its Selection of appropriate variables and values through heuristics reduces the computational effort required and improves the search ability (Liu and Wang 2007; Russell and Norvig 2009).

Apart from being applicable to solve a variety of problems, it has particular advantages in solving scheduling problems due to: (1) its efficient solution search mechanism, (2) flexibility to consider a variety of constraint types, and (3) convenience of model formulation (Menesi et al., 2013). In other words, the highly constrained problems associated with project scheduling can be best modeled and optimized using CP because of its characteristics (constraints are naturally incorporated into the problem description); (Chan and Hu 2002), as well as its flexibility in description of constraints, and its capability in processing complex and special constraints (Tang et al., 2014a). When solving an optimization problem, the objective function in the problem is treated as a constraint and this additional constraint forces the new feasible schedule to have a better objective value than the current schedule. The upper or lower bounds of the constraint are replaced as soon as a better objective function value is found. The propagation
mechanism narrows the domains of decision variables to reduce the size of the search space while recording the current best schedule. The search terminates when no feasible schedule is found and the last feasible schedule is the optimal schedule (Liu and Wang 2008).

CP is suitable for modeling and solution finding of the project scheduling optimization of linear projects and accordingly applied to schedule optimization phase based on LSM. This is because for LSM-based scheduling problems, prioritization of activities in linear scheduling problems becomes clear owing to the logical and sequential constraints in CP (Liu and Wang 2007). Also, the procedure for the solution of a problem does not require complex mathematical models and formula derivation, eliminating unavoidable simplification and ignorance, truthfully reflecting the original appearance of the problems and ensuring the quality of the solution. To facilitate the use of CP algorithms in scheduling problems, a powerful optimization package, termed ILOG CPLEX Optimization Studio (Beck et al. 2011), was developed incorporating a CP optimizer engine that offers features specially adapted to solving scheduling problems. ILOG CPLEX Optimization Studio was used and the ILOG OPL language was adopted as the model formulation language.

For the proposed model, the objective and variables were determined in the problem specification stage. In the research reported in this paper, the objective was considered as minimizing the total congestion area between prisms of different activities, and the decision variables include the start date, minimum and maximum productivity rates of linear activities. For this purpose, the optimum productivity rates of activities and their respective time interval (including start and times) are used as known information. In this optimization phase, different decision variables are taken into account in the optimization process. These variables include prism boundaries, i.e. min and max productivity rates of activities, as well as start time of activities. In other words, in order to minimize the congestion (intersection) areas between activities, the float prism for the either of the intersecting activities (or both) becomes narrower on the congested side; or the start time of the activities in moved to reduce the intersection area.

Changing the boundaries of the float prism on the congested side only, provides the advantage of not reducing the floats available to activities where it is not necessary (Figure 4). In other words, the floats are only compensated where their existence leads to occurrence of congestion between activities. This way, the generated schedule gives the planners a better sense of spaces and times that are practically available to activities. This capability enables the planners to make more practical decisions in using floats of activities when delays happen during execution of activities.

It should be noted that, the deadline constraint and precedence relationships between activities are considered as strict constraints which cannot be changed. The optimization data are listed in detail below:

**Constants:**

- \( SL_i \): Start location of activity \( i \);
- \( EL_i \): End location of activity \( i \);
- \( OptPro_i \): Optimum resource production rate of activity \( i \);
- \( P_{min_i} \): Minimum productivity rate of activity \( i \);
- \( P_{max_i} \): Maximum productivity rate of activity \( i \);
- \( D \): Project deadline

**Decision variables:**

- \( P_{1min_i} \): Minimum productivity rate of activity \( i \) which minimizes congestions;
- \( P_{1max_i} \): Maximum productivity rate of activity \( i \) which minimizes congestions;

\[
P_{1min_i} \in [P_{min_i}, OptPro_i]
\]

\[
P_{1max_i} \in [OptPro_i, P_{max_i}]
\]

- \( ST_i \): Start time of activity \( i \);
- \( ST_i \): Start time of activity \( i \) \( \in [0, D] \)

**Decision expressions:**

- \( ET_i \): End time of activity \( i \);
Where $A_{cong_{ij}}$ is the area of the intersection between space-time prisms of activities $i$ and $j$ respectively, $A_{cong}$ is the total congestion area available in the construction site, $x_1$ is the $x$ coordinate of vertex 1 and $y_n$ is the $y$ coordinates of the $n$th vertex.

For minimizing the potential congestion areas between construction activities, first, such areas need to be calculated taking into account the decision variables. To formulate this area, a mathematical formula for finding the area of polygons with known coordinates of vertices is used as presented in the Equation 1.

This area represents the possible interactions between successive prisms.

In order to use this equation, the coordinates of the intersection polygons between each two activities need to be formulated in terms of the decision variable; i.e. start times of the two activities and their prism boundaries. The intersection points are identified by getting the information from the second phase which includes the intersecting lines of the two polygons and the coordinate of the intersection points. Having identified the intersected lines, the system of line equations is set to find the intersection points in terms of decision variables.

After solving the parametric system the intersection points are found in terms of start time (ST) and minimum and maximum productivity rates ($P1_{min}$ and $P1_{max}$) of the intersecting polygons. The coordinates of the intersection points are feed into the area equation. Subsequently, the objective function of the optimization process is formed by summing up all the intersection areas in the project network schedule. The optimization process then optimizes the schedule by minimizing the total congestion in the project network. This is done through narrowing down the space–time float prism of one or both of the intersected prisms by changing their boundary slopes and/or changing start time of succeeding activities.

4 NUMERICAL EXAMPLE

The method presented here was applied to a case study to demonstrated and validated. The minimum and maximum productivities are assumed here, while in the real-world examples, project management teams are requested to enter general information about the project and respective activities. The project
includes construction of a 4-kilometer altering access road. Four activities (A, C, D and F) are assumed to be linear activities while the other two (B and E) were considered to be non-repetitive for this specific example. Accordingly, maximum, minimum were estimated (the inputs to the optimization module) for repetitive activities. The project was initially estimated to finish in 17 days. The description of each activity as well as inputs and outputs of the optimization process are included in Table 1 and Table 2, respectively.

As it is shown in Table 1, the input data of the congestion minimization process include Activity IDs, their start and end location, successors, their minimum and maximum achievable productivity rates, as well as their planned (optimum) productivity rates and its associated duration. The developed optimization engine uses this information to search for the optimum duration for the project for which the least potential congestion in the project is achieved, considering all logical and spatio-temporal (productivity) constraints to each activity. As shown in Table 1, the project deadline (17 days in this case) is another constraint which is inputted to the optimization process. The output of this process includes optimum minimum and maximum productivity rates for all repetitive activities (that also is representative of floats available to the resources at each point in time and space) as well as start and end times of all the activities, considering precedence relationships. The optimum duration for each activity and its associated duration are kept the same. The optimum duration achieved in this process might be longer than the previously duration for the project, but still satisfies the deadline constraint.

Figure 4 shows the initially generated schedule for this project along with the optimum schedule. As it can be seen in that figure, in the generated schedule the intersection between space-time float polygons for succeeding activities are detected and marked. These potential congestions are totally eliminated in the optimum schedule. The potential congestion area between intersecting activities as well as the total congestion inherent to the project schedule is calculated. As it can be seen in the Figure 4a, potential congestion in location/time exists between activities C and D, as well as between activities D and F. The project schedule’s total potential congestion is calculated to be 4.418 (km.day). Table 2 shows the results of the schedule after the proposed optimization process. It can be inferred from the table 2 that the scheme of the schedule generated using proposed model is significantly different from that of the initial schedule in which congestion was not considered. The schedule finishes at 16 days which still satisfies the 17 day deadline constraint. Although the achieved duration is 1 days longer than the original minimum duration, the potential congestions are reduced to zero in the optimized schedule. For this purpose, as can be seen in Table 2 and Figure 4b, activities D and F are moved by one day, i.e. from day 5 to 6 and 9 to 10, respectively. Also, the available productivity interval for activity D (its minimum and maximum productivity rates) is reduced from [0.2, 0.7] to [0.3, 0.5], which accordingly means less float will be available to the resources of this activity. The result attained through this example ensures the applicability of the method. This way, the approach presented here helps in providing realistic plans for linear projects both in terms of time and space, while satisfying all there logical constraints.

5 CONCLUDING REMARKS

In order to avoid or eliminate space-time conflicts in construction job sites, the subcontractors may frequently change their schedules. This occasionally cause a change in the materials delivery dates and/or the operation productivity or production rates. Such changes can be eliminated through detecting the potential space-time congestions in the planning phase and minimizing them before they happen. In this paper a method of detection, quantification and minimization of potential space time congestions of linear projects is presented. The method minimizes the potential space time congestions in the schedules of linear projects with due consideration to all their logical and precedence constraints. This is done by first, identifying the space time floats available to the resources of each activity, and then using this flexibility in predicting and accordingly minimizing the potential congestions. The method for time-space scheduling was subsequently validated through a numerical example. The results obtained promise applicability of the proposed method in managing linear construction projects. Running the optimization framework presented here for different number of resources will help project managers and decision makers to identify the potential spatial conflict that can affect the output of their projects.

Abstract: Hazardous proximity of construction resources, such as construction equipment, materials, and workers-on-foot has been identified as a distinct safety issue on construction jobsites. Spatial and temporal limits are practical constraints that coexist in movement of construction resources. Space and time conflicts could substantially hinder the productivity of ongoing activities as well as causing safety issues. Therefore, the spatial and temporal constraints and the state of construction resources need to be considered to prevent space-time conflicts and unsafe proximities. The state of a moving construction resource includes its position, moving direction/heading, speed, orientation, and other safety-related information. The area around each resource is divided into alert and warning areas which are quantified for them according to their corresponding spatial or proximity constraints. By integrating the states of resources, their warning/alert areas, and proximity constraints, as well as by visualizing them in time-integrated 2D space, a more precise understanding of potential hazardous situations can be achieved and therefore prevented. This paper presents a visual support tool aiming to reduce safety hazards in project planning stage by optimizing spatio-temporal proximities of resources. For this purpose, the developed method first optimizes potential movements of the resources by minimizing intersection of their warning areas and avoiding overlap of their alert areas. Thereafter, it visualizes the optimized locations of resources in time-integrated 2D space throughout the duration of their corresponding activities. In this way, the integrated visualization framework enables managers to make more judicious decisions and take corrective actions pertinent to safety hazards prevention. A numerical example with different scenarios and proximity measures is analyzed to test and validate the proposed framework.

Key Words: Construction Safety; Spatio-Temporal Constraints; Optimization; Alert and Warning Areas; Visualization

1 INTRODUCTION

Construction sites are generally comprised of multiple resources such as personnel, equipment, and materials moving in pre-defined spaces. These resources are involved in dynamic work tasks which require moving through space at different times on the job site. Because of their frequent unstructured and almost random motion, these resources can come in close proximity to each other. If not coordinated
and organized properly through optimized work planning (schedule and resource leveling), spatial interference can lead to incidents between two or more resources (personnel, equipment, material). These incidents can be characterized as contact collisions that can threaten the safety and health of construction personnel (Teizer et al., 2010).

Mustafa and Al-Bahar (Mustafa and Al-Bahar, 1991a) have identified risks sources central to construction activities to be physical, environmental, design and logistics based risks. Also the most frequent causes of accidental death and injuries were found to be falls, falling materials and collapses, as well as mobile resources’ accidents. Such risks can be reduced if the use of vehicles and mobile resources are properly managed. As a result, proper routing of resources can affect the cost and the time during construction projects by reducing safety risks. In addition, major productivity gains in terms of the reduction in wastage and working time can be achieved by planning the site from a logistics perspective (Mahdjoubi and Yang, 2001). Accordingly, during a construction project, site planners need to select paths for site operatives and vehicles. Such path planning in construction site spaces is a complex and multi-disciplinary task as it involves accounting for a wide range of scenarios and conditions. In other words, provision of safe paths could be used to control high-risk situations on the site and helps in having safe and efficient working conditions (Soltani et al., 2002).

Consequently, path/trajectory planning aids to improve safety and productivity margins by providing time-optimal and collision-free paths for navigating through the construction site that seek to prevent hazardous contacts between construction elements. To identify the potential of unsafe contacts between construction elements, it is essential to understand the potential regions of intensive activities not only during execution, but also in the planning phase. This definitely helps in having a more efficient activity resource planning which also increases safety on the job site. However, despite its importance, path/trajectory planning is not efficiently taken into account in the planning stage of construction projects. Further, although there are methods tending to optimize motion paths of resources or robots for special site operations (e.g. (Bernold, 1993, Olearczyk et al., 2010, Lee and Adams, 2004), still the time factor is very much neglected in both analysis and visualization. These methods mainly use shortest path algorithms such as Dijkstra to find 2D trajectories for construction resources. A common problem of current studies is that the distance between entities is the only factor taken into consideration and the direction of the entities’s movements (headings) are neglected. In some cases, the distance between two entities could be flagged and alarmed as an unsafe proximity while in reality, the entities are moving apart from each other.

To fill the gap in the literature, this paper aims at optimizing trajectories of construction resources in time-integrated 2D space in planning phase of the project. For this purpose, this study proposes and develops an unsafe proximity avoidance model focused on decreasing resources interactions throughout the planned activities’ duration. The model uses the attributes of distance and moving direction to define state of different resources and predict and optimize their motion through space and time. Subsequently, this paper discusses the key factors that should be considered in quantitatively defining the distance thresholds between resources. Current research either has not fully considered these factors, or has not described the relationship between the distance threshold and these essential factors (IHSA 2013; Marks and Teizer 2013). The thorough description of the proposed method is presented in following sections.

2 RELEVANT LITERATURE

Unsafe proximity of workers-on-foot to construction equipment or equipment-to-equipment has been identified as one of the distinct safety issues on construction jobsites (Pradhananga and Teizer 2012). Struck-by hazards are the second leading cause of construction fatalities, in which approximately 58% fatalities are resulted from struck-by-equipment (Wu et al. 2013). Thus, entities on construction jobsite have to interact and co-ordinate effectively with each other to maintain a safe environment. Even though such issue has been extensively studied in previous research efforts, the published casualty statistics indicate that contact collisions remain a major problem in construction industry. Hence, the trajectories of construction resources should be properly planned and monitored so that the potential collisions can be prevented in a timely manner. The trajectory of a construction entity includes the information regarding its
movement in space and time, taking into account its position, moving direction/heading, speed, orientation, and other safety-related information.

