## ABSTRACT

Several methods have been proposed for predicting the secondary structure of proteins. The method of Chou and Fasman (1974a, 1974b, 1978a, 1978b) is relatively simple in theory and reasonably accurate. Unfortunately, the rules of Chou and Fasman are sometimes ambiguous and can be interpreted differently by researchers.

Several attempts have been made for computerization of the rules of Chou and Fasman (Argos et al., 1976; Chou and Fasman, 1978b; Dzionara et al., 1977). However, they are for computation of only a portion of the protein secondary structure. The final assignment of the entire structure has to rely on the individual's manipulation.

In addition to three separate computer programs for prediction of the  $\alpha$ -helix,  $\beta$ -sheet and  $\beta$ -turn structures, a fourth program was written for clarifying overlapping areas between  $\alpha$ -helix and  $\beta$ -sheet. Although the predicted structures of 24 proteins with known conformation were in general satisfactory, there were a number of missing areas and boundary values different from X-ray diffraction patterns.

In an attempt to improve the accuracy of the prediction, the nucleation rules were modified to emphasize

importance of the type and positions of amino acid residues in the region.

Furthermore, an extra step for boundary adjustment was added to the search for  $\alpha$ -helix and  $\beta$ -sheet regions. This step compared the importance of the boundary conformational parameters and the possible interference of the different conformations at the boundaries of the predicted regions. These modifications produced predicted secondary structures which were in good agreement with the X-ray diffraction patterns and the predicted patterns of Chou and Fasman (1974b, 1978b).

The Matthews' coefficient (C) calculated for  $\alpha$ -helix and  $\beta$ -sheet were 0.39 or above, meaning that the prediction would be quite useful although there might be one or two helical regions missed or overpredicted. The paired-sample t-test revealed that the values of  $C_\alpha$  ( $P < 0.01$ ) and  $C_\beta$  ( $P \leq 0.05$ ) calculated for the present prediction were significantly improved from the values of Chou and Fasman. The computer-assisted technique described in this thesis, therefore, would decrease the discrepancy between the predicted data from different researchers due to the ambiguous interpretations of the rules of Chou and Fasman.

The second part of this study involved the application of the program to several food related proteins

(bovine serum albumin,  $\alpha_{s1}$ -casein,  $\beta$ -casein,  $\kappa$ -casein, chymosin,  $\alpha$ -lactalbumin,  $\alpha$ -lactoglobulin, ovalbumin, pepsin and trypsinogen). Although references could not be found for all proteins tested, the results obtained for  $\kappa$ -casein and  $\alpha$ -lactalbumin were comparable to those reported by other researchers.

Since conformational data have long been recognized as contributing to the information on protein and enzyme functionality, the computerization of the predictive method of Chou and Fasman will definitely be a tool for explaining the protein functionality in food processing.

## ACKNOWLEDGEMENTS

The author wishes to express her sincere appreciation to her supervisor, Dr. S. Nakai, Professor, Department of Food Science, for his constant advise, help and encouragement throughout the course of this study, and in the preparation of the thesis.

She is also thankful to the members of her graduate committee:

Dr. R. C. Fitzsimmons, Associate Professor,  
Department of Poultry Science

Dr. W.D. Powrie, Professor and Head,  
Department of Food Science

Dr. B.J. Skura, Assistant Professor,  
Department of Food Science

for their interest in this research and for the review of this thesis.

## INTRODUCTION

Broadly, the functional properties of proteins denote any physico-chemical property that affects the processing and behavior of proteins in food systems, as judged by the quality attributes of the final product. The functional properties are influenced by and vary according to: a) the source of proteins, b) the method of isolation and purification, c) the concentration of proteins, d) the type of modifications (enzymatic, acid, or alkaline hydrolysis), and e) environmental conditions (pH, temperature, and ionic strength).

An extensive review of the various studies on protein functionality was published by Kinsella (1976). In general most of the changes in protein functionality have been found to be related to the degree of denaturation that proteins undergo. For example, in gelation a heat treatment is usually required to cause at least partial denaturation or unfolding of the polypeptide chains. Those unfolded chains will then gradually associate to form a gel matrix if attractive forces and thermodynamic conditions are suitable.

It is necessary to consider the hydrophobic, electron-  
ic and steric parameters of molecules to understand the mechanism of folding and unfolding of proteins, their biological activity, and to predict their behavior upon certain treatments

(i.e., possible areas of denaturation, extent of unfolding, exposing of the hydrophobic core). The electronic parameters can be evaluated by electrophoresis , while a fluorometric method has been developed by Kato and Nakai (1980) for evaluation of hydrophobic parameters.

X-ray diffraction has been used to study the steric parameters of more than sixty proteins. In addition, X-ray diffraction has contributed a great deal to our knowledge of protein-protein, protein-metal, protein-solvent interactions (Liljas and Rossmann, 1974 ; Matthews, 1975b). However , these crystallographic analyses cannot be applied to most food proteins, or to many membrane and ribosomal proteins due to problems of crystallization. Furthermore, the X-ray technique is quite laborious, expensive and time-consuming.

Anfinsen et al. (1961), studying the reformation of reduced bovine ribonuclease, observed that the native structure of a protein is controlled by its amino acid sequence. This finding has become the motivation for many attempts to obtain patterns of protein structure from sequence data.

Although protein functionality depends on its unique three-dimensional topology, one can still learn much from the prediction of its secondary structure. Nishikawa and Ooi (1972, 1973), in a study of protein tertiary structure, based their energy calculations on the conformation derived from the

computation of sets of dihedral angles  $\phi$  and  $\psi$ . To fit the polypeptide chain of the tobacco mosaic virus protein (TMV) to a low resolution Fourier map, some information on the secondary structure was found to be desirable (Leberman, 1971).

Secondary structure predictions will provide useful information on areas of protein molecules where the X-ray pattern is not yet clearly resolved, especially at the N-terminal. For instance, areas predicted as helical by Chou and Fasman (1974b) for cytochrome b<sub>5</sub> and ferricytochrome c had not been detected by X-ray diffraction at 2.8 $\text{\AA}$  resolution. Their results were later confirmed by X-ray at 2.45 $\text{\AA}$  and 2.0 $\text{\AA}$  resolution (Dickerson *et al.*, 1971; Mathews *et al.*, 1972; Takano *et al.*, 1973).

Conformational information may also be used to design experimental models for checking the effects of conformational changes on hormonal or enzymatic activity (Dunn and Chaiken, 1975; Fink and Bodanszky, 1976; Peña *et al.*, 1975). Some researchers (Deber *et al.*, 1976; Kopple *et al.*, 1975) considered study of the  $\beta$ -turn a good starting point for elucidating the influence of sequence and surroundings on protein conformation. The  $\beta$ -turn structure is potentially identifiable and is simple enough to be characterized by experimental and predictive techniques (<sup>13</sup>C NMR, circular dichroism, confor-

mational energy calculations). It also helps to explain the mode of activation of biologically active peptides (Bradbury et al., 1976).

Another application of the secondary structure prediction is the comparison of proteins of the same family which may maintain some conformational homology despite variations in sequence data, such as the case of proinsulins and proteinase inhibitors (Chou and Fasman, 1978b).

The method of Chou and Fasman (Chou and Fasman, 1978a, 1978b) has been frequently considered the least complicated in use for the prediction of the secondary structure of proteins. Yet, it possesses an overall accuracy higher than random guessing for a three-state model ( $\alpha$ -helix,  $\beta$ -sheet and coil state). The percent of total residues correctly identified in a protein is 75 for this method versus 33 for random guessing. Furthermore, Chou and Fasman's work has improved on the earlier studies (Davies, 1964; Havsteen, 1966; Goldsack, 1969) since it takes into account combinations of residues that are  $\alpha$ -helix,  $\beta$ -sheet and  $\beta$ -turn formers and breakers. The computed percentage of secondary structure obtained by their method agrees quite well with estimates based on CD studies (Kawauchi and Li, 1974; Garel et al., 1975; Garnier et al., 1975; Green, 1975; Matthews, 1975a; Scanu et al., 1975; Holladay and Puett, 1976; Muñoz et al., 1976; Wallace, 1976).

With the exception of Argos et al. (1976), most of the laboratories that have applied the method of Chou and Fasman for specific investigations on protein structure have not yet reported a common computerized technique which can be used for other proteins. The objectives of this study were as follows: a) design a program which would provide similar results to those published by Chou and Fasman (1974b, 1978b) and b) if successful, extend this program to food related proteins so that possible correlation between protein functionality and conformational changes may be better understood.

## LITERATURE REVIEW

### Definition of the Different Conformational Regions

According to the IUPAC - IUB Commission on biochemical nomenclature (1970) the secondary structure of a segment of a polypeptide chain is the local spatial arrangement of its main chain atoms without regard to the conformation of its side chain or its relationship with other segments. The four typical conformations encountered in the secondary structure are the  $\alpha$ -helix, the  $\beta$ -sheet, the  $\beta$ -turn (bend), and the random coil.

#### A. Alpha-Helix

The  $\alpha$ -helix contains 3.6 amino acid residues per turn of the protein backbone, with the R groups of the amino acids extending outward from the axis of the helical structure. Hydrogen bonding can occur between the hydrogen of the NH group of one peptide bond and the oxygen of the CO group of another peptide bond four residues along the protein chain. The hydrogen bonds are nearly parallel to the axis of the helix, lending strength to the helical structure. Since natural amino acids exist in L configuration, a right-handed helix is more stable than a

left-handed helix. Therefore, if helical structures exist in proteins they are invariably right-handed helices (Anglemier and Montgomery, 1976). Since the  $\alpha$ -helix has the lowest feasible free energy, formation of this structure is spontaneous, provided there are no interactions between charged R groups or steric hindrance by residues on the larger amino acids. Examples of protein types in which the  $\alpha$ -helix predominates are enzymes and respiratory proteins.

Taking into account the structural requirements that are specific to globular proteins, Lim (1974a) proposed a number of conditions necessary for a helix to exist along the peptide chain. Each separate helical region must have at least one hydrophobic side group or a group which would permit the helix to attach itself to the hydrophobic core of the globule. From the analysis of immersion of the hydrophobic side chain situated on the  $\alpha$ -helix surface, Lim (1974a) emphasized the role of hydrophobic pairs, (1-5), and hydrophobic triplets, (1-2-5) or (1-4-5), in the attachment of the  $\alpha$ -helix to the hydrophobic core. Hydrophobic-hydrophilic triplets, (1-2-5) and (1-4-5), are also important for helix stabilization.

Another way to describe the conformation of a protein chain is to measure the dihedral angles  $\phi$  and  $\psi$  which correspond to rotations about the N-C $^{\alpha}$  and C $^{\alpha}$ -C bonds.

The  $\phi$ ,  $\psi$  angles for residues in a regular right-handed helix are given by (-57, -47°) (IUPAC-IUB, 1970). Since 3.6 residues are required to form a hydrogen bond in a single turn of the  $\alpha$ -helix, all consecutive sequences of four or more residues having  $\phi$ ,  $\psi$  angles within 40° of (-60°, -50°) are considered to be helical. Some residues at the helical ends may have dihedral angles that fall outside the range  $-100^\circ \leq \phi \leq -20^\circ$  and  $-90^\circ \leq \psi \leq -10^\circ$  but are included as helical if they show hydrogen bonding. Based on the above criteria a total of 152 helical regions were identified in 29 proteins (Chou and Fasman, 1978a, 1978b).

### B. Beta-Sheet

In this conformation, the peptide backbone forms a zig-zag pattern with the R groups of the amino acids extending above and below the peptide chain. Since all peptide bonds are available for hydrogen bonding, this conformation allows maximum cross-linking between adjacent peptide chains and, thus, good stability. Both parallel and anti-parallel pleated sheets are possible. This conformation predominates in many fibrous proteins such as silk and insect fibres.