Optimizing trajectories of resources and operations is a common practice in different industries. Specially, trajectory optimization methods are widely used for planning optimal trajectories of robotic systems and machineries (Posa et al., 2014, Ahmad et al., 2013, Betts, 1998). With the growing use of robots and automated systems in construction industry, the problem of trajectory planning of these systems has been raised. Previous work on trajectory and path planning analysis in construction focused on three principal categories: (1) navigation of multiple vehicles, (2) efficient jobsite geometric modeling, and (3) real-time motion planning and control of equipment (Cheng et al., 2012). These methods are either focused on the trajectory planning of robotic workers, or equipment used in special construction processes. The early works in this regard included simulated work studies focused on large vehicle routing around an industrial construction site (Varghese and O'Connor 1995), motion planning for automated construction excavation (Bemold, 1993), heavy lift planning (Lin and Haas 1996), interactive path planning for vehicle operations (Wi Sung. et al. 2000), and visualization of construction simulation (Kamat and Martinez, 2001).

In order to execute the construction activities in a safe and efficient manner, construction site spaces needs to be properly planned. The risky sources of construction activities were identified to be physical, environmental, design, logistics, financial, legal, political, and operational risks (Mustafa and Al-Bahar, 2011b)). As a result, the paths of construction resources need to be planned in a way to be associated with less risks and would not cause congestion on the construction site. In addition, routing of resources affects the cost and the time during construction projects, and major productivity gains in terms of the reduction in working time can be achieved. Soltani et al. (Soltani et al., 2002, Soltani and Fernando, 2004) presented the application of path planning on construction sites according to multiple objectives. In their method, they evaluated the performance of three optimisation algorithms namely: Dijkstra, A*, and Genetic algorithms. The optimised path in this approach was defined as the shortest path, the safest path, the most visible path or a path that reflected a combination of short distance, low risk and high visibility. Chi et al. (2008) examined crash avoidance algorithms for providing routes that prevent collisions with other movable objects on a construction site. While the calculated path avoided crashes, it was not necessarily the most efficient. Other methods used the highly parallel unconstrained Dijkstra approach in order to develop a new optimal algorithm in which paths were subjected to turning constraints such that the final solved path contained no turns greater than 45°((Solka et al., 1995, Hassoun, 1990). In this regard, Pei et al. (2009) also generated a basis for vehicle movement trajectory reconstruction in two-dimension collision accidents and accidents disposal. Recently, some methods also focused on providing potential optimized paths for special construction equipment or operations, e.g. (Filla, 2013, Lin et al., 2014, Wi Sung et al., 2012). Lin et al. (2014) performed motion planning for mobile construction machinery to generate collision-free path for multiple construction machines, including wheel-type, track-type and chain-type machines, moving simultaneously on a construction site, based on the true movement of construction machinery. (Wi Sung et al., 2012) also introduced a Genetic Algorithm-based Repetitive Tasks Simulation (GARTS) model for planning steel erection in high-rise building construction. This model produced an optimized movement path of a bolting robot for fabricating steel structures, proposed a collaboration plan between a robot and a worker, and quantified the uncertainty of the duration of steel erection.

Visual representation of the stated resource paths is the next step towards efficient planning of construction sites. In other words, visualizing simulated construction operations can provide valuable insight into the subtleties of construction operations that are otherwise non-quantifiable and presentable. This is because planners must comply with many considerations, such as increasing construction productivity, decreasing site congestion and providing a safe work environment during the process of site space planning which is more achievable when properly visualized (Zhou et al., 2009). (Kamat and Martinez, 2001) presented the Dynamic Construction Visualizer, which enabled spatially and chronologically accurate 3D visualization of modeled construction operations and the resulting products. William et al. (2007) also developed a dynamic path planning system to improve mobile robot navigation in a dynamic building construction site by integrating a set of sensor-equipped robots into a real-time indoor positioning system, using the ultra wide band (UWB) position system. The method then displayed the mobile robot movements and paths in a 3D CAD drawing in a real-time manner.
As stated, when dealing with heavy machinery and vehicles, following a safe and efficient path reduces the risk of worker injury and fatality, reduces collateral damage to equipment, and improves overall work efficiency. However, limited research in path finding on construction site has been conducted. In addition, although the 2D or 3D visualization of these paths has many potential uses toward the monitoring and maintenance of an automated construction site, still all the few available visual methods disregard the time aspect of the possible congestions when planning and visualizing the paths of actual resources. Up to now, such trajectories in construction industry are only available recently for unmanned Aerial Vehicles (UAVs) (Alejo et al., 2014) or for workers-on-foot (Dagan and Isaac, 2015). Their innovative method presented a new system for assembly and structure construction with multiple Unmanned Aerial Vehicles (UAVs) which automatically identifies conflicts among them. After detecting conflicts between UAVs, the system resolved them cooperatively using a collision-free 4D trajectory planning algorithm based on a simple one-at-a-time strategy to quickly compute a feasible but non-optimal initial solution. Further, the available methods still do not take into account the results of the interaction between two individual workers with different characteristics, which might create safety risks and their daily interactions with other site equipment and obstacles. As a result, the method presented in this paper tends to fill the gap in the current literature by proposing a time integrated framework for trajectory optimization of construction resources, aiming at preventing the proximity hazards in the construction job sites. The detailed description of the optimization method follows.

3 TRAJECTORY OPTIMIZATION-VISUALIZATION FRAMEWORK

As stated in previous sections, visualizing simulated construction operations in time-integrated 2D space can provide valuable insight into the subtleties of construction operations that are otherwise non-quantifiable and presentable. The optimization method presented in this paper aims at generating minimized-congestion trajectories for construction resources. This is done in two essential inter-related phases, namely trajectory optimization and visualization phases, as shown in Figure 1. This framework consequently enables spatially and chronologically accurate visualization of modeled construction operations and the resulting optimum planned trajectories for activity resources. This section describes the steps of the time-integrated 2D trajectory optimization-visualization framework.

![Diagram](image)

Figure 1: Trajectory optimization-visualization framework

The optimization method presented in this paper uses the unsafe proximity detection process presented by (Wang and Razavi, 2015). In this method, the authors divided the area around equipment into alert and warning areas. Further, the distance threshold used for unsafe proximity identification is differently considered when the piece of equipment is moving as opposed to staying stationary. The key factors that should be considered in quantitatively defining such distance thresholds are then described. This approach will prevent congestions between activity resources in the planning phase, which will subsequently lead to achieving more safety and higher productivity rates from the resources.
3.1 Quantification of Alert and Warning Distances

In this study, alert area is defined as the hazardous area around the equipment, and warning area is the area that has the potential to become hazardous under certain conditions. A hazard refers to a situation that an entity is within the alert area. For the proof of concept, circles are adopted as an approximation of the alert and warning areas for equipment and workers-on-foot (Figure 2). It should be noted that different equipment exhibits different alert distance (R1) and warning distance (R2). Accurately quantifying R1 and R2 can assist in effectively performing proximity detection methods and also contributes to enhancing mobility and productivity on the job site.

![Figure 2: Intersection between warning areas of a) two pieces of equipment and b) equipment-worker](image)

For one piece of specific equipment, alert distance R1 is the same under general condition, regardless of its static or moving state. This study uses forklift as sample equipment to explain the process of defining R1 and R2. It is expected that no intersection of alert areas occurs when the forklift comes to a complete stop. This study adopts 2 meters as the alert distance for the forklift with 2.5 tonne capacity. The determined 2 meters includes the length of the fork attached to the forklift. In order to take into account all conditions, including both congested and non-congested time periods, this paper proposes adjusting warning distances for the same equipment over time. The warning distance for equipment is adjusted by considering equipment reaction distance and equipment braking distance. Equipment reaction distance is the distance that equipment travels after the operator's realization of a hazard and before a determined response (e.g. brake) exactly comes into work. Equipment braking distance is defined as the distance the equipment will travel from the point when its brakes are fully applied to the point when it comes to a complete stop. As thus, R2 needs to be increased when the equipment is moving with a higher speed. Likewise, for the equipment with a lower speed, this distance is decreased in order to have efficient space allocation on the job site.

For workers-on-foot, an alert area with an average 1 meter diameter is adopted which is the area a worker demands for safety operation of different construction activities (Dagan and Isaac, 2015). An average 1.5 meters is adopted as the warning distance. The difference between the warning distance and the alert distance is 1 meter which is the distance a worker needs to achieve a complete stop upon realizing a hazard occurrence. It is obtained by multiplying the mean of actual comfortable gait speed of men at 30s and 40s (Bohannon, 1997) and the average reaction time of a normal people (Technology Associates, 2014).

3.2 Trajectory Optimization

This paper proposes a step-by-step optimization algorithm to find the safest trajectory for activity resources in the planning phase, based on the information available in this phase of the project. For this purpose, first, a set of check time intervals is defined based on the nature of the project. These check time intervals are then used to attain the optimum average location of each activity resource as shown in Table 1. It should be noted that, the step-by-step nature of the algorithm enables it to be applicable to planning as well as monitoring and tracking phases; i.e. when exact location and progress at one time is known, and the planned trajectory needs to be re-optimized to plan for following movements in space and time. The developed safety planning method was applied in MATLAB. Its application is carried out in the following steps.
3.2.1 Identification of resource locations and their safety areas

For construction equipment and workers-on-foot, safety area refers to their warning area and alert area. For temporary or permanent site facilities and obstacles, safety area refers to the area around them that other construction resources (static or dynamic) are not allowed to be inside except by authorizations. To start the optimization process, the approximate coordinates of the expected location of each resource is determined based on the nature and the schedule of activities they will be involved in. The alert distance (R1) and warning distance (R2) are also to be defined at each time. Subsequently, the step-by-step optimization is initiated. The process of defining R1 and R2 starts at the first check-time, which is generally the start of the project or the date on which a certain part of the project starts for which a safe trajectory needs to be planned. In each check-time, the alert and warning areas are created around the approximate planned location as shown in Figure 2. The location optimization will only take place in predefined check-time intervals. Therefore, whenever equipment is added or removed, its starting point will be added and then its optimization will start from the first nearest check time and then the whole trajectory will be demonstrated through space and time in the visualization phase.

3.2.2 Location optimization

The purpose of this phase is to minimize the potential hazardous contacts between resources that co-exist in each check-time. First, the distance between each two different resources (D) and the intersection of their safety areas need to be calculated. It should be noted that, the method is able to take into account not only hazardous contacts between resources, but also the possible contacts between these resources and any temporary or permanent site facilities and obstacles. Distance D is then defined as the center-to-center distance of the warning areas of two resources or a resource and an obstacle that is calculated using Equation 1; where (x₁, y₁) and (x₂, y₂) are the approximate coordinates of resource i and j, respectively, at check time t.

\[ D = \sqrt{[x_i(t) - x_j(t)]^2 + [y_i(t) - y_j(t)]^2} \]

When calculating the intersection between safety areas of each two resources, three possible situations might exist:

1. Distance D is greater than the summation of the waring areas of the two resources, in which no intersection area (IA) between safety areas would exist.

\[ D \geq R^2_i + R^2_j \rightarrow IA = 0 \]

2. Distance D is less than the subtraction of the waring areas of the two resources, in which intersection area is the area of the smaller warning area of the two.

\[ D \leq R^2_i - R^2_j , \ R^2_j \leq R^2_i \rightarrow IA = \pi R^2_j \]

3. Distance D is greater than the subtraction of the waring areas of the two resources, and less than their summation. This means the areas are partially overlapped. In such case intersection area is calculated as follows:

\[ R^2_i - R^2_j \leq D \leq R^2_i + R^2_j , \rightarrow \]

\[ IA = R^2_j \cos^{-1} \left( \frac{D^2 + R^2_j - R^2_i}{2DR^2_j} \right) + R^2_i \cos^{-1} \left( \frac{D^2 + R^2_i - R^2_j}{2DR^2_i} \right) - \frac{1}{2} \sqrt{(-D + R^2_j + R^2_i)[(D + R^2_j - R^2_i)(D - R^2_j + R^2_i)](D - R^2_j + R^2_i)(D + R^2_j + R^2_i)} \]

This paper focuses on the third case in which a partial overlap between safety areas occurs. Therefore, the objective is to minimize the total intersection areas of all resources that co-exist in each check time.
In this optimization process, the coordinates of each resource at time $t$ is set as decision variables. As a result, the optimization process seeks for the optimum coordinates for each resource that will minimize the total intersection areas considering the rules and constraints of the project. It should be noted that no overlap can be existed between two resources’ alert areas. In other words, no entity would be allowed to enter the alert area of the other entity. This condition is employed as a constraint to the optimization process as shown in Equation 7.

$$\text{min } [f(x,y)_t = \sum_{k=1}^{m} (IA_{i,j})_t]$$

$$m = \binom{n_t}{2} = \frac{n_t!}{2 \times (n_t - 2)!}, \ n = \text{number of resources at time } t$$

The optimization process is performed for all check-times. Consequently, vectors of the optimum trajectories for all the resources in time-integrated 2D space are created. The achieved optimum trajectories as well as the prisms are then realized in the visualization phase to give the planners a better sense of the safety hazards and the optimum trajectories. Based on the obtained plan, in the project implementation phase, the rates at which planned activities are expected to be carried out, and the rate achieved from the optimum trajectory can be compared to ensure optimality of the assessed productivities. Therefore, this method represents resources’ movements, and also verifies that they adhere to the planned productivities at all times.

### 3.3 Space-time trajectory visualization

In the presented study, time–space diagrams were developed to represent the actual movements of resources along different paths on the construction site. The time–integrated 2D space diagrams, whose $(x,y)$ axis represent the changing locations of resources on site and the vertical axis represents time, were developed as prisms representing the locations of resources as well as potential safe spaces available to them on the site at different time (Figure 3). The time-integrated 2D space diagrams are used to visualize the movements of resources and to ensure their safety through planning the safest distance between their prisms. Each optimum trajectory is simultaneously represented as a number of polylines in the diagram, connecting the optimum locations at each time interval to the next. Space distance between resources, introduced in time order to reduce safety risks, is represented as distances between the polylines.

![Figure 3: Realization of prism for one activity a) without and b) with site obstacles](image-url)
As stated earlier, in addition to the representations of the movements of equipment and workers on the site, certain static objects (i.e. temporary or permanent site facilities and obstacles) and areas on the site that may expose resources to hazards are also represented in the space-time diagram. For example, some of the workers may need to work at a certain distance from a crane, or from a storage area with flammable material. Such elements are represented as cylinders in the diagram. The footprint of the shape represents the portion of the site occupied by the object, and its height represents the duration for which the object remains on the site as shown in figure 3b. Figure 3a demonstrates the prism for equipment as well as the optimum trajectory throughout its execution period. Figure 3b illustrates the result of the optimization process when one piece of equipment is to perform, and one temporary and one permanent obstacle exist on the job site. Figure 4 demonstrates the intersection between resources with site obstacles as well as between two activities with different start and finish times in time-integrated 2D space. Table 1 and Figure 5 respectively represent the initial data inputs and visualization of a small sub project including three resources (equipment 1, 2 and 3). As shown in table 1 and figure 5, check time intervals of 7 days are considered in this example. However, for equipment 3 that starts at day 5 from start of the sub-project, its optimization starts on day 7, i.e. at the nearest pre-defined check time interval.

- Once the resources’ movements on site have been analyzed, the construction managers can implement controlling actions and approve of a safe construction plan. In cases in which the planned or actual distance between resources is not acceptable as a result of a special site condition, or the planned productivities deviate from the planned, the following actions can be taken:
Adjustment of the planned schedule, in order to move the resource space-time prisms in time by changing the timing of the activities they are to be carried out, or stopping it for some time in between and re-continuing when the space issue is resolved.

Adjustment of the way in which a planned activity will be carried out (for example, by allocating different equipment to a worker), in order to reduce the risks identified in the first stage of the application of the model, and consequently the safety distance that needs to be kept between the resources can be maintained.

Figure 5: Realization of the optimum space-time prisms for a) two and b) three activities

4 CONCLUSION

A methodology has been developed for analyzing and if necessary adjusting the planned locations of construction resources on sites, in order to prevent the hazards that occur due to an excessive proximity between different resources. Such hazards may occur due to the impact that the resources of an activity have on the safety of other resources carrying out other activities in adjacent locations on the site. This research focuses on the minimizing the intersection between safety areas considered for each resource, in a way to both prevent site congestions and unnecessary space allocations, since this problem has not been sufficiently studied so far.

The proposed methodology includes a step-by-step optimization method for the assessment of distances between resources, and the use of prisms to analyze the existing construction plan. These tools allow managers to take into account the dynamic activities of the resources on sites, as well as the different characteristics of different resource types which may reinforce or counteract risk factors. The proposed method can be particularly useful for projects in which activities are repetitive, reducing the complexity of resources' movements and increasing their predictability. By utilizing other shapes to represent the safety areas around equipment and site elements, such as using a rectangle for a permanent building on the job site, to further improve the effectiveness of the model is the future step of this study.

Abstract: While recent studies suggest that there is a relationship between indicators of project integration—such as early involvement of constructors—and the quality of project health and safety outcomes, there is no study that empirically investigates this relationship. To address this limitation in the current body of knowledge, the purpose of this paper is to explore the relationship between several characteristics of the integrated projects and construction safety performance. To achieve this objective, the following activities were conducted. First, to collect detailed information regarding recently completed building projects, a survey questionnaire was developed in which, safety performance metrics—such as the number of accidents—were considered as dependent variables, and project organization, team integration, and using emerging processes and technologies were included in the questionnaire as independent variables. Second, the questionnaire was distributed to reach a diverse set of respondents, and a database of 204 building projects was created. The collected data was validated by conducting follow-up phone interviews with respondents. Finally, the database was analyzed using various statistical techniques to investigate the relationship between project integration indicators and safety performance. The results of this study provide preliminary evidence that early decisions of owners and contractors to move towards more integrated projects can impact the safety performance of projects.

1 INTRODUCTION

Using more integrated project delivery systems are gaining traction in the construction industry. The integrated projects are usually characterized with usage of alternative delivery methods such as integrated project delivery method (IPD), team integration techniques such as partnering and colocation, and emerging processes and technologies such as building information modeling (BIM), prefabrication, and lean tools. There is an interest among both owners and contractors to understand the relationships among these new variables and typical definitions of project success such as cost, time, and safety outcomes (El-Asmar et al. 2013).

Considering its importance, several studies attempted to find empirical relationships between safety performance and other project related factors. Most significant studies conducted by researchers focused on using empirical evidence provided in accident reports in national databases such as the Occupational Safety and Health Administration (OSHA) Integrated Management Information System (IMIS) (Hinze et al. 1998, Huang and Hinze 2003, Goh and Chua 2013, and Esmaeili et al. 2015a, Esmaeili et al. 2015b).
Although these studies provide significant contribution to educate project managers regarding factors that contribute to accident occurrence, they provide limited knowledge about the impact of project integration on safety performance. In fact, national databases provide a little information about the type of delivery method used, time of involvement of a contractor in the design process, existence of a partnering statement, or using building information modeling in a project.

To address this growing knowledge gap, the objective of this study is to determine the role of project integration in terms of project organization, team integration, and application of emerging processes and technologies on safety performance. To achieve this objective, a comprehensive questionnaire was developed and distributed into the U.S. construction industry to create a large empirical database of building projects. Then, the database was analyzed using various statistical analysis. This study departs from the current body of knowledge by empirically measuring the impact of project integration—such as project organization, team integration, and using emerging processes and technologies—on the safety performance of building projects. It is expected that the results of this study will provide a guideline for both owners and contractors to understand the impact of their early decisions on safety performance.

2 BACKGROUND

In this section, the research team aimed to identify a dependent variable that measures safety performance and to identify several independent variables that explain project integration. The notable results of the literature review and discussion of dependent and independent variables are provided below.

2.1 Dependent variables

The dependent variables are safety outcomes that reflect the measured safety performance or number of accidents in the project. However, as worker-hours increase, the possibility that workers will get exposed to hazards and get injured will also increase. Rather than collect the number of worker-hours, which is a difficult undertaking, to consider the impact of project size and worker-hours, the number of recordable incidents were divided by the area of the building. Thus, the safety performance was calculated using the following equation:

$$\text{Safety Performance} = \frac{\text{Number of Recordable Incidents}}{\text{Area (ft}^2\text{)}} \times 100,000$$

2.2 Independent Variables

The independent variables are those factors that can impact performance outcomes. A comprehensive literature review was conducted to identify independent variables that define project integration. Four variables were selected to be included in the questionnaire for further analysis: (1) project complexity; (2) project organization; (3) team integration; and (4) using emerging processes and technologies. These variables are explained in more details in the following sections.

2.2.1 Project Complexity

One of the project characteristics that can influence project performance is complexity. Previous studies investigated the impact of complexity in design (Glavan and Tucker 1991) and scheduling (Nasser and Hegab 2006) of projects. In one of the recent studies, Puddicombe (2011) investigated the cost and schedule performance of 1,300 projects and found that complexity is an important characteristic of a project that has a crucial impact on project performance. However, there is no previous study that has empirically investigated the impact of project complexity on safety performance.
2.2.2 Project Organization

The construction industry is highly fragmented mainly due to the lack of communication among designers and contractors. The traditional delivery practices such as design-bid-build also exacerbate separation of design and construction process. Separation between different parties negatively impacts the potential for innovation as this division makes knowledge exchange more difficult. There are several empirical studies that investigated the impact of project organization on project performance (Konchar and Sanvido 1998, Molenaar and Songer 1998, Ibbs et al. 2003, Hale et al. 2009). Most of these studies had consensus that as one moves towards more integrated delivery methods, the possibility of cost and schedule growth decrease (Konchar and Sanvido 1998, Molenaar et al. 1999, Gransberg et al. 1999, El-Asmar et al. 2013). While the contribution of these studies is significant, none of them has considered the impact of different delivery method on safety performance of a project.

In addition to project delivery types, the project organization determines the time of involvement for different stakeholders. Song et al. (2009) studied the early involvement of contractors in design and its impact on construction schedule performance. They found that constructability input provided by contractor can improve drawing quality, material supply, information flow, and can indirectly impact construction schedule performance. One of the major limitations of previous studies in this domain is that they did not consider the impact of early involvement of project stakeholders on safety performance.

2.2.3 Team Integration

Three major characteristics of team integration that are investigated in this study are: partnering, co-location, and collaborative goal setting. The complexity, uncertainty, and time pressure existed in construction industry has increased the need for cooperation, flexibility, integration (Eriksson and Pesamaa 2007). One of the concept that can affect project performance through improving team behavior of project participants is partnering. Partnering facilitates knowledge and resource sharing, and improves collaborative relationships that are necessary for successful project completion (Cacamis and El-Asmar 2014). Some studies measured the impact of partnering on project performance. In one of the seminal studies, Gransberg et al. (1999) found that partnering could help to control cost and time growth on projects greater than five million dollar. Nevertheless, there are limited number of studies looked at the relationship between project’s safety performances and partnering.

One of the most notable differences between integrated and less integrated delivery methods is co-location in an environment, which encourages informal collaboration and face-to-face communication among stakeholders (Raisbeck et al. 2010). Within an open floorplan office, known as the “Big Room,” a team of the contractors, architects, and owners work in a collaborative environment during the design and construction of a project. According to Hall et al. (2014), co-location facilitates collaborative decision making, innovation, and transparency. In this study, the research team decided to assess impact of using co-location on safety performance of a project.

The third characteristics of team integration that was investigated by the research team was collaborative goal setting. According to the OSHA act, the employers or contractors are responsible for the safety of their employees, and the standard form of contracts in the construction industry—such as AIA A201 and EJCDC E-500—explicitly transfers responsibility of safety to general contractors. However, if the contractor or builder is participating in goal settings, he or she can inform owners and designers regarding the impact of various decisions on safety performance. In other words, as far as the contractor is concerned regarding safety of his or her employees, the contractor can convince other project stakeholders to consider safety as one of the objectives. A minimal number of studies have investigated the impact of team integration on safety performance.

2.2.4 Using Emerging Processes and Technologies

Three emerging processes and technologies that seem to have a significant impact on enhancing safety performance are offsite prefabrication, using lean construction tools, and using building information modeling (BIM). As prefabrication provides several benefits to the project in terms of cost, time, and
productivity, its usage has been steadily increased in past decades (CII 2002, Eastman and Sacks 2008). Previous studies claimed that prefabrication has the potential to enhance safety performance by reducing the hazard levels of a task (Gambatese et al. 1997, Toole and Gambatese 2008). For example, to reduce risk of fall accidents, work can be shifted from a high elevation to the ground; to avoid the risk of cave-in, work can be shifted from inside an excavation to grade; or to reduce the risk of suffocation, work can be moved from inside a confined space to an open space (Toole and Gambatese 2008). In addition, when work is shifted from the field to the factory, work can be conducted in an environment where the majority of risks are under control and equipment is in better condition.

Toole and Gambatese (2008) highlighted the importance of prefabrication in facilitating hazard prevention through design practices. They found that one of the main pathways that hazard prevention through design will progress in the future is in using prefabricated elements. Using prefabrication elements in design help designers to improve construction safety without fear of liability. In another study, Tanabe and Miyake (2010) proposed a safety design approach for an onshore modularization liquefied natural gas liquefaction plant. Their innovative design showed the feasibility of considering prefabrication elements in the design phase to enhance safety in downstream operations. While there is a common perception that prefabrication can enhance safety, there is no study that empirically supports this hypothesis.

Another independent variables that was identified from the literature is using lean construction tools. Lean production originated in the manufacturing and automotive industries, and after its successful contribution to the manufacturing industry, it has been used in the construction industry (Salem et al. 2006). Previous studies in the construction industry indicated that using lean tools has a positive impact of safety performance (Ohno 1988, Thomassen et al. 2003, Salem et al. 2006, Nahmens and Ikuma 2009, Wong et al. 2009, Womack et al. 2009). The research team decided to consider the impact of using lean construction tools beside other independent variables on safety performance.

Previous studies indicated that using building information modeling (BIM) has a great potential to improve safety performance in a project. Some of the potential applications are: (1) hazard identification; (2) design for safety; (3) site safety planning; and (4) training and education. First, BIM can be used to effectively enhance hazard identification by creating a 3D model of a project. Park and Kim (2013) developed a framework to integrate BIM, augmented reality, location tracking, and game engine technologies into a comprehensive site safety planning process. According to the framework, safety risk factors can be identified in the planning stage by visualizing 3D design and the required site safety facilities for project activities. Second, BIM enables designers to modify designs by considering safety constraints in early stages of a project (Rajendran and Clarke2011). To provide proof of concept, Qi et al. (2013) developed prevention through design (PtD) tools to provide feedback to designers about the hazards created by different design alternatives. Third, BIM-based site planning can improve safety performance by providing detailed spatial information of construction environments as wells as dynamic planning and 4D model (Sulankivi et al. 2009). For example, the visualization of a crane’s reach was carried out to examine the risk of load fall or the objects the crane’s rib could hit (Sulankivi et al. 2009). Finally, Rajendran and Clarke (2011) stated that 3D model of a building can be used in orientation sessions to enhance situational awareness of workers new to the working environment. Although previous studies stated that BIM can help to solve some of the safety issues on the site, a limited number of studies have empirically investigated the relationship between using BIM and safety performance.

3 RESEARCH METHODOLOGY

The purpose of this study was to explore the impact project integration measures—such as delivery method, team selection, and other behavioral and technological factors—have on project safety performance. The objective of the study was achieved by conducting the following activities: (1) questionnaire development; (2) data collection; (3) data compilation and validation; and (4) data analysis. First, a survey questionnaire was developed to collect the required data from owners and contractors with an industry advisory board (Esmaeili et al. 2013, Franz et al. 2014). Recordable accidents per square foot of a project were collected as a dependent variable to measure safety performance, and several independent variables were collected including: project complexity; project delivery method (i.e., design-
bid-build, construction manager at risk, design-build, integrated project delivery method; time of involvement of different parties; co-location; collaborative goal setting; and using offsite prefabrication, lean construction tools, and building information modeling.

Second, the survey was distributed by e-mail and postal mail to professional organizations in the U.S. construction industry. During the data collection process, more than 8500 project managers were contacted in the two years. A cover letter, set of instructions, and glossary of terms were attached to the survey in order to illustrate the project objectives and to explain the key terms. The diverse group of respondents was asked to answer the survey according to the most recent project that their organization completed (Franz 2014).

Third, the data collected via e-mail and postal mail were compiled and validated by conducting follow-up phone interviews. In total, 331 surveys were received and reviewed and compiled into a single database in Microsoft Access® with unique identification codes. The reviewing procedure included: verifying the project information to check for possible missing data, scrutinizing the consistency in given values, excluding out-of-scope projects, eliminating unverified projects, and resolving multiple response discrepancies. The reviewing procedure resulted in a database of 204 building projects (Franz 2014).

Forth, the descriptive statistics were examined for each variable and each distribution was checked for normality in the screening procedure. Then, correlations between variables were analyzed. Because all variables were non-normally distributed, correlations between them were analyzed using Spearman's rank-based correlation coefficient (Schumacker 2015). Correlation between recordable accidents were measured against other project performance measures such as cost, schedule, and delivery speed.

Kruskal-Wallis test was used for the group comparisons for recordable accidents per square foot area, because each of the response variables was significantly non-normal and the group sizes within could be relatively small for some categories. The Kruskal-Wallis test is a common nonparametric test that compares the overall population distribution for any number of groups. Since there are lots of "ties" in the data (observations with the same number of incidents) and in some cases quite a few groups, a chi-square approximation was used to calculate the p-value (Schumacker 2015). Post-hoc analyses were also conducted on significant groupings using pairwise Wilcoxon-Mann-Whitney tests with a Bonferroni adjustment. Since there were multiple comparisons in this data set, the Bonferroni adjustment kept the Type 1 error probability controlled. All analyses were done using R, which is an open-source statistical program (R Development Core Team 2011).