According to Lim (1974a),  $\beta$ -structural regions can be divided into three types by their relative position

to the surface of the globule: the internal, the surface, and the semi-surface type. In order to exist without violating structural requirements for globular proteins, each type should be formed from a certain number of hydrophobic/hydrophilic residues. For instance, entirely hydrophobic regions or hydrophobic regions with one or two hydrophilic residues in the first two and/or last two positions on the N- and C-terminal will favor the internal type.

The condition for a  $\beta$ -chain to be located on the surface of the globule requires that one side of the band have only hydrophobic groups and the other side only hydrophilic groups. The semi-surface type may exist in peripheral regions of the  $\beta$ -sheets. These regions must have only hydrophilic side groups or mainly residues of Gly.

The position of certain amino acid residues can also be very critical. Pro cannot be included in the  $\beta$ -structure because of the stereochemistry of its side group. The surface type must not have Gly on the hydrophobic side or Gly and Ala on the hydrophilic side. This is stipulated by the fact that the presence of Gly on the hydrophobic side will impede the tight packing formation in the hydrophobic core. Water molecules can loosen hydrogen bonds of the peptide groups neighbouring with the  $C^\alpha$  atoms of Gly or Ala when these two amino acids occur on the hydrophilic side.

The  $\phi, \psi$  angles for residues in a parallel-chain  $\beta$ -sheet and an antiparallel  $\beta$ -sheet have values of  $(-119^\circ, 113^\circ)$  and  $(-139^\circ, 135^\circ)$ , respectively (IUPAC-IUB, 1970). A consecutive sequence of three or more residues having  $\phi, \psi$  angles within  $40^\circ$  of  $(-120^\circ, 110^\circ)$  or  $(-140^\circ, 135^\circ)$  are considered to be in the  $\beta$ -conformation, even if these residues are not involved in hydrogen bonding. However, residues at the  $\beta$ -ends that have dihedral angles outside the range  $-180^\circ \leq \phi < -80^\circ$  and  $175^\circ \leq \psi \leq 70^\circ$  are included in the  $\beta$ -region if they participate in at least one hydrogen bond. The two end residues that are not hydrogen bonded in antiparallel  $\beta$ -sheets are not counted as  $\beta$ -residues but instead are assigned to the coil conformation and /or the  $\beta$ -turn conformation.

Chou and Fasman (1978a, 1978b), analyzing 137  $\beta$ -regions, observed 3 two-residue  $\beta$ -segments (papain 111-112, 130-131, and ferrodoxin 50-51), 10 three-residue  $\beta$ -segments, and 9 four-residue  $\beta$ -segments. This number increases to 28 and 24 for the five-residue and six-residue  $\beta$ -segments, respectively. The three longest  $\beta$ -regions contain 17 residues (thermolysin 16-32), 16 residues (ribonuclease 96-111), and 15 residues (lactate dehydrogenase 280-294). In contrast, Chou and Fasman (1978a, 1978b) identified 24 helical segments longer than 17 residues in 29 proteins. The reason that helices are longer

than  $\beta$ -sheets may be because of the greater ease of helical intrachain hydrogen bond formation compared to  $\beta$ -sheet interchain hydrogen bond formation.

### C. Coil Regions

Residues in the protein that are not classified to be in the helix or  $\beta$ -regions are assigned to the coil conformation, irrespectively of the  $\phi$ ,  $\psi$  angles of the residue. Hence, three consecutive residues having the  $\alpha$ -conformation or two consecutive residues having the  $\beta$ -conformation but without hydrogen bonding are considered to be in the coil state (Chou and Fasman, 1978b). The four longest coils regions found among 29 proteins contained 54 residues (thermolysin 181-234), 51 residues (carboxypeptidase 123-173), 46 residues (ferredoxin 4-49) and 41 residues (rubredoxin 14-54). These coil regions cannot be considered completely structureless since they may contain many  $\beta$ -turns. In the case of ferredoxin and rubredoxin, the flexibility of these coil regions is severely restricted by the iron-sulfur coordinations.

### D. $\beta$ -Turn Regions

The  $\beta$ -turn involves four consecutive residues in

a protein where the polypeptide chain folds back on itself by nearly  $180^{\circ}$ . It is these regions of chain reversal that give a protein its globularity rather than linearity. Lewis et al. (1971) proposed that chain reversals play the important role of bringing distant parts of the peptide chain together, enabling interactions between helix-helix, antiparallel-parallel  $\beta$ -pleated sheet, or helix- $\beta$ -sheet.

Venkatachalam (1968) was the first to characterize three types of turns in a tetrapeptide where there is a hydrogen bond between the CO group of residue  $i$  and the NH group of residue ( $i+3$ ). Most bends (80%) from 8 proteins contain at least one or more of the following residues: Ser, Thr, Asp, Asn and Pro. This supports the idea that these residues are responsible for bend stability and perhaps for bend formation. With the exception of Pro which can occupy only a few backbone conformations, these residues have been shown to be capable of forming side chain-backbone hydrogen bonds with their own backbone (Lewis et al., 1973).

Using the X-ray atomic coordinates from 29 proteins, Chou and Fasman (1977) computed the  $C_i - C_{i+3}$  distances of 4651 tetrapeptides. Those whose distances were below  $7\text{\AA}$  and not in a helical region were considered as  $\beta$ -turns. Of the 457  $\beta$ -turns elucidated, 243 of them also have  $O_i - N_{i+3}$

distances  $\leq$  3.5 $\text{\AA}$  and were considered to have hydrogen bonding. Chou and Fasman (1977) also assigned  $\beta$ -turns to 11 types similar to those of Lewis *et al.* (1973) based on the  $\phi$ ,  $\psi$  dihedral angles of the second and third residues of the bend.

#### Review of the Various Predictive Methods

Several researchers have attempted to predict the secondary structure of proteins from their sequence data.

Szent-Gyorgyi and Cohen (1957) through their study with the KMEF proteins (keratin, myosin, epidermin and fibrinogen) and with collagen, demonstrated that the helix content determined by optical rotatory dispersion (ORD) is inversely proportional to the percentage of Pro residues distributed throughout the sequence. They concluded that less than 3 percent Pro distributed randomly in a chain permits more than 50 percent  $\alpha$ -helix. About 8 percent Pro deforms the backbone into a rancom coil. Very high Pro content may favor a poly-L-proline helix type.

Davies (1964) using the  $b_0$  value of ORD, found a strong correlation between the helix content of fifteen proteins and the mole percentage of (Ser + Thr + Val + Ile + Cys), residues classified as "nonhelical-formers" by Blout

et al. (1960) and Blout (1962). No strong correlation between the helix content and the mole percentage of any particular amino acid was observed (Davies, 1964). Furthermore, the correlation reported by Szent-Gyorgyi and Cohen (1957) was not sustained when the number of proteins was increased to that used by Davies (1964). Therefore, the correlations previously mentioned should be applied with caution until they are supported by additional data.

Havsteen (1966) carried out a statistical analysis of the correlation between the content of certain amino acids in 40 proteins and their ORD parameter  $b_o$ . A linear relationship was observed between  $-1/b_o$  and the percentage content of (Ser + Thr + Pro); thus, supporting the previous findings on the interactions between hydroxyl groups of Ser, Thr and peptide linkages which may interfere with the formation of  $\alpha$ -helices. Pro residues tend to destabilize helices by requiring a  $90^\circ$  bend of the peptide chain. The presence of a  $\beta$ -form of left-handed helices also seems to markedly influence  $b_o$ . The influence of the amino acid side chains on  $b_o$  justify their classification as helix-favoring, helix-in-different, and helix-inhibiting groups.

Goldsack (1969), using the data of 107 proteins, demonstrated that the parameter  $b_o$  can be correlated to the total content of the so-called helix-forming amino acids

(Ala + Arg + Asp + Cys + Glu+ Leu + Lys), as well as, to that of the nonhelix-forming group of amino acids (Gly + Phe.+ Pro + Ser + Thr + Trp + Tyr). On the other hand, using the  $\alpha_0$  parameter, it seemed that no particular amino acid side chain grossly controls the amount of  $\beta$ -structure in a protein. Nevertheless. further ORD characterization of the different  $\beta$ -structures (intramolecular parallel and antiparallel, as well as, intermolecular cross- $\beta$  structure) will be useful to elucidate the relationship between  $\alpha_0$  and the amino acid composition.

These preliminary efforts in predicting protein conformation relied heavily on ORD data and amino acid composition. The X-ray analysis of protein structure was at an early stage of development and the amino acid sequence was still unknown for many proteins.

Scheraga (1960) attempted to construct a three-dimensional model of ribonuclease on the basis of available data on the primary, secondary and tertiary structures. Its importance lies in the fact that it provides a basis to plan experiments for the investigation of side chain group interactions and it may also be of help in Fourier analysis of X-ray data on ribonuclease crystals.

On the basis of known sequence and structure of myoglobin, alpha- and beta-hemoglobin, Guzzo (1965)

suggested that the presence of the four critical groups; Pro, Asp, Glu and His may be a necessary condition for a section of proteins to be non-helical. Analyses of Pro replacement by Asp and Glu in mutant and variant proteins supported his theory. This was applied in an effort to predict the secondary structure of lysozyme and tobacco mosaic virus. Absence of hydrophobic bonding and weakening of interpeptide hydrogen bonding as a result of water competition in the vicinity of those polar residues might be the reason for the unfavorable effect of those residues on helix formation.

Prothero (1966) compared his results to that of Guzzo (1965) on six proteins and proposed a rule which seems to achieve a reasonable degree of fit with the known protein structures. The rule states: any region of five residues will be  $\alpha$ -helical if at least three of its residues are comprised of Ala, Val, Leu, or Glu. Alternatively, any region of seven residues will be  $\alpha$ -helical if at least three residues are comprised of Ala, Val, Leu, Glu and an additional residue includes Gln, Ile, or Thr. Using this rule, goodness of fit between 65 and 68% was obtained for  $\alpha$ -,  $\beta$ - and  $\gamma$ -hemoglobin, lysozyme and myoglobin.

Periti et al. (1967) carried out a systematic statistical analysis of the available data for horse

hemoglobin, and sperm whale myoglobin. This led them to the consideration of helical and anti-helical pairs of amino acid residues (1 2, 1 3, 1 4, .... , 1 7; 2 3, 2 4, .... , 2 8, 3 4, .... ). Histograms for the recognition of helical segments of egg white lysozyme were constructed according to their method.

Finding that it was undesirable to represent the helical segments by the usual linear way, Schiffer and Edmunson (1967) proposed a two-dimensional representation called the "helical wheel". The wheels are projections of the amino acid side chains onto a plane perpendicular to the axis of the helix. Side chains interactions and general characteristics of the helices can be better visualized. Using data from four proteins, it was observed that areas with hydrophobic residues located in the  $n \pm 3$ ,  $n$ , and  $n \pm 4$  positions have the greatest potential for helicity. Such hydrophobic arcs are absent in nonhelical wheels. Hence, the wheel representation may be of help to identify areas with helical potential. Among the six proteins chosen for testing the wheel method, the prediction of helical segments in insulin is the most accurate and closest to X-ray data later proposed by Blundell et al. (1972)

Low et al. (1968) looked for sequence identities of length varying between that of di- and hexapeptides. The theory behind their method is based on the assumption that if helix-forming sequences in which local interactions predominate can be recognized then their position along the polypeptide chain may be irrelevant. A computer program was written to locate sequence identities from available data. Although this method gives less over-prediction of helical regions compared to other methods, it results in more omissions. The authors recognized that the procedure needs to be improved by taking into account the effects of long-range interactions and that of non-helical sequences.

Kotelchuck and Scheraga (1969), from earlier energy computations, formulated a set of rules in which various single peptide units were assigned as helix-forming (Ala, Val, Leu, Ile, Met, Thr, Gln, Glu, Phe, Cys, His, and Arg) or helix-breaking (Ser, Asn, Asp, Trp, Tyr, and Lys). Their designations were quite similar to those of previous studies (Prothero, 1966; Schiffer and Edmunson, 1967). This allowed correct identification of 61% of the helices and 78% of the total residues in four proteins; myoglobin, lysozyme, tosyl- $\alpha$ -chymotrypsin and ribonuclease A. They did attempt to define conditions for helix nucleation and termination, ruling that five or more peptide

units constitute the minimum length for any helical area and that a sequence of two helix-breakers will stop the helix propagation. They agreed, however, that their model was not very accurate for smaller protein systems where long-range interactions may play an important role in helix nucleation and stabilization.