4 RESULTS AND DISCUSSION

From 204 projects, 124 projects provided information about recordable accidents with a range of 62 and median of 1. Fifty-two percent of projects had at least one recordable accidents. These results indicate that, on average, safety performance of projects in the database was higher than the industry average. As mentioned earlier, in the questionnaire, several questions were asked related to independent variables such as project organization, team integration, and using emerging processes and technologies. The recordable incidents per square foot of a building for each of these independent variables are calculated and summarized in Table 1.

The results of the correlation analysis are summarized in Table 2. As is shown, only unit cost, project delivery speed, and construction delivery speed are significantly correlated with safety performance measures. This can be justified by considering that safety performance was calculated by dividing the number of accidents by area of the building; unit cost, project delivery speed, and construction delivery speed are also related to the total area of the building. Another project performance metric that is marginally correlated to the safety performance is construction cost growth.

According to the results, the project complexity has a statistically significant impact on safety performance. This is understandable since in more complex projects, contractors might have to use unfamiliar means and methods that expose workers to unknown hazards. The post hoc analysis revealed that very complex projects (Likert value=6) have lower safety performance than projects with medium (Likert value=5, p-value=0.005) and low complexity (Likert value=1~4, p-value=0.037).

As far as project organization is concerned, the type of delivery method and time of builder involvement in a project design had significant impacts on safety performance. The post hoc analysis showed that projects delivered by design-bid-build method had a better safety performance than projects delivered by construction manager-at-risk (p-value=0.032). This is a surprise finding as it is a common belief that constructability input provided by a CMR agent in design phase can have a positive impact on safety performance. To understand the underlying reasons for such a difference, one needs to conduct follow up interviews with project personnel. Conducting post hoc analysis for the time of builder involvement showed marginally significant difference between the safety performances of projects that the builder involved in design development phase versus projects that the builder involved in bidding phase (p-value=0.096). Because the number of projects in which the builders were involved in design development phase was only five and the results of Wilcox-Mann-Whitney test was marginally significant, the research team believes that the time of builder involvement should not be considered as a significant factor.

Although previous studies indicated that BIM can help to improve safety performance, the results of the study show that projects that did not use BIM had better safety performance. There are several other confounding factors that might have contributed to this finding. Empirical evidence provided in this study encourages further analysis to objectively measure impact of using various BIM functions on safety performance. Previous studies also claimed that using lean tools has a positive impact on safety performance; however, the findings of the current study imply that projects that used lean scheduling tools had more accident per square foot of a building (2.078) than projects that did not use any lean tools.
Further analysis of database revealed that projects that use lean tools, on average, had larger square foot area (335,431 SF) than the ones that did not use lean tools (151,457 SF). As discussed earlier, square foot area of a building plays a significant role in determining number of accidents.

The results of the study indicated that co-location of MEP and structural subcontractors have a significant impact on safety performance of projects; however, the post hoc analysis did not show any significant difference. The statistical analysis of results also could not find any significant relationship between safety performance and following independent variables: time of involvement of MEP and structural subcontractors; using partnering; builder participated in co-location; builder participated in goal setting; and using prefabrication in a project.

5 CONCLUSION

This study assessed the factors contributing to safety performance by looking at project integration measures. The safety performance was defined as the recordable incidents per square foot of a building and several independent variables were considered related to project organization, team integration, and using emerging processes and technologies. The study has practical implications for both academia and practice. The large database of 204 building projects created in this study can be used to answer numerous questions defined by academia and the results of the study can also provide empirical evidence for both owners and contractors to understand the impact of their early decisions regarding project integration on safety performance.

While this study is unique in its kind and provides significant contributions to the body of knowledge, there are several limitations that need to be addressed in future studies. First, one of the limitations of the current study is to use lagging indicators (e.g., number of accidents) as safety performance metrics. One should note that recordable and lost time work incidents are rare events in projects and do not capture unsafe behaviors that do not lead to an incident. Further studies should be conducted to explore the impact of project delivery decisions on leading indicators such as near-misses. Second, we could not collect the number of worker-hours in projects, which inhibited us from calculating some of the standard safety measures such as total recordable incidence rate (TRIR) and days away, restricted or transferred (DART). Future studies should be conducted to address this limitation. Third, most of the independent variables in this study were simplified so we could measure them using a Likert scale. For example, complexity has several definitions in the construction industry and future studies should be conducted to investigate the relationship between complexity in design and construction activities and safety performance. Finally, as safety performance depends on people, more qualitative studies should be conducted to understand the drivers of unsafe behavior in worksites. Nevertheless, the research reported in this paper is a pioneer study in establishing the relationship between safety performance and independent variables that define integrated projects.

Acknowledgements

The Charles Pankow Foundation is thanked for supporting the research reported in this paper. Any opinions, findings, and conclusions or recommendations expressed in this material are those of the writers and do not necessarily reflect the views of the Charles Pankow Foundation. The authors would also like to offer their sincere appreciation to Dr. Robert Leitch, Dr. John Messner, and Dr. Bryan Franz for their valuable support and collaborative efforts for this study. The contributions of the undergraduate research assistants who assisted with data collection are recognized, i.e. Kayleigh Arendt, Alexander Melle, Bryan Doyle, Shelby White, and Lars Anderson. We also like to thank those people who helped us in data collection.

Abstract: One of the early activities in any post-disaster management plan is to remove debris, clean the area, and reconstruct the damaged properties. However, a major focus of workers involved in cleaning operations after a disaster are concerned about construction safety because there are several unknown hazards that differ from hazards in a typical construction project. The risk can be compounded by the fact that construction activities after a disaster are usually conducted by small companies or even property owners with limited knowledge of safety. Therefore, the objective of this study was to develop a safety-risk management plan for recovery after disasters. The objective was achieved in two distinct phases. The first phase of the study focused on risk identification. An extensive literature review was conducted to identify hazards in post-disasters operations. The primary list of hazards was identified and classified into seven major groups: (1) physical; (2) chemical; (3) biological; (4) weather and temperature; (5) ergonomic (6) psychological; and (7) other (e.g., natural hazards and noise). During the second phase of the study, risk assessment was conducted to quantify the safety risk of the hazards identified in the previous phase. Fourteen safety professionals with an average 18 years of experience participated in the risk assessment. It was found that being caught-in/between a trench, getting electrocuted while using cranes or boomed vehicles near energized power lines, and getting electrocuted while using conductive tools, ladders, or scaffolds near energized power line are the hazards that cause the most severe injuries. Concurrently, working in cold or windy weather is the most frequent and risky hazard in post-disaster recovery operations. A risk matrix was developed for post-disaster operations by determining the likelihood and consequence of potential accidents using a 5-point Likert scale. It is expected that the results of this study will transform the current safety practices in post disaster recovery operations by providing an easy-to-use safety-risk management tool.

1 INTRODUCTION

On average, natural and man-made disasters cause approximately $24 USD billion worth of damage and affect the lives of 60 million people around the world (United Nations Human Settlements Programs, 2001). In the United States alone (1980-1999), thirteen hurricanes caused $68 billion in damages and more than 400 deaths (National Oceanic and Atmospheric Administration, 2000). Recently, in January 2010, the Haiti earthquake ruined around 250,000 houses (Arumala, 2012). To cope with such a huge loss, a large number of studies have been conducted to develop emergency response plans (Perry and Lindell, 2003; Sheu, 2007), revise land-use regulations (Burby and Dalton, 1994), improve building retrofitting programs (Erdik and Durukal, 2008; Rey, 2004), or design more effective early warning systems (Hooke, 2000; Zschau and Küppers, 2003).
Natural disasters, such as hurricanes and floods, cause severe damage and demand infrastructural recovery, operations that typically involve construction workers. The number of workers who are involved in post-disaster recovery and reconstruction depends on the scale of the catastrophe; however, this number can reach up to 18,000 workers (Rotimi et al., 2006). Workers involved in cleaning and reconstruction operations after a disaster face greater danger than traditional workers because they are exposed to chemical-biological materials, contaminated floodwater, downed energized power lines, confined space entry, potential structural collapse, or other high-risk situations. For this reason, careful attention should be paid to identifying and assessing potential safety risks for these workers. Unfortunately, there are currently a limited number of studies that investigate the potential hazards for workers involved in post-disaster operations.

To address this limitation in the body of knowledge, the overarching goal of the broader project is to enhance the safety of workers in post-disaster recovery and reconstruction operations. Within this large-scale project, our objectives are to: (1) identify common hazards in post-disaster recovery and reconstruction operations; and (2) quantify the safety risk of common hazards in post-disaster recovery and reconstruction. The results of the study will help practitioners to create more effective training programs for workers involved in post-disaster recovery operations.

## 2 LITERATURE REVIEW

In one of the seminal studies, Esworthy et al. (2005) published a report through the Congressional Research Service (CRS) Reports about the environmental considerations for cleanup activities after hurricane Katrina. This report includes a comprehensive review of activities that were carried out during the cleanup process. These activities included—but were not limited to—debris assessment and management, oil and other hazardous materials’ evaluation; the evaluation of previous contaminated sites; dewatering; cleaning up water; recycling, reusing or disposing of the debris; and monitoring. This report provides a unique insight into the difference between the common hazards in ordinary construction projects and cleanup response in recovery after a disaster.

According to Esworthy et al. (2005), one of the major differences between a post-disaster recovery operations and ordinary construction projects is that a natural or man-made disaster can cause large amount of debris. For example, the amount of debris created by Hurricane Katrina was estimated at 55 million cubic yards (Esworthy et al., 2005). The debris consisted of construction materials, damaged or destroyed building fragments, sediments, green waste (trees, limbs, leaves, and shrubs), white goods (utensils), asphalt, oil, chemicals, and other substances. To conduct an efficient debris management program, one needs to accumulate all debris and separate the hazardous materials from other substances. During these operations, construction workers are exposed to hazardous materials, such as pesticides, drain cleaners, cleaning supplies, paint, asbestos, and surfaces coated in lead-based paint.

Another early recovery after disaster activity is to remove the trapped water. For example, after Hurricane Katrina, 114 million gallons water had to be pumped out from the city of New Orleans (Esworthy et al., 2005). The difficulties of such an operation can be compounded by the fact that the water was contaminated with animal and human sewage, decaying bodies, oil, gas, and other chemicals. If water contains bacteria and poisonous metals (e.g., arsenic), then the area can be exposed to epidemic and contagious diseases. Even after draining the water, some pollutants can remain in the sediments, and the mixed water evaporation or the released chemical substances can affect the air quality of the disaster area. In addition, in such an unfavorable situation, the presence of rodents, insects, and the growth of fungi and molds (e.g., humid conditions) can also contaminate the area.

In another study, Reissman et al. (2008) studied emergency responders’ safety and health after a disaster by focusing on the situation of people involved in the September 11th World Trade Center disaster. The authors analyzed the emergency responders’ time of arrival and the duration of exposure to dust. The authors found that due to the combustion, people in the area inhaled a lot of toxic fumes, and many people got injured by rubble when the buildings collapsed. It was concluded that disaster
preparation activities should provide training regarding hazard identification, quick and effective scene control, personal tracking, and safety enforcement.

According to the literature, another common hazard in recovery after a disaster includes psychological disorders. These kinds of hazards are different from the ones in ordinary construction activities. In one of the studies, Kowalski et al. (2001) conducted research to enhance occupational health and safety of workers involved in emergency response. The authors found that work related stress can increase risk of injuries or psychological disorders. Various kind of stress, such as physical (bio-organic) and emotional (psycho-social) can cause fatigue, emotional withdrawal, and depersonalization. The authors stated that by obtaining knowledge of social science, safety managers might decrease the risk of work stress among workers. In another study, Reissman et al. (2008) found that disasters can increase the chance of psychological disease such as depression, panic disorder, and anxiety among workers. Working in high-stress environments in conjunction with viewing distressing scenes—i.e., those that include injuries and dead bodies—are factors for stress and other adverse psychological impacts (Benedek et al., 2007). Thus, to protect workers, this type of hazards should be taken into consideration as well.

Some researchers stated that assessment of a situation after a disaster using various data collection techniques can be helpful for reducing the risk of injuries. For example, to help first responders and civil engineers, Peña-Mora et al. (2012) developed a mobile workstation chariot (MWC) to conduct damage evaluation and hazard identification after a disaster. The workstation has a platform that provides mobility for people engaged in a disaster response and helps them collect, analyze, and distribute information to facilitate decision making. In another study, Gong (2013) suggested the use of mobile LiDAR to collect and analyze data for post-disaster recovery operations. The authors used this technique after Hurricane Sandy in the east coast and found that mobile LiDAR can outperform airborne remote sensing and typical ground survey data collection. While these innovative approaches can be used to enhance the situational awareness of workers involved in recovery after disaster operations, the current adoption rate of these innovations in actual construction operations is minimal. Therefore, there is a need to develop a practical way to identify hazards and assess their risk in post-disaster construction activities.

3 RESEARCH METHODS

The objective of the study was achieved by conducting two distinct tasks: (a) cataloging the common hazards in recovery after disaster operations; and (b) assessing the risks of the identified hazards. Prior to risk assessment, it was necessary to create a list of potential hazards in recovery after disasters for construction workers. Therefore, the first activity involved conducting a literature review to identify hazardous scenarios that lead to injuries in post-disaster recovery. Search engines such as the American Society of Civil Engineering (ASCE), Google Scholar, and Science Direct were used to find articles on these scenarios. A large number of studies have been conducted on post-disaster operations; however, studies on the safety risk of workers are limited. Therefore, to provide a comprehensive list of hazards, we also searched national databases such as those for the Occupational Safety and Health Administration (OSHA), Federal Emergency Management Agency (FEMA), and National Institute for Occupational Safety and Health (Niosh). These activities led to a list of common hazardous scenarios in post-disaster recovery and reconstruction operations.

The second activity served to quantify the safety risks associated with the common hazards identified in the previous task. We followed the traditional paradigm in risk quantification used in previous studies (Brauer, 1994; Hallowell et al., 2011; and Esmaeili and Hallowell, 2013) to obtain ratings of frequency and severity from industry experts. Since there is not enough archival data to make statistically significant inferences (Shapira and Lyachin, 2009; Rozenfeld et al., 2010) and since empirical data cannot be obtained in a realistic timeframe, to accomplish this activity, subjective risk-assessment techniques were employed. Accordingly, to quantify the safety risk of common hazards in post-disaster recovery and reconstruction projects, experts were asked to provide frequencies and severity of injury for each hazardous situation using five-point Likert scale. In this non-comparative scale, respondents were supposed to select a numeral value describes frequency and severity of each hazardous situation (Allen and Seaman, 2007; Jamieson, 2004).
To collect data, the questionnaire was distributed among safety professionals in the Midwest. Local contractors located in Lincoln and Omaha (Nebraska) were the main point of contacts. Other organizations such as the Nebraska Department of Roads (NDOR), the Midwest chapters of the Associated Builders and Contractors (ABC) and the Associated General Contractors of America (AGC) were also contacted. A copy of the questionnaire was sent to the safety managers of these organizations and encouraged them to distribute the questionnaire among people who might be able to fill it out. The research team also used their personal contacts with safety professionals to further increase the number of participants.

4 RESULTS AND ANALYSIS

As mentioned earlier, the first objective of the study was to identify common hazards in post-disaster recovery and reconstruction operations. This objective was achieved by conducting a comprehensive literature review on the current body of knowledge. In total, 45 hazards were identified and categorized into seven major groups (Table 1): (1) physical; (2) chemical; (3) biological; (4) weather and temperature; (5) ergonomic; (6) psychological; and (7) other (e.g., natural hazards and noise). The second phase of the study involved assessing safety risks associated with post-disaster recovery hazards. To accomplish this objective, we contacted 87 professionals and in total, 14 safety professionals returned the filled-out questionnaire. The people who returned the questionnaire were very well-qualified and had an average of 18 years of safety experience. Participants were mainly from the Midwest: 12 from the State of Nebraska, one from the state of Iowa, and one from the State of Illinois. The frequency and severity values for each hazard were independently quantified on a Likert scale and the results are shown in Table 1. To measure the internal reliability of data collected, Cronbach alpha was calculated for the frequency (0.984) and severity (0.992) scores reported in Table 1 that indicate excellent internal reliability.

4.1 Physical Hazards

Physical hazards include falls, struck-by, caught in/between, and electrocution hazards. These hazards are usually referred to as “the big four” because they are responsible for almost 60% of all injuries in the construction industry (OSHA Training Institute, 2011). In total, 17 different physical hazards were identified and included in the survey (Table 1). One of the interesting findings of the study is that, based on the safety managers’ judgment, in recovery after disasters operations physical hazards do not occur as frequent as ordinary construction activities. The highest frequency belongs to the “struck-by flying debris/objects.” On the other hand, physical risk have some of the most sever hazards.

According to the ratings provided by experts, struck-by flying objects is considered to be the most critical hazard in this category. Both the severity and frequency of this hazard were rated as 3. In addition, falling from structural frames, electrocution after contact with underground power lines, and struck-by personal vehicle were placed as the second and third most risky hazards. Furthermore, caught in/between a trench and electrocution from various sources were highlighted to have the worst consequences.

4.2 Chemical

Hazardous chemical substances are one of the potential safety risks that construction workers face when involved in debris-removal after a disaster. Although, we expected to see chemical materials as a frequent hazard in recovery after disaster operations, the experts who participated in the study rated this hazard with frequency ratings of one or two (Table 1). Inhaling welding fumes is found to be the most perilous hazard in this category and the highest severity belongs to entering confined places. Wearing suitable respiratory protection, work and rubber gloves, steel toe boots, outer clothing, and other PPE are the most common suggested approaches that can reduce the severity of chemical hazards (Grosskopf, 2010; OSHA 29 CFR, 1926; Health Hazards Workbook, 2012).

4.3 Biological

During rescue operations, unwatering, and cleaning up debris activities, workers are prone to various biological hazards. Allergies, dermatitis, asthma, and lung disease are the most common outcomes of exposure to biological hazards (Esworthy, 2006; Grosskopf, 2010). The results of the survey indicated that the range of risks for most biological hazards is between 4 and 6, and the safety managers do not consider them as fatal risks during recovery operations. Wearing protective clothing, respiratory devices, and proper gloves in conjunction with immunization (vaccination), carrying both insect repellant and first aid devices are the most recommended mitigation plans against this type of hazard (Grosskopf, 2010; Health Hazards Workbook, 2012).

4.4 Weather

Working under extreme weather conditions can be hazardous for the workers. For example, if workers are exposed to extreme sun, their skin might suffer from sunburn. In extreme conditions, exposure to sun can even cause skin cancer (melanoma). Experts identify this type of hazard to be the most frequent and severe hazard of all the selected conditions (Table 1). Temperature and weather effects are some of the most risky hazards identified in this study. Working for a prolonged time in adverse weather might cause problems such as frostbite, hypothermia, heat cramps, heat exhaustion, heat rashes, and heat stroke for the workers (Health Hazards Workbook, 2012). Some mitigation strategies are suggested below.

When the weather is extremely hot, several actions should be taken to protect workers: workers should eat small portions; they should not drink caffeinates beverages or alcohol; cool liquids should be provided for workers; frequent breaks should be allowed; and workers should be encouraged to wear cotton and proper clothes (Health Hazards Workbook, 2012). Working in an extreme cold weather (below - 32°C) can also be hazardous for workers. This condition can be exacerbated when the weather is wet and windy (Health Hazards Workbook, 2012). Wearing proper clothing and carrying relevant PPE are proper actions against cold weather. In addition, workers should put on dry clothes, drink a lot of warm beverages, take a break at regular intervals, and report any weird symptoms to the supervisor (Centers for Disease Control and Prevention, 2015).
4.5 Ergonomic hazards

Ergonomic hazards are defined as the possible incidents that might happen due to a poor relationship between work features and the mental and physical abilities of the employees (Faridah et al., 2008). Some of the most common ergonomic hazards are strains and sprains, fatigue, carpal tunnel syndrome (vibration), low back pain, and tendonitis (OSHA Publication 3125, 2000). Both the risk and consequence of performing an activity frequently (fatigue) is at the top of the ergonomic category (Table 1). The results of the study indicate that fatigue plays a significant role in potential injuries after a disaster. Removing debris from an exposed area requires extensive material handling and physical activity. Following measures can help the workers to reduce the ergonomic hazards (Ramsey et al., 2014): reducing the distance between the load and the body; avoiding excessive twisting; traversing with the load for fewer than 10 feet or using a conveyer; using proper personal protective equipment; having enough training (e.g., lifting techniques); taking breaks; wearing robust resistance gloves; and using pneumatic and power tools.

4.6 Psychological

The construction workers are one of the first people who will arrive in an area that has been hit by a disaster and will be exposed to numerous psychological hazards. Working in high-stress environments, such as recovery after disasters, can lead to post-traumatic stress disorder (PTSD) among workers. The symptoms of PTSD can be initiated by observing unpleasant experiences, such as seeing others’ injuries, suffering personal injuries, losing loved ones, or encountering dead bodies. Headaches, loss of asleep, nervousness, and nightmares are some the symptoms of people impacted by PTSD (Benedek et al., 2007).

The results of the survey demonstrated that psychological hazards threat workers approximately as often as chemical and biological hazards in post-disaster recovery and reconstruction (Table 1). Thus, these hazards should be taken more seriously. The risks of post-traumatic stress disorder, behavioral changes, and substantial distress in a recovery after a disaster operation have been designated as a 6 for all. Previous studies stated that improving social science can mitigate the consequences of psychological disorders (Benedek et al., 2007). To control for psychological hazards, periodic medical treatment, counselling service, training programs (e.g., relaxation, medication and biofeedback), and providing recreation activates can be helpful (World Health Organization, 2001).

4.7 Other hazards

Noise and natural hazards were viewed as moderate risks (Table 1). Every year many construction workers suffer from noise in construction sites. Due to the chaos conditions in post disaster environments, workers might suffer from noise hazards as well. Therefore, using hearing protection devices, performing supervisor’s controls in conjunction with restricting workers’ proximity to the damaging noise hazards areas can be enumerated as the most effective approaches used to reduce noise hazards (Health Hazards Workbook, 2012; Bergström and Strom, 1986; Franks et al., 1996).

After a disaster, due to the moist conditions, deficient hygiene, and prevalence of animal corpses; a large number of rodents might surge into exposed areas. Increasing rables aside, the presence of rodents make their hunters (snakes, scorpions, and spiders) follow them into the regions. Therefore, a careful attention should be paid to natural hazards. Finally, wearing proper pants, boots, gloves, and outer clothing will help workers to keep themselves safe during operations (Health Hazards Workbook, 2012).

To provide a visual representation, the findings are summarized in a risk matrix (Figure 1). As it is clear that weather-related hazards are the most critical safety risk-factors in post-disaster recovery operations. Several mitigation practices are suggested in this paper to help practitioners reduce the risk of injuries for workers involved in recovery after disaster operations.
5 CONCLUSION

After a disaster, workers who are involved in recovery and maintenance activities are exposed to a large number of hazards that are not similar to hazards related to typical construction activities (Faridah et al., 2008). Protecting workers from hazards during recovery after disasters is gaining attention in both academia and practice (Esmaeili et al., 2014). To address this emergent need, this study sought to identify common hazards in post-disaster recovery operations and to assess their safety risk in terms of frequency and severity. Practitioners can use findings of the study to identify high risk situations in post-disasters recovery operations and implement mitigation plans to reduce potential of injuries.

In future stages of this research project, we aim to develop a safety guideline for workers involved in recovery after disaster operations. The guideline will summarize best mitigation practices for dealing with safety risks in construction operations after a disaster. Furthermore, to disseminate the results of the study and reach a larger audience, a mobile application will be developed. Nevertheless, the findings reported in this paper will advance the subsequent tasks of our overall project in the years to come.

There are some limitations related to this research that need to be addressed in future studies. First, the frequency and severity rating were obtained from safety managers mainly located in Nebraska. This situation will limit the external validity of the study. Future studies should be conducted to collect data from larger and more diverse groups of experts. Second, assessing the frequency and severity of hazards using a Likert scale does not provide an accurate estimate of actual risk in sites. Further studies should be conducted to measure the safety risk of identified hazards more accurately. Despite these limitations, the study provides a significant contribution to the practice by helping safety managers to identify and strategically manage safety risks in post-disaster recovery operations.

COMMUNICATION ISSUES IN DESIGN-BUILD PROJECT DELIVERY METHOD

Allen Faught¹ and Daniel Tran¹,²
¹ Department of Civil, Environmental, and Arch. Engineering, University of Kansas, USA
² daniel.tran@ku.edu

Abstract: Design-Build (D-B) is a project delivery method in which the owner procures both design and construction services in the same contract from a single legal entity referred to as the design-builder. Having both design and construction in the hands of one contractual entity allows for a single point of responsibility and, in turn, provides improved project performance. There is a limited study on how communication among all parties involved influences the success of D-B projects. This paper investigates the modern-day communication issues that affect the D-B delivery method. A questionnaire was developed to collect data from professionals across the nation with an average of 22 years of experience related to D-B in commercial construction projects. The authors conducted five structured interviews to verify and validate the results from the survey questionnaire. The findings of this study indicate that the primary communication issues that have an effect on D-B are: (1) establishing the clear points of contact throughout the D-B communication process, (2) providing clear and understandable information among stakeholders during the D-B process and (3) the timely sharing of information to all stakeholders. It is recommended that further improvement strategies be implemented which include coordinating, clarifying, documenting and decision-making in order to better achieve project success. Understanding these communication issues will help professionals not only mitigate risk and uncertainty, but also enhance the likelihood of the success in D-B contracts.

1 INTRODUCTION

The design-build (D-B) project delivery method continues to grow as a viable delivery method in the construction industry. The Design-Build Institute of America (DBIA) reported that more than half of projects above $10 million are being completed using D-B project delivery (DBIA 2014). D-B has been used throughout the world for approximately 40 years (Lam et al. 2008) and its popularity has increased substantially over the last two decades.

A number of studies have investigated several topics related to D-B project delivery method in both building and transportation sectors. For example, studies have documented topics such as D-B performance (Konchar and Sanvido 1998), D-B evolution (Molenaar et al. 1999), D-B success factors (Chan et al. 2010), design-builder selection issues (Palaneeswaran and Kumaraswamy 2000), and impact of risk on D-B selection (Tran and Molenaar 2014) to name only a few. However, there is a limited study that focuses on the influence of communication issues on the D-B process. The objective of this study is to investigate the modern-day communication issues that affect the D-B delivery method in the building sector. This study defines communication in the D-B process as a two-way process of reaching mutual understanding in which participants impart or exchange information and ideas.
2 LITERATURE REVIEW

D-B is a project delivery method in which the owner contracts with a single entity to perform both design and construction. The single entity may be represented by a D-B firm with in-house design and construction teams or a joint-venture designer and contractor. Contractually, D-B offers the owners a single point of responsibility for design and construction service such as an overall project planning and scheduling (Konchar and Sanvido 1998).

The literature shows that D-B delivery method can bring about many benefits to a project. For example, in the building sector, the Construction Industry Institute (CII) has supported several studies that compare project delivery performance. Konchar and Sanvido (1998) defined a set of criteria for a performance comparison of different delivery methods, including D-B, a traditional design-bid-build (D-B-B), and Construction manager at Risk (CMR). They used a survey to collect post-project performance data from owners and contractors on 351 completed projects. The sample data consisted of a variety of project types and sizes (i.e., six different project types, project size varying from 500 to 200,000 m2). This study concluded that D-B performs better than D-B-B in terms of cost and schedule, and D-B performs better than both CMR and D-B-B in terms of quality. Another CII related study was conducted by Ibbs et al. (2003). This study compared cost growth, schedule growth and productivity between D-B and D-B-B based on 67 global projects from the CII database. The study concluded that D-B outperformed D-B-B in terms of schedule. However, D-B did not perform better than D-B-B in terms of cost growth and productivity in this sample.

Researchers showed that many factors impact the success of D-B projects. Chang et al. (2010) identified six project success factors for D-B delivery method, including project team commitment, contractor’s competencies, risk and liability assessment, client’s competencies, end-users’ needs, and constraints imposed by end-users. Lam et al. (2008) indicated that a clearly defined scope is vital for the success of a D-B project. Under D-B project delivery, the amount of information and the level of detail also play an important role in D-B contracts. Xia et al. (2012) showed that a sufficient amount of owner-provided design information should be provided in order to describe the owner’s requirements without compromising the potential for innovation.

The understanding and interpretation of the owners’ requirements along with communication between owners and design-builders was essential to the success of D-B projects. Adnan et al. (2012) pointed out that it is the responsibility of the design-builder team to provide care and attention to understanding the owners’ requirements. In addition, researchers claimed that communication is sometimes a problem in D-B contract due to the lack of contractual relationship between the owner and designers. Owners and design-builders need to have a proper and comprehensive checking and communication system to ensure the design is coordinated and construction complies with the design documents (Ling and Poh, 2008). One of the problems in D-B contract involved coordination issues arising from design and construction concurrence. Chang et al. (2010) concluded that further investigation into the coordination and communication issues resulting from the concurrence of design and construction is recommended.