Using a combination of the Kotelchuck and Scheraga (1969) and the Schiffer and Edmunson (1967) schemes, Leberman (1971) succeeded in correctly assigning 82% of all residues in seven proteins as helical and nonhelical regions. The omission of observed regions was explained as an effect of the tertiary or even the quaternary structure, or the binding of a prosthetic group (e.g., human hemoglobin, myoglobin).

Lewis et al. (1970) based their method on the Zimm and Bragg (1959)  $\sigma$  and  $s$  parameters for helix initiation and elongation. The parameters were obtained from melting curves of random copolymers of amino acids. Helix probability profiles constructed for eleven proteins yield 68% accuracy. Correlation between the propensity of a residue to be a helical former in the denatured protein and its occurrence in a helical area in the corresponding native protein was suggested. The correlation supports the hypothesis that residues in the  $\alpha_R$  conformation may be involved in the

nucleation of protein folding. A comparison was made of the conformational structure of denatured cytochrome c from various species (Lewis and Scheraga, 1971). They showed that, even though there were amino acid replacements in cytochrome c throughout evolution, there remains a conservation of the nature of the helix-forming power at each position in the chain.

Despite the progress in protein prediction, there was still a lack of information on  $\beta$ -sheet structure. This was because the earliest proteins elucidated by X-ray diffraction were hemoglobin and myoglobin which are devoid of  $\beta$ -sheet conformation. Hence, most of the researchers at that time often chose to ignore the  $\beta$ -sheet conformation in their calculations. Furthermore, it was difficult to obtain  $\beta$ -sheet in solution for spectrophotometric analysis. However, as more protein structures were elucidated by X-ray diffraction, it became increasingly apparent that the presence of  $\beta$ -sheet was as important as that of  $\alpha$ -helix. Interpretation of an electron density map at  $2\text{\AA}$  resolution indicates that the predominant conformation in concanavalin A is formed by two antiparallel  $\beta$ -sheets. Residues not included in the  $\beta$  structures are arranged in regions of random coil. One of the pleated sheets contributes extensively to the interactions among the monomers to form

both dimers and tetramers (Edelman *et al.*, 1972). X-ray analysis of tosyl- $\alpha$ -chymotrypsin revealed only a small fraction of  $\alpha$ -helix but several adjacent, anti-parallel pleated sheets stabilized by hydrogen bonds (Birktoft and Blow, 1972).

Ptitsyn and Finkelshtein (1970) classified the various amino acid residues as helical or antihelical, and tentatively as  $\beta$ -breaker or  $\beta$ -former according to their tendency of stabilizing the various  $\beta$ -structures. Nonpolar amino acids (Leu, Ala, Met) except Cys and Tyr, have a greater tendency to enter  $\alpha$ -helical zones than the polar ones. The amino acid residues with compact hydrocarbon sidegroups are assigned with positive  $\beta$ -potential whereas those with charged side groups and Pro are considered as  $\beta$ -breakers. Although their classification takes into account only the interactions of the side groups with the main chain backbone and not with each other, they obtained good agreement between their predictive method and X-ray data ( $Q\alpha = 79\%$  and  $Q\beta = 79\%$ ) for nine proteins. This supports the suggestion that instead of competing with local interactions and dictating the secondary structure, distant interactions work in harmony with the local ones and help to stabilize the conformation which mainly results from local interactions.

Nagano (1973) developed a computer method to predict helices, loops and  $\beta$ -structures from the primary structure. The basis of his method lies on the assumption that short-range interactions are due to amino acid residue pairs separated by  $m$  residues ( $m = 0, 1, 2, 5, \dots, 6$ ). Four prediction functions (helix, loop, random coil, and  $\beta$ -structure) were estimated by a linear combination of statistical quantities of different  $m$  values as a measure of the statistical constraint. The coefficients used in the combination were determined to make the number of correct assignments as large as possible. Very successful results were obtained (85.3% for helix prediction, 64.4% for loop, and 90.1% for  $\beta$ -structures).

On the basis of the influence of nearest neighbouring pairs of amino acids ( $n-1$ ) and ( $n+1$ ) on the conformation of amino acid ( $n$ ), Kabat and Wu (1973a, 1973b) designed, then later revised their 20x20 table of frequency of occurrences of various conformations tabulating three values:  $\alpha$ -helix,  $\beta$ -sheet and neither. The frequencies were then used to locate helix-breaking positions in various proteins. Due to limited data on proteins with extensive  $\beta$ -sheet fragments, recognition of the  $\beta$ -sheet breaking regions was made on papain only. The regions between two  $\beta$ -sheet breaking residues would be permissively  $\beta$ -sheet regions.

Application of the method on concanavalin A, which has many  $\beta$ -sheet regions, allows location of 10 out of the 13  $\beta$ -sheet areas. Although no guidelines were given to prevent overprediction of  $\alpha$ - and  $\beta$ -regions, the conjunction of this method with the helical wheel method or other schemes may lead to a higher degree of accuracy (Chou and Fasman, 1978b).

Lim (1974b) proposed another method that takes into account both quantitative evaluation of energy and qualitative stereochemical considerations. Based on the most characteristic features of globular proteins (compactness of form; presence of a tightly packed hydrophobic core; a polar shell) and the role of the different types of long-range interactions, different requirements were set up to find the most energetically advantageous conformations for the protein chain. Lim (1974a) also elaborated on the structural role of the different hydrophilic side groups in the stabilization of the proteins tertiary structure.  $\alpha$ -Helix and  $\beta$ -sheet are classified into various types according to their specific orientation relative to the globule surface. Regions which do not belong to helix or  $\beta$ -sheet type are classified as irregular regions. Through the use of helical and antihelical pairs and triplets at positions [1-2], [1-3], [1-4], [1-5], [1-2-5] and [1-4-5], Lim (1974b) developed a predictive

algorithm for helices. The search of  $\beta$ -structural areas is only done on fragments of the chain not attributed to  $\alpha$ -helical regions, because it is energetically more advantageous to have one long helix than several shorter  $\beta$ -regions. The accuracy of the predictive method applied to 25 proteins of known structure was 81% for  $\alpha$ -helix and 85% for  $\beta$ -sheet. The conformation of 25 unknown proteins was also tested with the method.

Chou et al. (1972) through CD conformational studies of poly(N(3-hydroxypropyl)-L-glutamine) and of copolymers of hydroxypropyl-L-glutamine with L-leucine reached the following conclusions. The helical content of the homopolymer and copolymers was found to increase with: a) decreasing temperature, b) increasing methanol concentration, and c) increasing molar ratios of Leu in the copolymers. A survey of the conformation of eleven proteins reveals that of all the amino acids occurring in the inner helical regions Leu occurs most frequently. This suggests that Leu may be the strongest helical-forming amino acid residue in polypeptides, as well as, in proteins (Chou and Fasman, 1973). For the first time, the helix and  $\beta$ -sheet conformational potential of all 20 amino acids were established in their hierarchical order. Following this study more complete investigation (Chou and Fasman, 1974a)

on the conformational parameters  $P_\alpha$ ,  $P_\beta$  and  $P_t$  of each amino acid residue in 15 proteins served as the basis for a new predictive method (Chou and Fasman, 1974b). The major advantages of their method are its simplicity and its accuracy. Without recourse to complicated computer analysis, one can expediently locate the helix,  $\beta$ -sheet and coil regions of proteins with 70-80% accuracy (Chou and Fasman, 1978a, 1978b) by simply averaging the  $P_\alpha$ ,  $P_\beta$  and  $P_t$  values of the residues in the segment under consideration. Another way of locating the various conformations is to assign each residue as a former, an indifferent, or a breaker based on its helix and  $\beta$ -sheet potential. The  $\beta$ -turn conformational parameter  $P_t$  was also computed, enabling the prediction of chain reversals and tertiary folding in proteins. The simplicity and effectiveness of the method are the main reasons for its wide use (Chou and Fasman, 1978b). Indeed, according to Argos *et al.* (1976), the complexity of some proposed algorithms is such that their computerization has not been developed. This problem may be the reason why these methods have limited popularity compared to the method of Chou and Fasman or other popular methods (Lim, 1974b; Kabat and Wu, 1973a).

## MATERIALS AND METHODS

### The Predictive Method of Chou and Fasman

Using the criteria of dihedral angles and hydrogen bond formation, Chou and Fasman (1978a, 1978b) first determined the different conformational states in 29 proteins. The frequency of all 20 amino acids in each conformation was then calculated by dividing their occurrence in the conformation under consideration by their total occurrence in the 29 proteins. The percentages of residues in the 29 proteins found in the helical, sheet, coil, and  $\beta$ -turn regions are respectively represented by their average fractions  $\langle f_{\alpha} \rangle = 0.38$ ,  $\langle f_{\beta} \rangle = 0.20$ ,  $\langle f_c \rangle = 0.42$ , and  $\langle f_t \rangle = 0.20$ . Each residue is assigned to the  $\alpha$ ,  $\beta$ , or coil state so that  $\langle f_{\alpha} \rangle + \langle f_{\beta} \rangle + \langle f_c \rangle = 1.00$ . The  $\beta$ -turn residue assignment is made independently. Each amino acid is then assigned as former, indifferent, or breaker according to its conformational parameters  $P_{\alpha}$ ,  $P_{\beta}$  which are obtained by dividing the frequency of its occurrence in a conformation by the respective average frequency (e.g.,  $P_{\alpha} = f_{\alpha}/\langle f_{\alpha} \rangle$ ,  $P_{\beta} = f_{\beta}/\langle f_{\beta} \rangle$ ,  $P_t = f_t/\langle f_t \rangle$ ). The conformational parameters  $P_{\alpha}$  and  $P_{\beta}$  for the 20 amino acids are listed in Table 1 in hierarchical order along with their assignment as former, indifferent, or breaker.

<sup>b</sup>Helical assignments: H <sub>$\alpha$</sub> , strong  $\alpha$ -former; h <sub>$\alpha$</sub> ,  $\alpha$ -former; I <sub>$\alpha$</sub> , weak  $\alpha$ -former; i <sub>$\alpha$</sub> ,  $\alpha$ -indifferent; b <sub>$\alpha$</sub> ,  $\alpha$ -breaker; B <sub>$\alpha$</sub> , strong  $\alpha$ -breaker.

<sup>c</sup> $\beta$ -sheet assignments: H <sub>$\beta$</sub> , strong  $\beta$ -former; h <sub>$\beta$</sub> ,  $\beta$ -former; I <sub>$\beta$</sub> , weak  $\beta$ -former; i <sub>$\beta$</sub> ,  $\beta$ -indifferent; b <sub>$\beta$</sub> ,  $\beta$ -breaker; B <sub>$\beta$</sub> , strong  $\beta$ -breaker.

The symbols H and h may be thought of as strong and moderate hydrogen bonding, respectively with the subscripts  $\alpha$ ,  $\beta$  denoting helical or  $\beta$ -sheet conformation. Each amino acid residue can also be characterized by its boundary conformational parameters ( $P_{\alpha N}$ ,  $P_{\alpha C}$ ,  $P_{n\alpha N}$ ,  $P_{n\alpha C}$ ,  $P_{\beta N}$ ,  $P_{\beta C}$ ,  $P_{n\beta N}$ ,  $P_{n\beta C}$ ) as listed in Tables 2 and 3.

When all the residues in a protein sequence have been classified, one can use the empirical rules discussed below to predict its secondary structure (Chou and Fasman, 1978a, 1978b).

#### A. Search for Helical Regions

The search was carried out according to the method of Chou and Fasman (1978a, 1978b), which can be described as follows:

1. Helix nucleation. A cluster of four helical residues ( $h_\alpha$  or  $H_\alpha$ ) out of six residues along the protein sequence will initiate a helix. A weak helical residue ( $I_\alpha$ ) counts as  $1/2 h_\alpha$  (i.e., three  $h_\alpha$  and two  $I_\alpha$  residues out of six may also cause helix nucleation).