A review of the literature indicated that although a number of studies have investigated the benefits of D-B projects, the overall D-B process, and D-B success factors, limited studies have explored the impact of communication on the D-B process. To fill this knowledge gap, this paper investigates the modern-day communication among all project participants involved corresponding to each of the typical phases in D-B delivery method.

3 RESEARCH METHODOLOGY

This study employed a survey questionnaire and interview methodology to examine the impact of communication on major phases of D-B projects. An online questionnaire survey was developed and distributed to 282 members of the DBIA Mid America region. The web-based software allowed for an anonymous link to be used and sent to potential participants. The use of this anonymous link was a requirement of the DBIA, because it allowed the responses of the participants to remain confidential.
participants were divided into five different groups based on their roles in the D-B delivery method and the type of services their organization provided:

- **Owner Agency**: A private or public organization that advertises awards and supervises the design and construction of the project.
- **General Contractor**: The general construction contractor who physically completes the construction with its own forces and/or who holds the construction subcontracts.
- **Design-Build Firm**: An organization that has the internal capability to complete both the design and construction of a project.
- **Engineering/Design Firm**: An organization that completes the design portion of the D-B project prior to and during construction. This includes both architects and engineers.
- **Other**: This group includes specialty firms, consultants and educators that have experience with D-B.

The survey questionnaire included thirty-one questions that were either multiple choice or open-ended questions. The questionnaire consisted of three parts. In the first part, the participants were asked to read a series of definitions related to communication and the D-B delivery method. These definitions were necessary to establish uniformity in the participant’s interpretations and to avoid misunderstandings. The second part of the survey consisted of collecting the participant’s background information. The respondents were asked to describe which type of group or organization they worked for. They were also asked to provide their job title and their years of experience in the building industry. Finally, respondents were asked to provide their email information if they were willing to be available for additional follow-up questions. The third part involved D-B communication issues, which was divided into six different sections corresponding to the key phases in the D-B process as follows:

1. Request for Qualifications (RFQ)/Qualifications Statements;
2. Request for Proposal (RFP);
3. Design-Builder Evaluation and Selection;
4. Design Development Phase; and
5. Construction Phase.

In addition to the survey questions, the authors conducted five structured interviews to verify and supplement the findings from the survey. These five interviews, including three with owners and two with design-builder firms were selected based on the responses from the survey questionnaire and their relevant D-B experience. During these interviews, the authors focused on the collection of empirical data by asking project-based questions.

### 4 RESULTS AND ANALYSIS

Out of the 282 professionals invited for the survey questionnaire, the authors received 59 completed questions. The response rate is 21%. On average, the respondents have more than 23 years of relevant experience. Figure 1 shows the percentage of survey responses associated with the different aforementioned groups. Figure 2 shows the participant experience on D-B project delivery method. The following sections briefly present communication issues associated with the five key phases in the D-B process resulted from the survey and interviews.
4.1 Request for Qualification and Qualification Statements

The owner's requirements for offerors are defined and articulated in a RFQ either by in-house staff or by outside consultants (Beard et al. 2001). After the project is advertised and the RFQ has been issued, the potential design-builder teams submit their qualification statements. The qualification statement is a description of the design-build team's composition and organization. To examine the communication issues regarding this phase, the questionnaire asked participants regarding what types of communication and clarification factors can affect their decision to pursue a D-B project. The survey results indicated that the content and presentation of RFQ is essential for D-B projects. Specifically, 38 out of 40 respondents (95%) agreed that the presentation of RFQ affected their decision to pursue the project. It is noted that 14 owner participants did not respond to this question. The completeness of RFQ documentation and how it is written to request the right information was a critical factor for design-build firms to submit their quantification statements. In addition, a number of respondents indicated that the
willingness of an owner to meet and discuss the project has a significant impact on their decision to pursue the project. Overall, almost all respondents indicated that they would like to receive more clear and understandable information, timely responses to their questions, and discuss the project with the owner or owner's representative directly. The results from the structured interview confirmed this finding. One of the interviewees, who works for a General Contractor firm, stated that "sometimes the owner doesn't provide any information on the project itself that significantly hinders their decision on submitting the qualification statement."

The owner participants were asked what types of communication and clarification factors influence their decision to select or "short-list" a design-builder for a project. Out of 14 owner participants, nine (64%) stated that clarity, readability and technical approach of the qualifications statement was the primary selection factors. The owner representative in the interview process confirmed that "they selected the shortlisted design-builder based on their ability and clarity in their statements of qualification that demonstrate the understanding of a given D-B project requirement."

### 4.2 Request for Proposal

Design and cost proposals are solicited from the shortlisted design-builders in an RFP. Among the items found in a typical RFP are project design criteria, program requirements, performance specifications, site information, contract requirements, selection procedures, and proposal requirements or deliverables. The survey questions were developed to investigate the impact of communication between the owner and proposer on the D-B solicitation process.

Almost all respondents (81%) agreed that developing a clear, comprehensive and well-defined RFP is a critical success factor for D-B projects. However, six respondents (10%) slightly disagreed and five respondents (8%) disagreed that they received RFPs that clearly and comprehensively describe and the owner's needs and requirements. The survey results also indicated that it is important to enhance communication between the owner and proposers during the solicitation process. In addition, the participants were asked how communication and coordination issues can be improved during the solicitation process. The main responses (66%) involved documenting questions and answers/clarifications and provided them in a timely manner. One contractor in the interview stated that understanding the selection criteria and how the project would be awarded was the essential for his firm to compete for the project. This participant also emphasized that his firm sometimes received RFPs that were not clear in the scope and they need to make assumptions and interpretations. His concern is that each proposer may interpret the RFP differently and the final comparisons would not be fair and transparent. Another contractor in the interview pointed out that "the timeliness of responses, lack of response, clarity of the responses and the time allowed for asking and answering questions were their primary concerns" during the solicitation process. Another interviewee, who works for a public owner, believed that there is some confusion regarding the final decision makers among the owner's representatives. He stated that sometimes this causes issues because the design-builder does not know who to speak with or get decisions from.

### 4.3 Design-Builder Evaluation and Selection

Once received, proposals are evaluated on the basis of quantity, quality, functional efficiency, aesthetics, price and other factors (Beard et al., 2001). Compared to Design-Bid-Build (D-B-B) projects, it is more difficult to evaluate D-B tenders because of the need to evaluate both price and design (Ling and Poh, 2008). Effective communication is an integral part of the D-B evaluation and selection process.

Out of 59 respondents, 51 (86%) agreed that a well-established evaluation system along with a guideline for how to use it would be critical for selecting a design-builder. However, eight respondents slightly disagreed that they always received the guidelines for the evaluation process. The participants were also asked whether or not the level of communication between the owner and the proposer during the selection process was insufficient in need of improvement. Twenty eight respondents (47%) believed that the level of communication in their projects were sufficient while 31 respondents (53%) indicated that the level of communication between the owner and proposers need to improve. These 31 respondents suggested several approaches to improve communication between all parties involved in the selection process.
The main theme involves increasing the number of meetings to resolve confusion, especially face-to-face meetings, and specifying the right point of contact during the selection process. With the prolific use of online communication, many respondents would like more face-to-face meetings during the selection process as they believe this would help with communication during the process.

In the structured interview, a participant from a design-build firm stated that “email is a distribution device and not a communication device and the face-to-face meetings are very important in the design-builder evaluation and selection process.” This interview also mentioned that all project information needs to be clear and in writing, especially meeting minutes. Documenting and understanding which information is available to share during the evaluation process is very important. The interviewee stated that “many of the design-builders and general contractors felt that during the evaluation process, there should be clear instructions on what will or will not be shared with competitors.”

4.4 Design Development Phase

After a design-builder is awarded the contract, a notice to proceed with the design work is issued by the owner. In accordance with the design-builder’s proposal and the owner’s comments, the team proceeds to develop more detailed architectural and engineering documents, often in close coordination with representatives of the owner and local building code officials (Beard et al. 2001). Communication is sometimes a problem because once the D-B contract is awarded, owners may be out of the loop if all design and construction decisions and tradeoffs are internal to the design-build team and do not involve the owners (Ling and Poh 2008).

In this phase, the participants were asked to explain the impact of communication on solving conflicts in design between the owner and design-builder. The survey results indicated that 25 respondents (42%) agreed that there was insufficient communication between the design-builder and owner to solve design issues occurred during the design development phase. The common theme of these responses is that the majority of projects only have one meeting between the owner and design-builder during design. This finding is consistent with the literature. The researchers showed that there is insufficient communication between the owner and the design-builder team because of the absence of a contractual relationship between owners and the design-builders’ design consultants, subcontractors and suppliers. In fact, owners may be concerned that exclusion from the D-B team discussions may compromise project quality (Ling and Poh 2008).

The respondents also agreed that enhancing communication between the owner and design-builder and timelines for approvals were important to solve any potential design conflicts. Forty five respondents (76%) showed that they preferred to have a weekly meeting between the owner and design-builder during the design development phase. Figure 3 illustrates the different methods of communication. One can observe from Figure 3 that email, face-to-face meeting, and phone conversation are common communication methods in the design development process.
The respondents also indicated that allowing direct communication and using multiple methods of communication would be helpful in solving design issues. One of the interviewees agrees that the single-contract basis of D-B almost always limits any communication too strictly between the owner and design-builder entity. This fact makes the communications process extremely linear in both directions and limits the flow of project information.

The participant was also asked for the challenges of coordination and communication during the design phase in a D-B project, and some of the strategies to overcome such challenges. The major challenges included (1) timely and understandable decisions by the owner's group; (2) meeting owner design expectations; (3) timely and successful sharing of information. The main strategy to overcome these challenges involved establishing a centralized information storage and sharing system to ensure effective communication between the owner and design-builder.

4.5 Construction Phase

For D-B projects, construction can begin prior to design completion. When the owner approves the construction documents for all elements or for specific parts of the work, construction can start (Beard et al. 2001). During construction the owner's representative will monitor the work for quality and degree of completion. After the completion of construction, the owner's representative will examine the facility for compliance with the initial program and performance requirements, as well as with the design-builder's proposal and its construction documents (Lam et al. 2008). Similar to the design development phase, 43 respondents (73%) showed that they preferred to have one meeting per week between the owner and design-builder during the construction phase. Additionally, communication methods such as email, face-to-face meeting, and phone conversation are common in the construction phase. Figure 4 shows the different communication methods resulted from the survey.
To investigate further the impact of communication on the construction phase, all participants were asked to identify the challenges of coordination and communication during the construction phase in a D-B project, and the strategies to overcome such challenges. The typical challenge involved timely and successful sharing of information among all project participants in the construction phase. One contractor in the interview process stated that when questions are not asked, assumptions are made which can result in incorrect information being assumed. When answers are not given in a timely manner, the lack of response can affect the proposal, design and/or construction. The contract discussed that “more and more D-B projects are being done because they save time. Response time should be fast. Owners understand the need for responsiveness, but don’t always behave the way that would be best.”

The typical strategy to overcome such challenge is to enhance communication between the owner and design-builder. The survey results showed that 45 responses (76%) agreed that one meeting between the owner and design-builder per week appears to be the standard during the construction phase. In addition, the design and construction teams need to communicate clearly and understandably to one another though they are one team during construction.

5 CONCLUSION

This paper examines the communication issues during each typical phase of D-B projects. The survey questionnaire and follow-up interviews were employed to collect data in the building sector. The results suggested that the primary communication issues that have an effect on D-B include: (1) establishing and meeting with the clear points of contact and decision makers throughout the D-B process, (2) providing clear and understandable information among project participants involved, and (3) and the timely and successful sharing of information. In addition, the results suggested that coordination, clarification, documentation of relevant information in each phase of the D-B process is essential to the success for D-B projects. These findings furnish stakeholders with an understanding of the communication issues that are occurring in D-B. These findings also deepen the current body of knowledge and serve to enlighten professionals regarding D-B communication issues.

There are several limitations to this study. First, the survey questionnaire was only sent to the members of the DBIA Mid America region. It is expected that the accuracy and validity of the finding will increase if
the survey was nationwide distributed. Second, while the response rate of the survey questionnaire was adequate to determine the major communication issues, an increased response would enhance the verification and validation process. Finally, the follow-up interviews included only five participants. Additional interviews can provide more data and input to augment the findings for this study. It is recommended that future studies should seek additional industry input as well as conduct case studies in order to better document how the communication issues affect the D-B delivery method.

STATISTICAL MODELING OF PUBLIC ATTITUDES TOWARDS WATER INFRASTRUCTURE RETOOLING ALTERNATIVES IN SHRINKING CITIES

Kasey M. Faust¹,², Dulcy M. Abraham¹ and Hamed Zamenian¹
¹ Lyles School of Civil Engineering, Purdue University, USA
² faustk@purdue.edu

Abstract: Many US cities, such as Gary, Indiana and Detroit, Michigan, have and continue to experience substantial population decline. The footprint of the built infrastructure in these cities does not contract with urban decline, but remains relatively unchanged, consequentially resulting in underfunded and underutilized infrastructure. Right sizing the physical footprint for the current and projected population needs has the potential to stabilize or reduce the rising per capita cost of services. While unilateral infrastructure decisions may save time and money, they pose risks, such as inefficient or unsuccessful implementation or unsustainable infrastructure projects, due to public opposition. The objective of this paper is to assess the public attitude concerning water infrastructure management alternatives. In November 2013, a voluntary survey was deployed to residents of 21 medium or large US shrinking cities. Binary probit models were estimated to determine the demographic and geographic variables influencing the support (or opposition) of five water infrastructure management alternatives. The statistical models indicated that different alternatives have different probabilities of support (or opposition) in varied geographic locations. Demographic variables, such as age, employment status, and income, have a propensity towards (or against) select management alternatives. This study demonstrates a method for understanding and incorporating public opinion into the pre-planning process for potentially reducing public opposition. Potential opposition regarding infrastructure management decisions may be alleviated through participatory processes and targeting identified demographic groups for involvement in new infrastructure projects and decisions.

1 INTRODUCTION

Many US cities, such as, Cleveland, Ohio, and Buffalo, New York, have and continue to experience substantial population decline (Pallagst 2008). As the populations decline, these cities, termed shrinking cities, face a multitude of infrastructure-related challenges, including a decreasing tax base, a reduced number of customers demanding infrastructure services, and a built infrastructure footprint that remains relatively unchanged in spite of the shrinking populations. These challenges result in an excess of underutilized and underfunded infrastructure. Approximately, 75 to 80 percent of water infrastructure costs to provide service are fixed costs (Herz 2006; Hummel and Lux 2007; Schlör et al. 2009). These fixed costs must still be recovered in the presence of the urban decline and a reduced number of customers, potentially resulting in infrastructure services becoming prohibitively more expensive per capita (Rybczynski and Linneman 1999; Herz 2006; Butts and Gasteyer 2011; Beazley et al. 2011). Further straining this financial situation with regard to water service is the financial capital necessary to meet the increasingly stringent regulations set by the state and federal government (Roberson 2011).
Prior literature regarding water infrastructure in shrinking cities has: (1) qualitatively discussed water infrastructure management alternatives to reduce the physical footprint for the current and projected population, such as decommissioning/razing or repurposing underutilized infrastructure components (Hoornbeek and Schwarz 2009; USEPA 2014), and (2) examined the relationship between urban decline and rising per capita water/wastewater service costs (Herz 2006; Hummel and Lux 2007; Schlor et al. 2009; Butts and Gastayer 2011). To the authors’ knowledge, the literature has not addressed the attitudes towards possible water infrastructure retooling alternatives in shrinking cities. Water infrastructure retooling alternatives are changes to the systems, whether physical, operational, or managerial, that may have the potential to reduce or stabilize the cost or increase the level of service of the systems. Prior work regarding public views has evaluated the perceived quality of life in areas of urban decline and perceptions towards abandonment and vacancies (Greenberg and Schneider 1996; Bright 2000; Hollander 2010; Hollander 2011). Understanding the public attitude and ensuring adequate public support may increase the success of an infrastructure project by mitigating the possibility of inefficient or unsuccessful implementation, or unsustainable alternatives arising from public opposition (Susskind and Cruikshank 1987, Global Water Partnership Technical Advisory Committee 2000, Gerasidi et al. 2009, Nancarrow et al. 2010, Faust et al. 2013). Sustainability, in the context of this paper, refers to managing and maintaining the water infrastructure system’s ability to provide adequate service to the current and projected populations.

This study aims to evaluate the attitude of residents in shrinking cities towards select water infrastructure retooling alternatives. A survey was deployed to residents of shrinking cities to evaluate the public attitudes towards five water infrastructure retooling alternatives using statistical modeling: (1) investing in more infrastructure, (2) razing or decommissioning infrastructure components, (3) repurposing the existing infrastructure, (4) investing in the maintenance of the current infrastructure, and (5) doing nothing (make no changes) to the current infrastructure. Of interest to this study are the outcomes of the statistical models, which provide insight into the geographical and demographic characteristics of the public that increase the likelihood of supporting or opposing the implementation of different water infrastructure retooling alternatives. Understanding the attitudes of the public in shrinking cities (that is, which locational and demographic characteristic have an initial propensity towards certain alternatives) may help facilitate the analysis of implementable alternatives within these communities (Faust et al. 2013) that have minimal public opposition.

2 METHODOLOGY

A survey was deployed in November 2013 to the general public to capture the perceptions, attitudes, awareness, and knowledge regarding specific retooling alternatives and water sector infrastructure challenges. The attitude questions were posed as a binary question, agree/support or disagree/oppose, to avoid decision paralysis and force a stance that is often missed when questions are posed on a multi-point scale with a neutral or an I do not know option (Tversky and Shafir 1992). These attitude questions directly asked what the respondent thinks should be done in his or her city, and thus, may capture factors such as, the NIMBY theory (“not in my backyard”). It should be noted that the attitudes expressed in this paper represent the public views at a snapshot in time. Attitudes are dynamic, changing with external factors such as, additional information, experience, education, and outreach.

Qualtrics, a web-based survey software, was used to format and deploy the voluntary survey to residents over the age of 18 in 21 US shrinking cities (Table 1). The survey was validated via content review by 11 subject matter experts with expertise in issues inherent to shrinking cities, water sector infrastructure management, or survey analyses. Following content validation, the survey underwent IRB review at Purdue University and was pre-deployed to 25 people with limited knowledge of water sector infrastructure issues to confirm that residents could easily respond to, and understand the posed survey questions. The responses from the pre-deployment were not included in the final sample pool used for the statistical modeling.

The respondent pool consisted of residents from shrinking cities that had peak populations greater than approximately 100,000, and have experienced a decline of at least 30% of their population since the peak
population (Table 1). As of the 2010 census, the combined population of the targeted cities was approximately 4.6 million (US Census Bureau 2011). A confidence level of 95% with a confidence interval of 5% was obtained with a sample size of 455 complete surveys from these 21 the shrinking cities. A minimum of 10 responses was gathered from each targeted city. Responses were sought from cities spanning multiple states to reduce the potential that responses reflect local policies, and to allow the comparison of the attitudes of residents across cities/states.

</table>

To determine the demographic and location parameters that influenced the attitudes of the respondents towards the five infrastructure retooling alternatives, different statistical models were assessed to identify the best-fit models. Ultimately, binary probit models were used to identify the parameters influencing public attitude. The binary probit models were estimated with the standard maximum likelihood method and assumed normally distributed error terms (ε) with a mean of zero. The binary probit model:

\[
P_i(YES) = \Phi \left( \frac{\beta_{YES} X_{YES}}{\sigma} \right)
\]

estimates the probability of outcome 1 for observation \(i\). \(\Phi\) is the standardized cumulative normal distribution, \(\beta_1\) are the estimable parameters for outcome \(i\), and \(X_{ij}\) are the vectors of the observable characteristics (e.g., demographic characteristics, cities) that determine if “1” is the suggested outcome of observation \(i\) (Washington et al. 2011).

Marginal effects, which are the average changes in probability resulting from a one-unit change in the independent variables (or a change for zero to one for indicator variables), are used to interpret the impact of each parameter (Washington et al. 2011). The reported marginal effects presented in the tables below for each significant parameter is the average of the individual marginal effect for all observations. For model selection, the Akaike information criterion (\(AIC\)) and the Bayesian information criterion (\(BIC\)) were used. Both criterion incorporate the same goodness-of-fit term and, with \(k\) equal to the number of
parameters in the model and log-likelihood function $f(y \mid \beta)$, where $AIC = -2 \ln f(y \mid \beta_0) + 2k$ and $BIC = -2 \ln f(y \mid \beta_k) + k \ln n$ (Cavanaugh 2012). $AIC$ is asymptotically efficient, selecting the model that minimizes the mean square error, and thus, is appropriate as a predictive criterion (identifying, via a pairwise comparison, which model most efficiently predicts the outcomes). $BIC$ is consistent, identifying the model with the factors that are the most influential, and thus, is appropriate as a descriptive criterion (Cavanaugh 2012). When selecting models, the smallest $AIC$ and $BIC$ are indicative of the best fitted models (Schneider and Schneider 2009).

3 RESULTS

Of the survey’s respondents, approximately 60% were male and approximately 50% were over the age of 50 years old. A majority of respondents had an individual annual income of less than $35,000. Descriptive statistics of the significant demographic variable in the statistical models are shown in Table 2.

The final survey sample’s raw data indicated that only 18% of respondents had no interest in being actively involved in the decision-making process for water infrastructure needs. Approximately 20% of the respondents stated that they did not trust their water provider to make appropriate decisions, denoting potential for opposition or unstable relationships with the public in the absence of participatory
involvement. By understanding the public attitudes towards the different retooling alternatives and accounting for the public views in decision-making, some of the indicated distrust between the public and utility providers may possibly be alleviated, allowing for the transition towards more sustainable infrastructure systems.

The results in Tables 3-7 show the quantification of the significant parameters that increase the propensity towards agreeing/supporting (disagreeing/opposing) with the implementation of specific retooling alternatives. A positive (negative) parameter indicates an increased likelihood of agreeing/supporting (disagreeing/opposing) with the respective alternative, with the marginal effects of each parameter shown in the adjacent column.

4 DISCUSSIONS

When exploring viable infrastructure retooling alternatives, decision-makers may use the estimated models to identify the demographic and locational parameters of individuals having an increased likelihood of opposition (i.e., disagreeing with an alternative). Educational outreach or incorporating participatory processes involving these groups of residents may mitigate potential public resistance towards the alternative(s). In the statistical analyses, locational parameters were recurring, significant parameters for indicating an initial propensity to agree or disagree with the implementation of the different infrastructure retooling alternatives. Specific locations in which residents had an increased propensity to agree with the implementation of an alternative included:

- **Cleveland, Ohio.** Cleveland residents have a 0.162 increase in the probability of agreeing with measures to invest in more physical water infrastructure.
- **Flint, Michigan.** Flint residents have a 0.112 increase in the probability of agreeing with decommissioning or razing water infrastructure.
- **Gary, Indiana.** Gary residents have a 0.263 increase in the probability of agreeing with investing in more physical water infrastructure.
- **Scranton, Pennsylvania.** Scranton residents indicated a 0.241 increase in agreeing that the probability that the utility providers should maintain the status quo (i.e. do nothing).
- **Trenton, New Jersey.** Trenton residents have a 0.311 increase in the probability of agreeing with measures to invest in more physical water infrastructure.

The locations in which residents disagreed with select retooling alternatives were:

- **Shrinking cities in Ohio.** Residents of shrinking cities in Ohio have a 0.058 decrease in the probability of agreeing with decommissioning or razing water infrastructure.
- **Shrinking cities in Pennsylvania.** Residents of shrinking cities in Pennsylvania have a 0.151 decrease in the probability of agreeing with increasing the financial investment of maintaining the current water infrastructure.
- **Trenton, New Jersey.** Trenton residents have a 0.372 decrease in the probability of agreeing with measures that increase the financial investment of maintaining the current water infrastructure.

Location parameters are important to consider for decision-makers when considering viable, sustainable retooling alternatives to explore further for potential implementation. The initial propensity to agree/support or disagree/oppose with different infrastructure retooling alternatives may be due to a communication gap or lack of awareness regarding infrastructure issues typical to shrinking cities. For instance, albeit being residents in shrinking cities, the residents of Cleveland, Gary, and Trenton are more likely to support investing in more infrastructure, indicating a lack of knowledge regarding the relationship between the fixed grid infrastructure system and the declining population. This location specific information may be a conversation starter between the public and utility providers on how to move forward towards a sustainable infrastructure system, to dispel incorrect information regarding utilities in the context of urban decline, or to discuss the viability of infrastructure alternatives to promote increased likelihood of support of the implemented infrastructure retooling alternative.

The five models also revealed many demographic characteristics to be significant in influencing the attitude towards retooling alternatives. Age was a signification demographic variable, with individuals younger than 35 years old being more likely to disagree with the status quo/do nothing alternative and more likely to support maintaining existing infrastructure. Conversely, individuals over the age of 50 were more likely to oppose repurposing infrastructure. These findings may be capturing a resistance to change as openness for progressive change has been shown to decline as individuals age (Westerhoff 2008).

Men are more likely to agree with repurposing infrastructure, possibly reflecting the importance that males can play in household incomes and decision-making (Wang et al. 2013). Additionally, individuals who are single, divorced, or separated, are more likely to agree with repurposing infrastructure further supporting that retooling alternatives may be viewed as a viable method to stabilize costs when living expenses are not shared amongst partners.
Individuals with incomes less than $35,000 are more likely to agree with increasing the investment in more infrastructure and less likely to agree with doing nothing. However, those individuals who are out of work are more likely to agree with investing in maintaining the current infrastructure, likely recognizing this alternative to be seemingly less financially burdensome on the customers/rate-payers.

Ownership of cars increased the likelihood of disagreeing with the ‘do nothing’ alternative. Consistent with this finding is that individuals with more than two cars were more likely to support decommissioning or razing infrastructure, and households with at least one car were more likely to agree with maintaining existing infrastructure. This finding may be capturing some measure of wealth and mobility that would make individuals in these groups less likely to be impacted by increasing investments for maintenance, or may simply reflect the economics involved in owning additional cars which results in less disposable income. This measure of wealth associated with less disposable income may be a motivation to find a way (decommissioning or razing infrastructure or maintain infrastructure) to stabilize future utility rates.

Ownership of homes was a significant parameter. Renters were more likely to disagree with investing in more infrastructure, possibly capturing a disinterest in investing in an area that the renter is not permanently tied to or the economics involved in renting a household and having less disposable income (as discussed with car ownership). If the home is owned via a loan, the individual is more likely to agree with doing nothing to the water infrastructure. This home-ownership parameter seemingly captures the decrease in disposable income due to loan payments, and the view that doing nothing in the near future will not require increasing the water rates that further strain the low incomes rampant in these cities.

Those individuals who are responsible for their water bill were found to be less likely to agree with the doing nothing for water infrastructure retooling alternative. Additionally, individuals who were raised in the city, or individuals who have retired from regular employment are less likely to agree with doing nothing for water infrastructure. As the average income in shrinking cities is typically below the average income for the state (US Census Bureau 2011), these individuals may see these alternatives as viable methods to stabilize or reduce water service costs, one of many living expenses.

The primary source of news of the respondents was a significant parameter in many models. The significance of this parameter may be due to the different age groups using the medium as the primary source of news. For instance, radio is often the primary source of news for older generations (Kohut et al. 2010). Another reason for the significance of this parameter may be due to the stories that are highlighted via the medium and the flexibility to search for own stories of interest. The Internet provides for flexibility to choose from a wide range of news, whereas the radio provides the listener with limited flexibility.

5 SUMMARY AND CONCLUSIONS

As cities experiencing urban decline explore water infrastructure retooling alternatives, understanding the sources of opposition/disagreement and which alternatives are likely to be supported/opposed by the community may possibly mitigate opposition towards the implemented alternative(s). In this study, less than 20% of the survey respondents expressed no desire to participate in the decision-making processes regarding water infrastructure. This low percentage indicates that communication avenues must be open between the utility providers and the public making decisions regarding water infrastructure. Incorporating some level of participatory decision-making may allow for sustainable outcomes and increased support with efforts for stabilizing or reducing the costs of services. This paper contributes to the body of knowledge by illustrating the viability of evaluating public attitudes towards underground infrastructure and potential infrastructure retooling alternatives using survey analyses and statistical modeling.

Underground infrastructures (e.g., water, wastewater, natural gas) are unseen, and the public generally lacks the same level of awareness of operations and conditions of these systems compared to those of above-ground infrastructure systems, such as roads and bridges. However, price elasticity studies (e.g., USEPA ND; Espey et al. 1997; Lipsey and Chrystal 1999; NRDC 2012) have shown that consumers are sensitive to price changes with water utility services, illustrating that consumer behavior is directly tied to the utility service provided. Infrastructure retooling alternatives have the potential to reduce or stabilize
the costs of service. However, depending on how the necessity of these alternatives is perceived, the public may not agree with a specific alternative. Understanding public attitude is critical for the successful implementation of retooling alternatives since decisions lacking adequate public support may lead to inefficient or unsuccessful implementation (Susskind and Cruikshank 1987; Global Water Partnership Technical Advisory Committee 2000, Gerasidi et al. 2009, Nancarrow et al. 2010, Faust et al. 2013).