2. Helix propagation. Extend the helical segment in both directions as long as adjacent tetrapeptides are not helix breakers (see below). When overlapping segments all satisfy the helix nucleation rule, they are linked together into a long helix. The nucleated helix of six

<sup>a</sup> $\beta$ -sheet boundary residues include the three residues on both ends of a  $\beta$  regions and the three non- $\beta$  residues adjacent to the  $\beta$ -sheet end residues, a total of six residues on each end of the  $\beta$ -sheet region.  $P_{\beta N}$  = normalized frequency of residues in the N-terminal  $\beta$  region;  $P_{\beta C}$  = normalized frequency of residues in the C-terminal region;  $P_{n\beta N}$  = normalized frequency of residues in the N-terminal non- $\beta$  region;  $P_{n\beta C}$  = normalized frequency of residues in the C-terminal non- $\beta$  region.

residues should contain at least two thirds h's, while the propagated helix should be comprised of one half or more helix formers. It is important to utilize the rule that a weak helical former ( $I_\alpha$ ) counts as  $1/2h$  in the segment. Both the helix nucleation segments and the entire helix should have fewer than one third helix breakers ( $b_\alpha$  or  $B_\alpha$ ).

3. Helix Termination. The propagated helix is terminated on both sides by the following tetrapeptide breakers with  $\langle P_\alpha \rangle < 1.00$ :  $b_4$ ,  $b_3i$ ,  $b_3h$ ,  $b_2i_2$ ,  $b_2ih$ ,  $b_2h_2$ ,  $bi_3$ ,  $bi_2h$ ,  $bih_2$ , and  $i_4$ . Some tetrapeptides, such as  $hi_3$  and  $h_2i_2$ , may have  $\langle P_\alpha \rangle < 1.00$  but are not listed as breakers since they allow helix propagation to continue. Once the helix is defined, some of the residues (h or i) in the above tetrapeptide breakers may be incorporated at the helical ends. For example, the hi of the breaker bbhi may be added to the predicted helix only at the N-terminal side, but the bb may not be included at either the N- or C-terminal helix. The notations i, b, h in the tetrapeptide breakers also include I, B, and H, respectively. Adjacent  $\beta$ -regions that have higher  $\beta$ - than  $\alpha$ -potential (i.e.,  $\langle P_\beta \rangle > \langle P_\alpha \rangle$ ) can also terminate helix propagation.

4. Proline as Helix Breaker. Pro cannot occur in the inner helix or at the C-terminal helical end but

can occupy the first turn (i.e., third residues) in the N-terminal helix.

5. Helix boundaries. Pro, Asp<sup>(-)</sup>, Glu<sup>(-)</sup> are incorporated into the N-terminal helical end, while His<sup>(+)</sup>, Lys<sup>(+)</sup> and Arg<sup>(+)</sup> are incorporated into the C-terminal helical end. I<sub>α</sub> assignments are given to Pro and Asp (near the N-terminal helix), as well as, Arg (near the C-terminal helix) if necessary to satisfy condition A.1. Glu is still assigned as H at the N-terminal helix while His and Lys are still h and I, respectively, at the C-terminal helix.

Rule 1. Any segment of six residues or longer in a native protein with  $\langle P_{\bar{\alpha}} \rangle \geq 1.03$  and  $\langle P_{\alpha} \rangle > \langle P_{\beta} \rangle$ , and satisfying conditions A.1 through A.5, is predicted as helical.

### B. Search for β-sheet Regions

The search for β-pleated sheet regions was carried out by applying the set of rules outlined by Chou and Fasman (1978a, 1978b) as follows:

1. β-sheet Nucleation. A sequence of three β-formers ( $h_{\beta}$  or  $H_{\beta}$ ) or a cluster of three β-formers out of four or five residues along the protein sequence will initiate a β-sheet

2.  $\beta$ -Sheet Propagation. Extend the  $\beta$ -sheet segment in both directions as long as adjacent tetrapeptides are not  $\beta$ -sheet breakers (see below).  $\beta$ -Sheet formation is unfavorable if the entire segment contains one third or more  $\beta$ -sheet breakers ( $b_\beta$  or  $B_\beta$ ) or less than one half  $\beta$ -sheet formers.

3.  $\beta$ -Sheet Termination. Apply conditions A.3 outlined for helix termination by utilizing the same tetrapeptide breakers with  $\langle P_\beta \rangle < 1$  for stopping  $\beta$ -sheet propagation. Adjacent  $\alpha$ -regions that have higher  $\alpha$ - than  $\beta$ -potential (i.e.,  $\langle P_\alpha \rangle > \langle P_\beta \rangle$ ) can also terminate  $\beta$ -propagation.

4. Strong  $\beta$ -Sheet Breakers. Glu and Pro are the strongest  $\beta$ -sheet breakers and should not be incorporated into  $\beta$ -sheets unless they occur in tetrapeptides with  $\langle P_\alpha \rangle < \langle P_\beta \rangle > 1$ .

5.  $\beta$ -Sheet Boundaries. Charged residues and Pro are unfavorable to  $\beta$ -sheet formation and should not be incorporated into  $\beta$ -sheets unless they occur in tetrapeptides with  $\langle P_\alpha \rangle < \langle P_\beta \rangle > 1$ .

Rule 2. Any segment of three residues or longer in a native protein with  $\langle P_\beta \rangle > 1.05$  and  $\langle P_\beta \rangle > \langle P_\alpha \rangle$ , and satisfying conditions B.1 through B.5 is predicted as  $\beta$ -sheet.

### C. Overlapping $\alpha$ - and $\beta$ -Regions

In most cases, utilization of the set of rules described above was adequate to locate the secondary structures of proteins. However there were regions in proteins containing both  $\alpha$ - and  $\beta$  residues where ambiguities arose, so that additional measures were required to resolve the dilemma. Chou and Fasman (1978a, 1978b) followed the procedure described below to determine whether the overlapping region was predominately  $\alpha$  or  $\beta$ .

1. Calculate the  $\langle P_\alpha \rangle$  and  $\langle P_\beta \rangle$  for the overlapping region; if  $\langle P_\alpha \rangle > \langle P_\beta \rangle$ , the region is helical, if  $\langle P_\beta \rangle > \langle P_\alpha \rangle$ , it is  $\beta$ -sheet. The  $\alpha$ - and  $\beta$ -potential of the overlapping residues can also be compared by grouping the  $\alpha$ - and  $\beta$ -assignments. Thus a region of six residues with  $(H_2h_2ib)_\alpha$  and  $(Hh_3iB)_\beta$  assignments should be helical, since there are two strong  $\alpha$ -formers ( $H_\alpha$ ) and one  $\alpha$ -breaker ( $b_\alpha$ ) compared to one strong  $\beta$ -former ( $H_\beta$ ) and one strong  $\beta$ -breaker ( $H_\beta$ ).

2. Use Tables 2 and 3 on the frequency of helix and  $\alpha$ -sheet boundaries to delineate whether the region is  $\alpha$  or  $\beta$ .

3. Since helices are longer than  $\beta$ -sheets, a long segment containing both  $\alpha$ - and  $\beta$ -potential is predicted as helical if  $\langle P_\alpha \rangle > \langle P_\beta \rangle$ , even though there may be a smaller fragment, that is, five residues within the segment whose  $\langle P_\beta \rangle > \langle P_\alpha \rangle$ . Hence, in the example given above for carboxypeptidase, 173-186 is predicted as one long helix instead of a short helix 173-178 and a  $\beta$ -region 179-183.

4. Regions with both  $\alpha$ - and  $\beta$ -potential adjacent to a predicted  $\beta$ -turn (see below) are predicted to be  $\beta$ -sheet as long as there are at least three  $\beta$ -formers on each side of the  $\beta$ -turn; that is, the minimum  $\beta$  length is reduced from five to three, with the middle two residues of the  $\beta$ -turn counting as coil residues. For example, regions 105-110 and 115-124 in ribonuclease have both  $\alpha$ - and  $\beta$ -potential. However, the high probability of a  $\beta$ -turn at 113-115 easily allows the assignment of 105-110 [ $(H_3^h I b)_\beta > (H h_2 I_2 i)_\alpha$  and  $\langle P_\beta \rangle = 1.31 > \langle P_\alpha \rangle = 1.10$ ] and 115-124 [ $(H_3^h I_2 I b_3)_\beta > (H h_5 i_2 b B)_\alpha$  and  $\langle P_\beta \rangle = 1.13 > \langle P_\alpha \rangle = 1.02$ ] as  $\beta$ -sheets rather than  $\alpha$ -helices.

Rule 3. Any segment containing overlapping  $\alpha$ - and  $\beta$ -residues is resolved through conformational boundary analysis (C.2) with  $\langle P_\alpha \rangle > \langle P_\beta \rangle$  for the predicted

$\alpha$ -region (C.1).  $\beta$ -Formers may be incorporated into a long helix if they are not helical tetrapeptide breakers (C.3). Helix propagation may be terminated by  $\alpha$  residues if these same residues favor the formation of antiparallel  $\beta$ -sheets.

In summary, according to Chou and Fasman (1978b), there are only three basic rules for predicting protein secondary structure. While the  $\alpha$  and  $\beta$  search conditions elaborated above seem to be quite extensive they are given so that incorrect predictions will be minimized.

#### D. Search for $\beta$ -Turns

At present, 408  $\beta$ -turns have been elucidated from 29 proteins and the frequency of occurrence for the 20 amino acids in those 408 turns, at positions  $i$  to  $i+3$ , as well as their  $P_t$  values ( $P_t = f_t / \langle f_t \rangle$ ) are given in Table 4. (Chou and Fasman, 1977, 1979). The probability of  $\beta$ -turn occurrence at residue  $i$  is computed from  $p_t = (f_i) (f_{i+1}) (f_{i+2}) (f_{i+3})$  with the aid of Table 4. The average probability of  $\beta$ -turn occurrence is  $\langle p_t \rangle = 0.55 \times 10^{-4}$ . Two cut-off values were selected:  $p_t = 1.0 \times 10^{-4}$  (a value approximately double that of the average) and  $p_t = 0.75 \times 10^{-4}$  (a value that is 1 1/2 times that of the average). According to Chou and Fasman (1979),

Table 4. Frequency Hierarchies of Amino Acids in the  $\beta$ -Turns of 29 Proteins.<sup>a</sup>

	i	i + 1	i + 2	i + 3	P <sub>t</sub>	P <sub>t2</sub>

Table 4. Frequency Hierarchies of Amino Acids in the  $\beta$ -Turns of 29 Proteins.<sup>a</sup>  
(cont'd)

---

<sup>a</sup> $a_i$ ,  $i+1$ ,  $i+2$ , and  $i+3$  represent the frequencies of the first, second, third, and fourth residues, respectively, in a reverse  $\beta$ -turn.  $P_t$  is the conformational potential of a residue in a  $\beta$ -turn based on all four positions of a reverse turn.  $P_{t2}$  is the conformational potential of a residue in a  $\beta$ -turn based on the second and third positions of a reverse turn. This frequency table was based on 408  $\beta$ -turns in 29 proteins.

the lower cut-off value predicts more bend residues correctly while the higher cut-off value predicts more non-bend residues correctly. However it appears that the predictive accuracy is similar for the two values. The cut-off value of  $0.75 \times 10^{-4}$  has been used by Chou and Fasman (1978b, 1979) in their search for  $\beta$ -turns in 29 proteins.

Rule 4. Tetrapeptides with  $p_t > 0.75 \times 10^{-4}$  as well as  $\langle P_t \rangle > 1.00$  and  $\langle P_\alpha \rangle < \langle P_t \rangle > \langle P_\beta \rangle$  are selected as probable bends. Adjacent probable bends (i.e., 11-14, 12-15, 13-16) are compared pairwise, and the tetrapeptide with the highest  $p_t$  value is predicted as a  $\beta$ -turn.

#### E. Evaluation of the Predictive Accuracy

To evaluate the success of any predictive scheme it is necessary to compare the predicted conformational state for each residue of a protein with the observed assignment based on X-ray diffraction. The percentage of residues  $n_k$  predicted in the conformational state  $k$  is given by:

$$\%k = \frac{100 (n_k - n_x)}{n_k} \quad (1)$$

where  $k$  represents the  $\alpha$ -,  $\beta$ - or coil regions in the native protein structure as determined by x-ray crystallography and  $n_x$  is the number of incorrectly predicted residues in the state  $k$ .

The percentage of overprediction is given by the criteria:

$$\%_{nk} = \frac{100(n_{nk} - n_{nx})}{n_{nk}} \quad (2)$$

where  $\%_{nk}$  represents the percentage of correctly predicted residues not in the conformational state  $k$ ,  $n_{nk} = N - n_k$ , and  $n_{nx}$  is the number of  $k$  residues overpredicted. Hence the quality of prediction for a given type of conformational  $k$  can be expressed as the mean of  $\%_k$  (eq. 1) and  $\%_{nk}$  (eq. 2).

$$Q_k = \frac{\%_k + \%_{nk}}{2}$$

A value of 100% for  $\%_k$ ,  $\%_{nk}$ , and  $Q_k$  indicates total agreement between observation and prediction, while 0% indicates total disagreement (Chou and Fasman, 1978a, 1978b).

Recently, Matthews (1975) introduced a correlation coefficient that indicates how much better a given prediction is than a random one.

$$C_{\alpha} = \frac{[(n_{\alpha} - \alpha_m)/N] - [(n_{\alpha} - \alpha_m + \alpha_o)/N] (n_{\alpha}/N)}{\{[(n_{\alpha} - \alpha_m + \alpha_o)/N] (n_{\alpha}/N) (1 - n_{\alpha}/N) [1 - (n_{\alpha} - \alpha_m + \alpha_o)/N]\}^{1/2}} \quad (3)$$

The correlation coefficient for  $\beta$ -sheet and  $\beta$ -turn may be obtained by substituting  $\beta$  and  $t$ , respectively, for  $\alpha$  in equation 3. A correlation of  $C=1$  indicates perfect agreement between prediction and observation,  $C=0$  indicates that a prediction is no better than random, and  $C=-1$  indicates total disagreement or 0% accuracy. If  $C_{\alpha} \geq 0.6$ , the predicted structure is near that of the observed structure with no helical regions generally missed but with N- and C-terminal points off by a few residues. If  $C_{\alpha} \geq 0.4$ , generally one or two helical regions might be missed or overpredicted, however the prediction would still be quite useful. Similar statements can be made regarding sheet and turn (Argos *et al.*, 1976).

#### Amino Acid Sequence of Proteins

The amino acid sequence of the various proteins used for testing our program comes from the Atlas of protein sequence and structure (Dayhoff, 1972, 1973, 1976, 1978).

## Programming

The program was written in Fortran language and tested at the UBC computing centre. The amino acid sequence of each protein was converted into a sequence of integers. The 20 amino acid residues were sorted alphabetically and each of them assigned a fixed number between 1 and 20. For instance: 1 → Ala, 2 → Arg, ..., 19 → Tyr, and 20 → Val. Hence in order to use the program, one must convert the protein sequence into a corresponding series of integers. All the necessary details concerning the use of the program are given in the appendix.

## RESULTS AND DISCUSSION

### Programming of the method

Following the rules outlined by Chou and Fasman (1978a, 1978b) four different programs were written to predict  $\alpha$ -helix,  $\beta$ -sheet, and  $\beta$ -turn, and to solve the overlapping areas between  $\alpha$ -helix and  $\beta$ -sheet.

Each program consisted of the main program and several subroutines. In every case, the purpose of the main program was to read in the sequence of the protein under consideration, and then to assign to each amino acid residue the corresponding values of the conformational parameters ( $P_\alpha$ ,  $P_\beta$ ,  $P_t$ ) and the boundary conformational parameters ( $P_{\alpha N}$ ,  $P_{\alpha C}$ ,  $P_{n\alpha N}$ ,  $P_{n\alpha C}$ ,  $P_{\beta N}$ ,  $P_{\beta C}$ ,  $P_{n\beta N}$ ,  $P_{n\beta C}$ ). The subroutines were then called on to search for  $\alpha$ -helix,  $\beta$ -sheet, and  $\beta$ -turn regions, and to solve overlapping areas.

#### A. Scheme for the search of $\alpha$ -helix and $\beta$ -sheet regions

In the case of  $\alpha$ -helix and  $\beta$ -sheet prediction, once the whole sequence has been recorded, the first subroutine is called to detect the areas in the sequence with helix or  $\beta$ -sheet potential according to rule 1 or rule 2, respectively. Then within the limits of those potential areas, the rules for nucleation, propagation and termination are

applied to locate the different sections more accurately. Those rules were elaborated in the second and third subroutines. The various important factors such as strong helix or  $\beta$ -sheet breakers, and helix or  $\beta$ -sheet boundaries were also taken into account.

#### Main Program

- Read protein sequence
- Assign  $P_\alpha$ ,  $P_\beta$  to each residue

#### Subroutine 1

- Rule 1 / Rule 2
- Search for potential helix or  $\beta$ -sheet areas

#### Subroutine 2

- Helix/ $\beta$ -sheet nucleation within those potential areas

#### Subroutine 3

- Helix/ $\beta$ -sheet propagation and termination

Print out helix/ $\beta$ -sheet sections

## B. Scheme for the $\beta$ -Turn Search

For the  $\beta$ -turn search, only one subroutine was needed to locate the different turns according to rule 3 and to compare the adjacent predicted turns so as to consider only the one with the highest probability of occurrence ( $p_t$ ).

### Main Program

- Read in sequence
- Assignment of  $P_t$  and frequency of occurrence

### Subroutine

- Rule 3
- Then comparison of adjacent turns

Print out position of turns.

## C. Scheme for Solving Overlapping $\alpha$ - and $\beta$ -Areas

In this case, the purpose of the main program was to record the whole sequence of each protein as well as the consecutive pairs of overlapping areas which were formatted

in the following manner: H1 S1 H2 S2 H3 S3 H4 S4 ...

H1 - H2 : boundary values of the helical fragment

S1 - S2 : boundary values of the  $\beta$ -sheet fragment

The first subroutine carried out the comparison of the average  $P_\alpha$  and  $P_\beta$  of each fragment itself and that of the overlapping area. In case the  $\beta$ -sheet was contained within the  $\alpha$ -helix, the overlapping area was the  $\beta$ -sheet itself. The results obtained at this step could already suggest whether the entire fragment ( $\beta$ -sheet/ $\alpha$ -helix) and the overlapping area had a higher propensity to exist in one of the conformations than the other (i.e., in helical state if  $\langle P_\alpha \rangle > \langle P_\beta \rangle$ ; or in  $\beta$ -sheet conformation if  $\langle P_\alpha \rangle < \langle P_\beta \rangle$ ).

In the second subroutine, instead of assigning to each amino acid residue in the fragments under consideration the alphabetic representation of  $H_\alpha$ ,  $H_\beta$ ,  $I_\alpha$ ,  $I_\beta$ ,  $B_\alpha$ ,  $B_\beta$ , the alphabetic representations were converted to numerical ones (i.e.,  $H_\alpha, H_\beta \rightarrow 2.00$ ;  $h_\alpha, h_\beta \rightarrow 1.00$ ;  $I_\alpha, I_\beta \rightarrow 0.50$ ;  $i_\alpha, i_\beta \rightarrow 0.25$ ;  $b_\alpha, b_\beta \rightarrow -0.50$ ;  $B_\alpha, B_\beta \rightarrow -1.00$ ). Hence, instead of comparing sets of characters ( $H_u, h_v, I_x, i_y, b_z, B_w$ ) as did Chou and Fasman (1978a, 1978b), numerical values were used to represent the conformational potential of the regions under consideration. This "character analysis" was performed

on the  $\alpha$ -helix and  $\beta$ -sheet fragments, as well as, on the overlapping area.

The "boundary analysis" was carried out in the third subroutine. This consisted of summing up the boundary conformational parameters of the three residues belonging to the fragment and those of the three residues adjacent to the fragment ends, using the values from Tables 2 and 3.

$$\text{e.g. } P_{\alpha N} (H1) + P_{\alpha N} (H1+1) + P_{\alpha N} (H1+2)$$

$$P_{\alpha C} (H2) + P_{\alpha C} (H2-1) + P_{\alpha C} (H2-2)$$

$$P_{n\alpha N} (H1-1) + P_{n\alpha N} (H1-2) + P_{n\alpha N} (H1-3)$$

$$P_{n\alpha C} (H2+1) + P_{n\alpha C} (H2+2) + P_{n\alpha C} (H2+3)$$

Similar procedures were applied to the  $\beta$ -sheet fragment. The "boundary analysis" thus took into consideration the influence of the neighbouring residues at the boundaries. Hence, if a fragment has very high potential for the helical state, the neighbouring residues at the boundaries may participate in stabilization of the helix if they are favorable to its presence.

## Main Program

- Read in sequence
- Read in different overlapping areas
- Assignment of  $P_\alpha$ ,  $P_\beta$

## Subroutine 1

- Comparison of  $\langle P_\alpha \rangle$ ,  $\langle P_\beta \rangle$
- In each fragment itself
- In the overlapping area

## Subroutine 2

- Grouping of  $\alpha$ - and  $\beta$ -assignments ( $H_\alpha$ ,  $H_\beta$ , ...,  $B_\alpha$ ,  $B_\beta$ )
- In each fragment itself
- In the overlapping area

## Subroutine 3

- Boundary analysis ( $P_{\alpha N}$ ,  $P_{\alpha C}$ , ...,  $P_{n\beta N}$ ,  $P_{n\beta C}$ )
- For each fragment itself

### Efficiency of the $\alpha$ -helix prediction

When the rules established by Chou and Fasman (1978a, 1978b) were strictly followed, several areas were missed in the present prediction and the boundaries of the predicted regions were quite different from those of Chou and Fasman or from X-ray analysis (Table 5, p. 189)

However, when the results obtained for the various proteins were analyzed, the difference between the boundary values of the present study and those of Chou and Fasman or from X-ray analysis could be reduced by taking into account factors such as: a) the boundary conformational parameters ( $P_{\alpha N}$ ,  $P_{\alpha C}$ ,  $P_{n\alpha N}$ ,  $P_{n\alpha C}$ ) and b) the  $\beta$ -turn or  $\beta$ -sheet potential in the vicinity of the helical boundaries. In other words, after going through the entire procedure of helical search, if a region delineated by two values J1 and J2 (J1: N-terminal of the predicted region and J2: C-terminal of the same region) was predicted as  $\alpha$ -helix then the values  $P_{\alpha N}$  of J1 and  $P_{\alpha C}$  of J2 would be compared to those of their neighbouring residues so that the new boundaries  $J1 \pm n$ ,  $J2 \pm n'$  ( $n$  and  $n'$ : integers) would have the most favorable  $P_{\alpha N}$  and  $P_{\alpha C}$  for helix stabilization. The parameters  $P_{n\alpha N}$  and  $P_{n\alpha C}$  of the nonhelical residues adjacent to the helical bound-

aries were also important in this "move of the boundaries".

When considering the possibility of  $\beta$ -turn presence at the helix boundaries or the overlapping of the end residues with a fragment possessing high  $\beta$ -sheet potential, it may also be necessary to move J1 and J2 to new positions which are dictated by  $P_{\alpha N}$ ,  $P_{\alpha C}$  respectively (cf. subroutines MOJ1, MOJ2, RMJ1, and RMJ2 for  $\alpha$ -helix prediction).

The following are some examples of  $\alpha$ -helix boundaries adjustment to illustrate the concept of "move of boundaries".

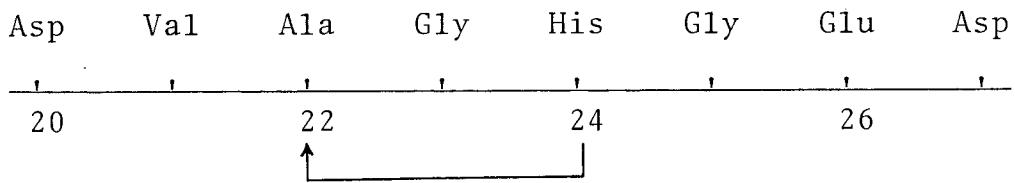

(1) J1 = J1 - 2

a.  $\alpha$ -Hemoglobin: 8-17

Ala	Asp	Lys	Thr	Asn	Val
	6		8		10

Asp (6) has the second highest  $P_{\alpha N}$  value. As there is neither  $\beta$ -turn nor  $\beta$ -sheet potential in this region, by moving back to Asp (6), the helical area 8-17 gains 1  $h_{\alpha}$ , Lys (7), and 1  $I_{\alpha}$ , Asp (6). There is no need to move further to the N-terminal because the program has already predicted the area 1-8 as helical.

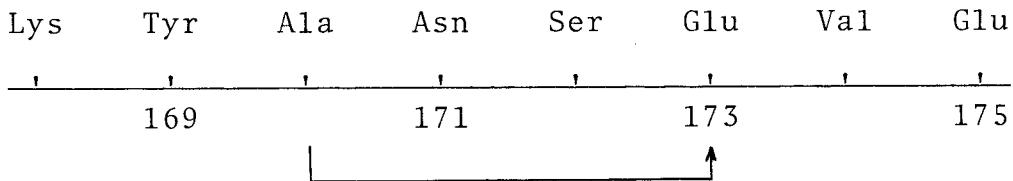

b. Myoglobin: 24-36

Ala (22) has a higher  $P_{\alpha N}$  value than His (24). The incorporation of a breaker, Gly (23) is balanced by that of Ala, a strong helix former. This boundary adjustment helps to link the helical regions 13-22 and 24-36.

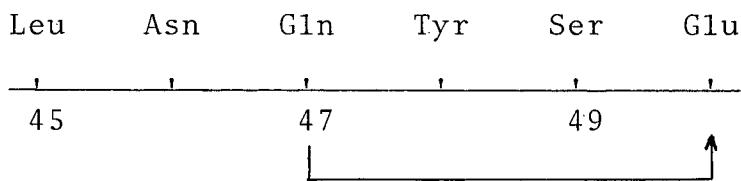

(2)  $J_1 = J_1 + 3$

a. Carboxypeptidase: 170-182

The boundary adjustment is justified by the strong potential  $\beta$ -turn of the tetrapeptide 169-172 and by the very high  $P_{\alpha N}$  of Glu (173). Furthermore, Asn (171) and Ser (172) have the highest  $P_{n\alpha N}$  values, hence their presence is favorable to Glu (173) if this residue is chosen as the N-boundary.

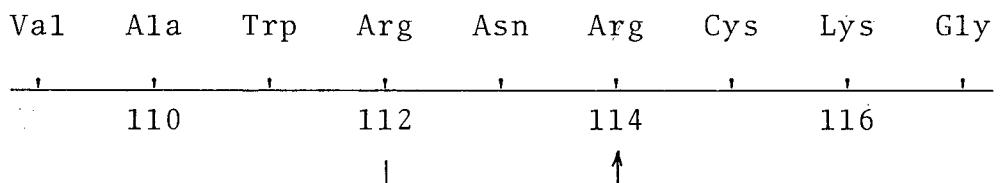

b. Papain: 47-60

By moving the N-boundary to position 50 (Glu), advantage is taken of the good  $P_{\alpha N}$  of Glu and at the same time the helix breaker Tyr (48) and the helix indifferent Ser (49) are removed. Ser (48) has high propensity to be found at the nonhelical N-boundary.

(3)  $J_2 = J_2 + 2$

a. Lysozyme: 105-112

The region 105-112 has enough helix formers to balance the incorporation of an extra helix breaker, Asn (113). And Arg (114) has good  $P_{\alpha C}$  value which justifies its consideration as the new C-boundary. The residues Cys (115), Lys (116) and Gly (117) are favorable to the new position of  $J_2$ .

b. Carboxypeptidase: 297-303

Met	Glu	His	Thr	Val	Asn	Asn
301		303		305		307

↑

Despite the lower  $P_{\alpha C}$  of Val (305) compared to that of His (303), the move of J2 to J2+2 allows the addition of an extra  $i_{\alpha}$  (Thr) and  $H_{\alpha}$  (Val) to the region. In fact  $P_{\alpha C}$  of Val is higher than the average value and the two residues Asn (306, 307) are listed second for their  $P_{n\alpha C}$ .

(4) J2 = J2 - 3:

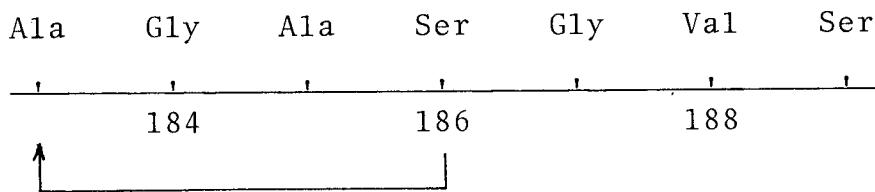

a. Papain: 47-60

Asp	Cys	Asp	Arg	Arg	Ser	Tyr	Gly

↑

The tetrapeptide 57-60 has  $\beta$ -turn potential and although  $P_{\alpha C}$  of Asp (57) is lower than that of Cys (56), the helical conformational parameter of Asp ( $I_{\alpha}$ ) is higher than that of Cys ( $i_{\alpha}$ ). The residues Arg (58, 59) exhibit good  $P_{n\alpha C}$ .

b.  $\alpha$ -Chymotrypsin: 172-186

The tetrapeptide 185-188 exhibits  $\beta$ -turn potential and by moving J2 to J2-3, there are two advantages. First, the breaker, Gly (184), is avoided and second, a new boundary with relatively good  $P_{\alpha C}$ , Ala (183), is obtained.

The boundary adjustment procedures were elaborated in the subroutines MOJ1, RMJ1 and MOJ2, RMJ2 for the residues J1 and J2, respectively. Although such considerations are not always simple and may give unexpected results because the boundary conditions vary from fragment to fragment as well as from protein to protein, they still help to save part of the analysis of overlapping areas between helix and  $\beta$ -sheet and to avoid conflicts between  $\beta$ -turns and helices.

A certain number of segments were missed in the prediction by the present program due to one of the following reasons:

It was ruled that the nucleation segment should contain fewer than one third helix breakers ( $B_\alpha$  or  $b_\alpha$ ). This condition strictly eliminated some segments which have two breakers out of six residues although they met

the requirement of having at least two thirds h's (e.g.  $\alpha$ -hemoglobin 23-28 and papain 120-126).

- The nucleation segment did not have at least two thirds h's (e.g. carboxypeptidase 116-121 and lysozyme 80-85) , although by incorporating an extra residue, the final segment (carboxypeptidase 116-122) would respect the rule, or by shifting the whole fragment by one position to the left (lysozyme 79-84) the new boundaries (J1-1, J2-1) would have better  $P_{\alpha N}$  and  $P_{\alpha C}$  respectively.

- The position of the residue Pro at the N-terminal end is also critical. For example, in concanavalin A 83-88, although this fragment had the right number of h's, the presence of Pro as the fourth residue (position 86) impeded the fragment from being taken into account. In this case it was not possible to shift the fragment to the right to position 84-89 because from position 89 the area had higher  $\beta$ -sheet than  $\alpha$ -helix potential. Therefore we attempted a preliminary consideration of the fragment 83-88 as a possible helix then tried to shift it to avoid having Pro as the fourth residue (e.g. concanavalin A 80-85).

- For Russell's Viper Venom 47-55, as there were more  $I_\alpha$ ,  $i_\alpha$  and  $b_\alpha$  than  $H_\alpha$  and  $h_\alpha$  in this part of the polypeptide chain, the nucleation search skipped the entire area because none of the combinations of six consecutive amino acid

residues had at least two thirds h's. Nevertheless the "one half h's" requirement was met by the entire fragment 47-55 (5 h's out of 9 amino acid residues). Hence this requirement could not be applied strictly in all cases, and it may be modified to such an extent that the final predicted segment will not be considered as having deviated from the normal criteria.

- The gathering of two or three Pro residues in the same area was another possible reason for missing a fragment (e.g. bovine colostrum inhibitor 5-10). The fragment 1-10 of this protein contained three Pro at positions 4, 5, and 11, hence the program could only detect the segment 9-14 as the most suitable to avoid having Pro in the inner helix. However, if the residue Pro 5 was considered acceptable as an N-terminal end residue (good  $P_{\alpha N}$ , although not at the third position), then the fragment 5-10 would be a potential  $\alpha$ -helix since it met the requirement for two thirds h's.

In summary, in order to obtain results which are closer to those of Chou and Fasman or to X-ray data, the nucleation rule was slightly modified (i.e., under specific circumstances the nucleation segment may have one third breakers, which then must be compensated by the addition of h's during the  $\alpha$ -helix propagation, and the presence of Pro at the 2 first positions of the N-terminal end instead of

at the third one does not always constitute an obstacle to  $\alpha$ -helix formation). In addition, before asserting a segment of the polypeptide chain as  $\alpha$ -helix, the search for its most suitable boundaries was first carried out. This extra analysis was developed in two extra subroutines, the first one dealing with the N-terminal residue (cf. subroutines MOJ1, RMJ1) and the second one with the C-terminal residue (cf. subroutines MOJ2, RMJ2).

The following program, for the  $\alpha$ -helix search, was eventually adopted.

### Efficiency of the $\beta$ -sheet prediction

As indicated in the previous section strict adherence to Chou and Fasman's set of rules led to the missing of a certain number of regions and to some differences between the boundaries of predicted areas from this study and those of Chou and Fasman and X-ray analysis (Table 6). Analysis of the results obtained showed that the observations made for the helical search could also be applied for  $\beta$ -sheet. This involved moving the boundaries J1 and J2 to a more suitable position through consideration of the boundary conformational parameters  $P_{\beta N}$ ,  $P_{\beta C}$ ,  $P_{n\beta N}$  and  $P_{n\beta C}$  of the neighbouring residues.

Some examples of boundary adjustment for predicted  $\beta$ -sheet regions are listed below:

(1) J1 = J1 - 2:

Concanavalin: 49-57

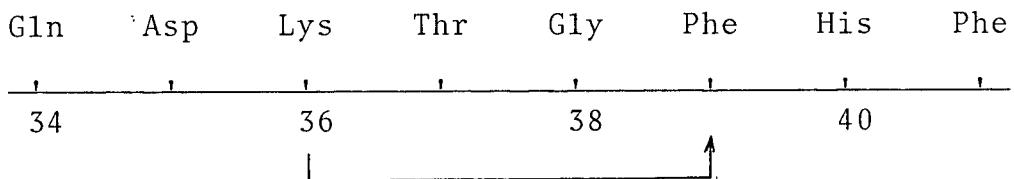

Val	Gly	Thr	Ala	His	Ile
'	'	'	'	'	'
47		49		51	

Val (47) is listed second for its  $P_{\beta N}$  and it is a strong  $\beta$ -former. Hence, besides the fact that its presence balances the breaker Gly (48), it also ensures a very stable

N-boundary to the predicted  $\beta$ -sheet.

(2) J1 = J1 + 3

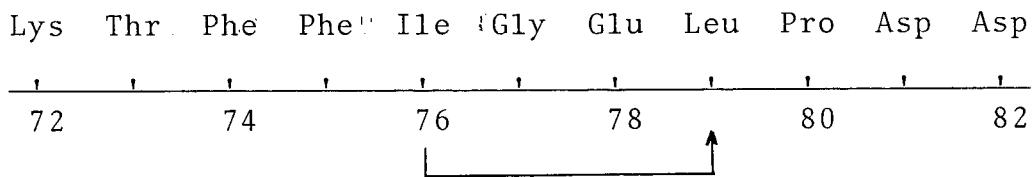

$\alpha$ -Chymotrypsin: 36-42

Besides the good  $P_{\beta N}$  of the residue Phe (39), by moving J1 to position J1+3, Phe (39), two  $\beta$ -sheet breakers, Lys (36) and Gly (38) are avoided, as well as, the tetrapeptide 35-38 which exhibits  $\beta$ -turn potential.

(3) J2 = J2 + 3

Cytochrome b<sub>5</sub>: 73-76

The region 73-76 contains enough  $\beta$ -sheet formers to balance the addition of two breakers, Gly (77) and Glu (78). Leu has been ranked fifth for its  $P_{\beta C}$  and the residues Pro (80), Asp (81) and Asp (82) possess good  $P_{n\beta C}$ .

(4)  $J_2 = J_2 - 3$ :

Concanavalin A: 25-32

Asp	Ile	Lys	Ser	Val	Arg	Ser	Lys
28	30	32		34			

↑  
25-29

Although Ile 29 has a lower  $P_{\beta C}$  than Val 32, the new region 25-29 still has a stable C-boundary and is itself more stable because of elimination of the two breakers Lys 30, and Ser 31. In fact, region 25-32 has 4 breakers out of 8 residues.

(5)  $J_2 = J_2$ :

Carboxypeptidase A: 277-281

Tyr	Gly	Phe	Leu	Leu	Pro	Ala	Ser	Gln
277	279		281		283		285	

↑  
277-281

Considering its neighbouring residues, Leu 281 appears to be a good choice for the C-boundary since it is ranked fifth for its  $P_{\beta C}$  and is a  $\beta$ -former. The residues Pro 282 and Ser 284 exhibit good  $P_{n\beta C}$  which may favor the stabilization of the sheet C-terminal.

These boundary analyses for the  $\beta$ -sheet prediction were elaborated in two extra subroutines added to the end of the propagation procedure (subroutine FOUR deals with the N-boundary adjustment and subroutine FIVE with the C-boundary adjustment). Again, it was recognized that such analyses were quite tedious and did not always ensure completely satisfying results due to the complexity of protein arrangement.

The nucleation procedure was also subjected to some modifications to reduce the number of missing residues. In most cases, once an area with  $\beta$ -sheet potential was located, the nucleation search would start again from its (C-terminal + 1) residue to avoid repetition in the same area (cf. subroutine FIRS). However, for some proteins (e.g. bovine colostrum inhibitor, glucagon, Black Mamba Toxin K and Russell's Viper venom), such a procedure resulted in the omission of some regions (Table 6, p. 205).

The problem was solved by starting the search again every time from the (N-terminal + 1) residue of the previous fragment. The major drawback of such a procedure was the tedious repetition of the search for high molecular weight proteins. The proteins for which the new procedure improved the quality of the prediction were: bovine colostrum inhibitor, glucagon, Black Mamba Toxin K and Russell's

Viper Venom. These proteins have molecular weights of 7,511, 3,483, 6,566 and 6,850, respectively, which are lower than those of other proteins used in this study. Hence it is possible that in low-molecular weight proteins, short range interactions between adjacent residues may lead to the formation of  $\beta$ -sheets under circumstances not encountered in bigger proteins.

The requirement of less than one third  $\beta$ -sheet breakers may sometimes provoke a section or a protein with 3 h's out of 5 residues to be ignored in the nucleation search (e.g.  $\alpha$ -chymotrypsin 197-201, ribonuclease 116-124). In addition , the presence of Pro 198 and Pro 117 in  $\alpha$ -chymotrypsin and ribonuclease, respectively, is unfavorable to  $\beta$ -sheet nucleation according to rule B.1. Therefore, in the modified program, two distinct decisions were made:

(1) for  $\alpha$ -chymotrypsin, once segment 197-201 has been considered as a possible  $\beta$ -sheet, boundary analysis allows shifting of the entire fragment to the right. The final value 199-204, besides having the advantage of being closer to X-ray results (199-203), also has better  $P_{\beta N}$  (Leu) and  $P_{\beta C}$  (Asn).

(2) for ribonuclease, instead of shifting fragment 116-120, the addition of an extra tetrapeptide (121-124) with an acceptable  $\beta$ -sheet potential makes the presence

of Pro 117 less unfavorable to  $\beta$ -sheet conformation and it eventually leads to the prediction of a  $\beta$ -sheet area with very favorable  $P_{\beta N}(\text{Val})$  and  $P_{\beta C}(\text{Val})$ .

As Lys did not occur often at the N-terminal of a  $\beta$ -sheet section, the change of its assignment from a  $\beta$ -sheet breaker to a  $\beta$ -sheet former could not readily be made because of the possible result of erroneous predictions. However, in the case of ribonuclease 61-65 it was necessary to have Lys 61 equivalent to a h $_{\beta}$  ( $P_{\beta N}(\text{Lys}) = 1.00$ ) so that this section did not violate the requirement of two thirds h's.

The presence of a strong B $_{\beta}$  such as Asp could interrupt the preliminary search of areas with  $\beta$ -sheet potential (e.g. papain 4-9). This disruption resulted in an inability to start any nucleation procedure on the two fragments arising from this disruption (papain 3-6, 7-10). These two fragments could not by themselves meet the requirement of two thirds h's. Hence in such conditions the nucleation rule may be slightly modified so that eventually, with the combination of boundary analysis, one could still locate an appropriate  $\beta$ -sheet area. A somewhat similar situation was encountered with subtilisin 44-51. The two adjacent fragments 42-45 and 49-52 could not be the starting point for  $\beta$ -sheet formation. They were separated by a section with quite low  $\beta$ -sheet

potential (Gly-Gly-Ala:  $\langle P_{\beta} \rangle = 0.76$ ). Nevertheless the entire section 44-51 was detected as  $\beta$ -sheet by Chou and Fasman (1974b) and by X-ray diffraction (Chou and Fasman, 1974b). It also has good end residues, Val (44) and Val (51), and  $\langle P_{\beta} \rangle$  is greater than  $\langle P_{\alpha} \rangle$  (1.045 versus 1.040).

In summary, by taking into account the important contribution of the boundary conformational parameters (subroutines FOUR and FIVE) and the necessity of allowing more flexibility to the nucleation rule (subroutine SECO) under the specific conditions previously mentioned, the following program was adopted for the  $\beta$ -sheet search. Only the different subroutines are presented here since the main program for  $\beta$ -sheet prediction is identical to the one used for  $\alpha$ -helix search, except that the  $\beta$ -sheet boundary conformational parameters replace those pertaining to  $\alpha$ -helix characterization.

### Efficiency of the $\beta$ -turn prediction

Although some small differences existed between the results in this study and those reported by Chou and Fasman (1977, 1979) (e.g. carbonic anhydrase 71-74, 109-112;  $\alpha$ -chymotrypsin 148-151;  $\alpha$ -hemoglobin 81-84; thermolysin 19-22, 43-46), in general the results in this study agreed very well with those of Chou and Fasman (1977, 1979). Therefore, no modification was needed for  $\beta$ -turn prediction. The program used for  $\beta$ -turn prediction consisted of the main program and one subroutine. The subroutine was the only part presented in this study because the main program was similar to the one used for  $\alpha$ -helix and  $\beta$ -sheet search.

### Efficiency of the resolution of overlapping $\alpha$ - and $\beta$ - areas

In general, the procedure outlined by Chou and Fasman (1978a, 1978b) was effective to solve the dilemma. In the present program, if more than half of the conditions tested ( $P_\alpha$ ,  $P_\beta$ ; character analysis; boundary analysis; ratio of helix length to  $\beta$ -sheet length) favored one of the conformations, then this conformation would be adopted. However, it happened that some cases could not be easily solved because both conformations ( $\alpha$ -helix and  $\beta$ -sheet) were equally favored. Although the calculations showed that  $\langle P_\alpha \rangle < \langle P_\beta \rangle$ , the overlapping section may contain more  $H_\alpha$  than  $H_\beta$ , or less  $B_\alpha$  than  $B_\beta$ . This may be explained by the higher values of  $\beta$ -sheet conformational parameters compared to helix; thus, they compensate the lower number of occurrence of  $H_\beta$  in the overlapping regions.

For ambiguous situations (e.g. papain 26-33, ribonuclease 49-59, myoglobin 100-119, lysozyme 107-114, subtilisin 269-275, thermolysin 138-150, thermolysin 160-175, thermolysin 175-180, thermolysin 261-274, thermolysin 234-246), more weight was given to factors such as: a) presence of antiparallel  $\beta$ -sheets. According to rule 3 for solving overlapping areas, antiparallel  $\beta$ -sheets are preferentially predicted due to interactions which enhance conformational stability. Thus, in case antiparallel  $\beta$ -sheets are absent,

preference for long  $\alpha$ -helix over shorter  $\beta$ -sheet is one of the major factors to be considered; especially when the helical conformation is supported by only half or less than half of the conditions tested. b) ratio of helix length to -sheet length ( $R_1 \geq 2.0$ ) and c) character analysis (to take into account the different types of residues, former, indifferent to, or breaker of  $\alpha$ - and  $\beta$ -conformation).

Staphylococcal nuclease 13-18, 30-39; concanavalin 125-133; ribonuclease 94-110;  $\alpha$ -chymotrypsin 85-91; papain 161-166 are examples of antiparallel  $\beta$ -sheets being predicted instead of longer helices, although these regions also exhibit good potential for helical conformation.

The reference to known proteins in the prediction of unknown ones is very useful, especially when some homology exists between the known and unknown proteins (Argos *et al.*, 1976). This was observed in the present study for the prediction of proteinase inhibitors.

The following program was written to assess the different important factors contributing to the resolution of overlapping  $\alpha$ - and  $\beta$ -regions. An extra part to read pairs of overlapping helices and  $\beta$ -sheets was added to the main program common to the search of  $\alpha$ -helix,  $\beta$ -sheet and  $\beta$ -turn.

### Comparison of the predictive accuracy

In Tables 5 and 6 (p. 189 and 198) the results of Chou and Fasman (1974b), those of X-ray analysis (Chou and Fasman, 1974b) and those obtained before and after refinement of the program of this study are pooled together. The prediction of the different conformations of lysozyme (egg white) was chosen as an example of the output yielded by the present program (Appendix). The quality of prediction was assessed by the parameters  $Q_\alpha$ ,  $Q_\beta$  and the coefficients  $C_\alpha$ ,  $C_\beta$  calculated for most of the proteins used in this study (X-ray data were not available for some proteins). For the  $\beta$ -turn search, as results of the present study were almost the same as those of Chou and Fasman (1979), it is reasonable to assume that the accuracy obtained in this study is comparable to that of Chou and Fasman (1979). Although Chou and Fasman reported their results and compared them to X-ray data (Chou and Fasman, 1979), this entire procedure will not be repeated again.

Tables 7 and 8 (p. 207 and 209) list the values of  $Q_\alpha$ ,  $C_\alpha$  and  $Q_\beta$ ,  $C_\beta$ , respectively as obtained by Chou and Fasman (1974b) and by the present program. As an extra reference, values reported by Argos *et al.* (1976), who used joint prediction histograms resulting from the combination of five computerized methods (including the method of Chou and Fasman) were also used

The good agreement between X-ray data and the prediction from this study ( $C \geq 0.40$ ), except for concanavalin A and  $\alpha$ -chymotrypsin ( $C_\alpha = 0.39$ ), was expected since this was the aim in refining the program. In general, the predictive accuracy reported by Chou and Fasman (1974b) was clearly superior to that of Argos et al. (1976), except for cytochrome c and myogen ( $Q_\alpha$ ,  $C_\alpha$ ). The paired-sample t-test revealed that the values of  $C_\alpha$  ( $P < 0.01$ ) and  $C_\beta$  ( $P \leq 0.05$ ) calculated for the present prediction were significantly improved from the values of Chou and Fasman (1974b). One may argue about the validity of the parameters Q and C in this study, and the reliability of the present program when applied to unknown proteins since the present program was adjusted to fit X-ray data on the basis of a limited number of samples (24 proteins). Chou and Fasman (1978b) studied the influence of neighbouring residues ( $n-1$ ) and ( $n+1$ ) in dipeptides and tripeptides on the conformation of amino acid n. They noted that the interactions of some residues with high  $\alpha$ -helix or  $\beta$ -sheet potential may result in dipeptides or tripeptides with much lower conformational parameters (e.g., the combination of Lys and Glu). Hence efforts to improve the quality of the predictive methods are still necessary and one may expect that the eventual program will become more and more complicated since so many different factors must be considered in order to obtain good agreement with X-ray data. Argos et al.

(1976) suggested that a perfect predictive algorithm should include a consideration of energy minimization, thermalization, and long-range interactions. In their study, the use of joint prediction histograms, which were shown to be superior to any individual prediction, did not always yield good agreement with X-ray data. Hence, in the present study, the modifications made to the present program are not completely useless because if the models used are adjusted to fit experimental data, they can still provide some useful guidelines for unknown systems. In fact, in refining the present program, more consideration to the influence of the neighbouring residues, especially at the boundaries, and to the conformational potential of the adjacent segments, was emphasized. As a result, the number of overlapping areas between  $\alpha$ -helix and  $\beta$ -sheet or between  $\alpha$ -helix and  $\beta$ -turn was decreased (Table 5). In general, the predicted regions also had boundary residues with favorable conformational parameters. Hence, at least one may be confident that areas with strong potential for a specific conformation will not be missed when using the present program. Special situations may not permit the attainment of satisfactory results.

Argos et al. (1976) and Matthews (1975a) agreed that no favorable prediction can be expected for unknown proteins unless they possess some common organization with the known ones through sequence homology. Further modifications

of the present program will be made when additional data or extra rules for the predictive algorithm are reported by Chou and Fasman or other researchers. As it has been emphasized by Fasman (1980), the lack of high accuracy of the present predictive methods should not stop researchers from using them to obtain a suggestive model for proteins. This will partially help to get an insight on protein behavior while X-ray data are not yet available.

In summary, in the present study, the major framework for the secondary structure search based on the method of Chou and Fasman (1978a, 1978b) has been computerized. Extra modifications which will be necessitated by the advent of improvements in the predictive methods are not perceived as being of any great obstacle to the use of the basic programs developed in this study.

## Conformations of some food related proteins

The second objective of this study was to obtain some information on the conformation of food related proteins such as bovine serum albumin (BSA),  $\alpha_{s1}$ -casein,  $\beta$ -casein,  $\kappa$ -casein, chymosin,  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, ovalbumin, pepsin, and trypsinogen. Table 9 lists the percentage of  $\alpha$ -helix,  $\beta$ -sheet, and  $\beta$ -turn found for each protein using the modified program. Table 10 shows the possible locations of the different conformations. The schematic diagram corresponding to each of the tested proteins can be found in Figures I to X. Some references were found to corroborate the reliability of the prediction from the present study. Loucheux-Lefebvre et al. (1978), using the method of Chou and Fasman (1974b), obtained 23%  $\alpha$ -helix, 31%  $\beta$ -sheet, and 21%  $\beta$ -turn for  $\kappa$ -casein (bovine). These results are quite comparable to those of the present study (20, 33, and 29%). The locations of the different conformations were almost the same, except for helix 90-97 which was predicted as  $\beta$ -sheet by the present program, and helix 62-68 which was not predicted by Loucheux-Lefebvre et al. (1978).  $\alpha$ -Lactalbumin was predicted by the method of Lim (1974b) to contain 43% helix and 12%  $\beta$ -sheet compared to 38% helix and 15%  $\beta$ -sheet obtained in the present study. Ovalbumin was reported to be composed of 40% helix by Yang and Doty (1957) using ORD, while a value of 25-30% helix was found by Gorbunoff (1969). Extra ref-

erences would be useful to evaluate the precision of the results of Yang and Doty (1957), of Gorbunoff (1969), and of the present study (44% helix).

The bovine gastric proteases, chymosin and pepsin, are very homologous in their amino acid sequence and their zymogens may even be activated by a similar mechanism (Foltmann et al., 1973). This is partially reflected in the prediction from the present study which yielded high percentages of  $\beta$ -sheet and very low percentages of  $\alpha$ -helix for both (40.2 versus 3.7% for chymosin, and 33.4 versus 1.8% for pepsin). The difference in the values between the two enzymes may be explained by difference in their source, chymosin from bovine source and pepsin from porcine source. The pancreatic proteases,  $\alpha$ -chymotrypsin and trypsin, also exhibit homology in their primary structure (Huang and Tang, 1970). Hence, it was not surprising to observe a very similar conformational pattern between the two enzymes: 33.5%  $\beta$ -sheet versus 9.0%  $\alpha$ -helix for  $\alpha$ -chymotrypsin with X-ray diffraction (Chou and Fasman, 1974b), and 31.0%  $\beta$ -sheet versus 13.5%  $\alpha$ -helix for trypsin with the present program.

Although no reference was found for BSA, it may be reasonable to compare it to ovalbumin as they both belong to the albumin group. The high percentage of  $\alpha$ -helix predicted for BSA (52.1%) may be comparable to that of ovalbumin

(44.1%). However, the percentage of  $\beta$ -sheet was much lower for BSA (2.2%) compared to 20.5% for ovalbumin.  $\alpha_{s1}$ -Casein and  $\beta$ -casein were predicted to contain very similar percentages of the three types of conformation (14.6, 26.1, and 30.1% for  $\alpha_{s1}$ -casein versus 13.9, 23.0, and 33.0% for  $\beta$ -casein). Unfortunately, there is no reference to check the present results. No reference was found to assess the precision of the prediction for  $\beta$ -lactoglobulin (35.8%  $\alpha$ -helix and 30.9%  $\beta$ -sheet)

All the results concerning food related proteins should be considered as suggestive and should be confirmed by other techniques (CD, ORD, X-ray). Nevertheless, one advantage of the method of Chou and Fasman (1987a, 1978b) is that it allows the detection of areas exhibiting potential for both  $\alpha$ -helix and  $\beta$ -sheet conformations. Hence, conformational changes observed with CD may be explained by the transitions that those sensitive areas have undergone. All the conformational transition phenomena may help to understand protein functionalities such as gelation, foaming, and emulsifying activity. It has been observed that denaturation of proteins must occur to some extent before those properties are actually exhibited. For instance, for glucagon (29 amino acid residues), it has been hypothesized that the transition from  $\alpha$ - to  $\beta$ -conformation of the region 19-27 is necessary for the receptor binding because of the more compact structure.

resulting from such a transition (Chou and Fasman, 1978b). It was also observed that glucagon in the gel state has a higher percentage of  $\beta$ -sheet (52%) than glucagon in solution (21%) (Gratzer et al., 1967; Epand, 1971). The predictive method can help to locate the sensitive area 19-27 (Chou and Fasman, 1978b). In sickle cell hemoglobin, the replacement of some  $\alpha$ -formers or  $\beta$ -breakers by strong  $\beta$ -formers (Val) results in the transition from  $\alpha$ - to  $\beta$ -conformation of the section 1-6. This leads to the aggregation of hemoglobin cells due to interchain interactions replacing intrachain ones (Chou and Fasman, 1978b).

In summary, even though a complete picture of protein behavior cannot be expected without the consideration of the three-dimensional organization which has a great impact on the whole problem, the knowledge of the secondary structure remains one of the useful means to explore the complex nature of proteins.

Table 9. Percentages of Helix,  $\beta$ -Sheet and  $\beta$ -Turn of Some Food Related Proteins Obtained from the Present Program

	Helix (%)	Sheet (%)	Turn (%)
Bovine serum albumin (582 aa)	52.1	2.2	29.6

## CONCLUSIONS

A computer program has been written in Fortran language to predict the secondary structure of proteins based on the method of Chou and Fasman (1978a, 1978b), which mainly relies on the frequency of occurrence of each amino acid residue in a certain conformation. This led to the classification of the 20 amino acids as either former, indifferent to, or breaker of the conformations.

Four programs have been designed to locate each type of conformation involved in the secondary structure ( $\alpha$ -helix,  $\beta$ -sheet and  $\beta$ -turn) and to solve the possible overlapping  $\alpha$ - and  $\beta$ -areas. Each program consists of the main program and several subroutines which correspond to the various steps to be followed in the method (nucleation, propagation and termination), or to the various conditions to be checked ( $\langle P_\alpha \rangle$ ,  $\langle P_\beta \rangle$ , character assignment, conformational parameters of the boundary residues, and possible presence of antiparallel  $\beta$ -sheets). For the  $\beta$ -turn search, because of the constant number of residues involved (four) and the less complicated predictive rule, the program corresponding to it is much simpler than the other ones.

On testing the present program on 24 different proteins, some missing areas and differences in the boundary residues between the results of the present study and

those of Chou and Fasman were observed. After a thorough analysis of the problem, some modifications were added to the program of this study, including the following. The condition that at least two thirds of formers for helix nucleation may not be satisfied in some cases, although the eventually predicted area met the general requirement of being comprised of one half or more helix formers. Similarly the requirement of less than one third of breakers for  $\beta$ -sheet nucleation may lead to the omission of a potential  $\beta$ -sheet area, although it contains enough  $\beta$ -formers. Hence, the type of residues in the nucleation area, as well as, the surrounding residues may stabilize the area conformation such that the presence of some breakers cannot provoke its disruption. For the boundary residues of the predicted  $\alpha$ - and  $\beta$ -areas, the use of the boundary conformational parameters ( $P_{\alpha C}$ ,  $P_{\alpha N}$ ,  $P_{\beta C}$ ,  $P_{\beta N}$ ) results in predictive values closer to those of Chou and Fasman (1974b, 1978b) and of X-ray data (Chou and Fasman, 1974b, 1978b). The use of those parameters also helps to avoid predicting too many overlapping  $\alpha$ - and  $\beta$ -areas, or overlapping  $\alpha$ -helix and  $\beta$ -turn.

The method outlined by Chou and Fasman (1978a, 1978b) to solve the problem of overlapping  $\alpha$ - and  $\beta$ -regions proved to be useful in most cases. However, ambiguous situations may occur where the area under consideration exhib-

its strong potential for both conformations. In such cases more emphasis should be given to the presence of antiparallel  $\beta$ -sheets and to the type of residues present in the area although it may happen that the average  $\langle P_\alpha \rangle$  or  $\langle P_\beta \rangle$  does not support the same conformation as the residue assignment. The ration of length of the predicted  $\alpha$ -helix and  $\beta$ -sheet is another useful factor to evaluate the importance of each one. It is not unexpected that for the prediction of unknown proteins which exhibit some homology with known ones, this procedure gives less problems than for completely unknown proteins.

Comparing the predictive accuracy parameters  $Q_{\alpha(\beta)}$ , and  $C_{\alpha(\beta)}$  obtained by Chou and Fasman (1974b), Argos et al. (1976) and the present program, it appears that predictions from the present study and those of Chou and Fasman (1974b) are in general better than those of Argos et al. (1976). The paired-sample t-test revealed that the values of  $C_\alpha$  ( $P < 0.01$ ) and  $C_\beta$  ( $P \leq 0.05$ ) calculated for the present prediction were significantly improved from the values of Chou and Fasman (1974b). For most of the proteins used in this study, except for concanavalin A and  $\alpha$ -chymotrypsin ( $C_\alpha = 0.39$ ), good agreement with X-ray data ( $C \geq 0.40$ ) was observed as an expected consequence of the modifications given to the present program.

Stimulated by those positive results, the program developed in this study was applied to food related proteins so as to provide a possible means of explaining and predicting food protein behavior under various conditions. Although references could not be found for all of the proteins tested (bovine serum albumin,  $\alpha_{s1}$ -casein,  $\beta$ -casein,  $\kappa$ -casein, chymosin,  $\alpha$ -lactalbumin,  $\beta$ -lactoglobulin, ovalbumin, pepsin, and trypsinogen), the predicted regions for  $\kappa$