The statistical analyses show that a wide variety of factors influence the attitudes of residents in shrinking cities pertaining to water retooling alternatives. Results from the five water infrastructure retooling model estimations show that many of the same socioeconomic and demographic variables influenced the attitudes spanning the five models. These socio-economic and demographic findings may be used to evaluate the population in specific shrinking cities to determine the initial viability of different retooling alternatives, and to tailor information campaigns for specific groups to mitigate potential opposition towards different infrastructure retooling alternatives. Specific socio-economic and demographic results that had an increased propensity towards agreeing or disagreeing with different retooling alternatives included age, gender, income, number of cars, employment status, and primary source of news. Understanding the sources of support/opposition among the populations, while considering these attitudes in the decision-making process may allow for shrinking cities to transition towards strategies for stabilizing or reducing the per capita costs of utility services.

APPLICATION OF PROSPECT THEORY TO MANAGEMENT DECISIONS UNDER RISK ON CONSTRUCTION PROJECTS

Jean-Charles Fiolet\textsuperscript{1,2}, Carl T. Haas\textsuperscript{1}

\textsuperscript{2} jfiolet@uwaterloo.ca

\textbf{Abstract:} Working on a construction project requires making important decisions quickly and frequently. Most of these decisions are made under risk in that the outcomes are not known, but their probabilities and impacts can be estimated, however imprecisely. Deciding to pave, given temperature predictions, is an example of such a decision. When the impacts are aggregated, they can represent a non-negligible amount compared to project budgets. Understanding project leaders’ behaviour when they make such decisions under risks may create opportunities to avoid future losses that result from suboptimal choices. As those decisions are numerous on a construction project, it might be difficult for the project leaders to always make the best choice. By using a questionnaire referring to potential construction project situations, this study shows how some behavioural tendencies can influence the choices of construction leaders. This paper mainly focuses on one aspect of the study, which is the impact of the certainty effect on projects leaders’ decision making. It demonstrates how project leaders are sensitive to the behavioural tendency associated with the certainty effect. This observation leads to the question of how to detect those problems and, how to correct them so as to avoid non-negligible loss of money for construction projects.

\section{INTRODUCTION}
Project leaders are required to quickly make many day-to-day decisions on their construction projects. When aggregated, those decisions can have a significant influence on cost and schedule performance. Many of those decisions are made under financial risk. An example is the decision whether to place concrete on a day for which the risk of rain has been estimated. Studies have investigated this question of decision under risk in terms of gambling and investments, and they have proven that people will illogically avoid and chase risk under different circumstances. This paper reports on an investigation of this phenomenon with respect to decisions made on construction sites.

It begins with a literature review of relevant behavioural economics principles and findings. Based on this review, a set of experiments were designed in the form of a questionnaire that would test basic hypotheses to determine sensitivity to risk and influence on judgment when day-to-day decisions are being made. Project leaders such as foremen, general foremen, superintendents, and managers were asked to answer the questionnaire.

The results of these experiments partially demonstrate the impact of risk on decisions made by project leaders. Results mostly follow the behavioural tendencies previously identified in Behavioural Economics research which indicate that risk influences judgment. For example, when the risk-option was more advantageous in terms of expected value, most people made the logically correct decision, but a
significant subset made the other choice, and this represents a loss of money for companies. Also, different parameters of the project, such as the cost performance, may have influence on decisions. Respondents were less risk averse when the project was described as under budget, but many also chased risk when the project was over budget. These are expected behaviours based on behavioural economics theory. Demonstrating and understanding how some decisions made under risk can lead to a predictable non-negligible loss of money is a first step in this research. The ultimate goal is to help project leaders avoid making illogical decisions when sufficient information is available to avoid such decisions.

2 DEVELOPMENT OF BEHAVIOURAL ECONOMICS AND APPLICATION TO THE CONSTRUCTION SECTOR

2.1 Emergence of Behavioural Economics

Economics studies conducted in the second half of the last century have shown that making decisions under risk is not as easy as people might think. When people are making decisions, they are not using expected utility theory; other parameters influence their choices. This specific field in economics is called “Behavioural Economics”. It deals with the subfield of psychology which describes what guides people when they are making a decision.

The research field of behavioural economics can be classified in two categories: the process of judgment and the process of choice. Judgment deals with how people estimate probabilities, and choice is about how people select an action among others. The goal of this field is to understand how people are making their decisions, when they are facing risk.

But, some economists have also found that there are some effects which can generate problems during the phase of decision-making under risk. For example, people prefer earning an amount disproportionately more than their aversion to losing the same amount (Kahneman and Tversky 1979). Similarly, people generally give more value to what they already have compared to or referenced than to what they can have in a deal in objective and absolute terms. This effect is called reference-dependence (Knetsch 1992).

Psychologists also define different mechanisms which violate some principles of basic economics, like expected values. Such mechanisms, as “certainty effect” or “loss aversion” affect the process of choices when people are making a decision under risk. It is hypothesized that those mechanisms can also influence construction leaders when they are facing a risk and have to make a decision.

2.2 Factors influencing construction decisions

The decisions of construction project leaders are influenced by factors external or internal to the construction project. For instance, the experience of the decision-maker has an influence on his future choice: events that actually occurred are easier to imagine compared to ones that have not yet occurred in their experience (Kahneman and Frederick 2002).

Some factors can also influence the process of judgment such as the environment and the context. For example, if the same problem is presented or seen in two different ways, then it can lead to different answers from the decision maker. People will not react the same way if the problems are presented in terms of gains, or in terms of losses. This is called the “framing effect” (Tversky and Kahneman 1981).

Lists of parameters influencing the success of a construction project have been made numerous times in the literature (Sanvido et al. 1992, Chan et al. 2004). They can be human related, management related or process related. One objective of this study is to identify key factors and link them to a behavioural tendency to explore if the behavioural tendency will have an impact on a category of decisions made for the construction project.
2.3 Application of Behavioural Economics to the Construction Sector

Behavioural Economics knowledge has been applied to different sectors and to construction project management. An important area of construction project management to which it has been applied is the bidding process. As this step of the project can deal with large amounts of money, applying behavioural economics to understand how construction leaders make bidding decisions makes sense (Han et al. 2005, Chen et al. 2015).

Behavioural economics has many applications in the construction sector. Another example would be the application of social norms on typical construction project problem such as absence behaviour to understand those (Ahn et al. 2014).

This paper focuses on the application of behavioural economics to small decisions that are made frequently on projects. Taken individually, those decisions may not seem important enough to matter compared to the size of projects, however aggregated together they can represent a non-negligible amount. This paper describes an experiment applying behavioural economics to those kinds of decisions.

3 DESCRIPTION OF THE EXPERIMENT AND OF THE QUALITY OF MATERIALS QUESTION

3.1 Description of the Global Experiment

3.1.1 Goal of the experiment

Creating a controlled experiment that places construction decision makers under financial risk and which observes their decision making behaviour under such conditions is, ironically, fraught with risk and not likely to receive research ethics review process approval. A reasonably close and ethically acceptable approximation of the preceding approach is to develop a research tool that implements an experiment in which decision makers are asked to make a choice as if the conditions described were real. Such a tool has been developed in the form of a questionnaire. This timed questionnaire is used to conduct the experiment.

The experiment has three goals. The first goal is to determine the sensitivity of construction project leaders to different typical risks during the decision making process. The second goal is to study the impact of key parameters on those decisions. The final goal is to estimate the financial impact that those decisions can have on a construction project when they are compared with the same decisions problem resolved following expected utility theory.

Specifically, the questionnaire contains close-ended questions, each with two possible options. The participants are asked a series of questions that describe typical construction project situations. The reasons for this choice are:

- Approximation of action based experiment: As explained above, this approach approximates adequately a controlled experiment with real consequences.
- Simplicity of analysis: Compared to an open-ended questionnaire, the answers, here called options, for this kind of questionnaire are easier to read because there are only two possible choices for each question. The question is reduced to a specific problem, and the data linked with that question can be directly interpreted.
- Simplicity for understanding and focus: All the questions built for this questionnaire are as simple as possible to maximize likelihood of understanding and to maximize consideration of externalities that might influence the respondents’ decisions.
- Simplicity for answering: The close-ended questionnaire allows people to answer faster.
- Correspondence with research goals: Previous successful studies that focused on behavioural tendencies almost invariably used close-ended questionnaires (Allais 1953, Kahneman and Tversky 1979). This form of questionnaire is useful for isolating behavioural tendencies, because it forces the participant either to choose or to avoid the risk, and it makes the result easier to analyze as well using conventional statistics.
3.1.2 Development of the questions – Behavioural tendencies

The first problem was to determine how many questions should be in the questionnaire, what kind of questions would be included and how they should be presented to the participant. For this experiment, it was decided to build the questions around behavioural tendencies such as “certainty effect” or “loss aversion”, by identifying situations on construction projects in which those behaviours might be exhibited. Thus, one of the most important parts of the development of the questionnaire was to build situations where a behavioural tendency might appear, and make it realistic for the participant. Based on this rationale, some construction situations were chosen and linked to a behavioural tendency in order to construct each question. The questions were in four groups:

- Choice between two techniques – testing for Perception of Change
- Choice between two kind of shingles (Quality of the materials) – testing for Certainty Effect
- Construction of a set of bored piles – testing for Non Compliance
- Decision to work with a risk of rain – testing for Loss Aversion

3.1.3 Development of the questions – External Influences

When project leaders are working on a construction project, they can be influenced by many external factors. Those factors can influence their choice in day-to-day decisions when they are facing risk. From the behavioural economics literature, it is clear that current financial position typically influences decisions made with respect to possible future gains and losses (Tversky and Kahneman 1986). Project cost performance is a good proxy for this factor as it reflects on the project leader’s perception of their own situation, performance, and related future rewards or penalties. Thus, each question is framed in terms of the following three project cost performance situations:

- on budget
- over budget
- under budget

3.1.4 Development of the questions – Expected Values

The expected value (EV) of an option corresponds to the sum of the expected values of the possible outcomes. Expected value is calculated using equation 1.

\[ EV = \sum_{i=1}^{n} p_i c_i \]  

For both options to each question the associated expected value is computed and then compared to the expected value of the other option. Two cases occur:

- The expected value of both options are equal
- One option has an advantage over the other one in terms of expected value

These two cases are used in the questionnaire for different objectives. The first case, when the expected values of both options are equal, is intended to highlight the presence of a behavioural tendency, if it exists. For the second case, the option that comprises a risk is advantaged compared to the other one. This time the goal is to qualify the subset of participants who are averse to risk.

3.1.5 Distribution of the questions

All the questions are built to test for one behavioural tendency and one external influence. The expected values of their options are either equal or different depending on the experimental hypothesis for each behaviour. The different questions prepared for this questionnaire are shown in Table 1. The questions were mixed randomly in the questionnaire, so that two similar questions did not appear in sequence.

3.2 Construction of the “Quality of materials” Question

3.2.1 Materials of the question

This conference paper, due to limitations, focuses on the “Quality of the materials” questions where the construction project is on budget (Q15 and Q2). However, the distribution and experimental design of the full set of questions are presented. The “Quality of the materials” question deals with the certainty effect.

The certainty effect is the psychological effect referring to the reduction of probability from certain to probable in the perception or utility function of the decision maker. Usually, reducing a probability of winning creates some effects, such as displeasure. This displeasure leads the individual to a reaction of risk-aversion because the small possibility of not winning is perceived as a loss. This risk-aversion reaction is bigger when the probability is reduced from certain to probable than from probable to less probable (Tversky and Kahneman 1986). Conversely, extremely small probabilities are invariably overvalued, leading to behaviours such as the purchase of lottery tickets.
The “Quality of materials” question plays with this behavioural tendency of certainty effect. The question offers one option with a complete assurance of the quality that is relatively expensive and a second option where the assurance of the quality is close to complete, but it is not, and this option is less expensive compared to the first one. Here, it is important that the probability of acceptable quality for each shingle for the second option is close to 100% or else other parameters would enter in the question such as the time of replacement, cost of disposal, and shipment. The intent was for the respondent not to factor in these other issues. An example of this question is shown in Figure 1. This question deals with the installation of shingles, but no qualifications are needed to answer this question, so every project leader or decision maker should be able to answer it.

### 3.2.2 Choice of the values – Decision Trees

The “Quality of materials” question where the construction project is on budget appears twice in the questionnaire: once when the expected values are equal (Q15) and a second time when the risk option (shingle A) is advantaged in terms of expected values (Q2). The decision trees of these questions are shown in Figure 2. Both questions offer a probability of cracking of 97% during the installation of which is close to 100% and so corresponds to the criterion defined before. The price of the shingles is around $200 for both questions. It makes sense because nothing about the shingle was specified in the question.

The expected value is computed for each option. Equation 1 is used for this computation. For option B, the expected value is easy to compute because the probability linked is 100%. However, computing the expected value for option A is more difficult, because the broken shingles have to be replaced by the same kind of shingle and the operation can last infinitely in theory. However, this calculation corresponds to the sum of a series. These expected values appear in the decision trees of Figure 2.

### 3.3 Progress and methodology of the experiment

The data collection process was established within the guidelines of the Office of Research Ethics of University of Waterloo. The participants were given an information letter about this study, and they had to fill a consent form so that their data can be used. Once this first step was done, the participants were allowed to fill the questionnaire. Filling the questionnaire took approximately half an hour. To finish, after
they gave back their questionnaire, they received a feedback letter, explaining the objectives of this experiment.

The data from the answers of the questionnaire was then analyzed, question by question, testing for the behavioural patterns explained before. It was also studied and analyzed in relation with external influences and characteristics from the participants such as their position or their age to observe how those parameters can influence their choices and their reactions facing those behavioural patterns.

In total, this study had 53 participants; they are all construction project leaders, mostly located in North America, and at different levels: foremen, project managers, executives and a few teachers and researchers. Those people were chosen randomly with respect to their age, their location and their position. The range of age is large, from the twenties to the sixties, so it results in participants with different levels of experience. Some have a whole career behind them, while others just started their job. This absence or not of experience may influence the way they make decisions under risk, so it is important to have a sample representative of the population of construction workers.

4 ANALYSIS OF THE RESULTS

4.1 Results of the “Quality of the Materials” Question

The percentages of participants who chose option A or option B for these two questions are shown in Table 2. As expected, the majority of participants chose to avoid the risk and took option B (no risk) for the question where the expected values are equal. This result shows the impact of the certainty effect on the participants’ choice. The significance of this value will be determined in the next section by computing the 95% confidence interval.

Concerning the second question where option A (risk taking) was advantageous, most of the participants made the best decision in terms of expected values. However, 28% of the participants chose to avoid the risk even if it was obviously more attractive in terms of expected values. This represents a significant number of participants, and consequently, potential non-negligible loss for companies. Computing the expected utilities linked to this question may explain this behaviour. This will be shown in the next section.
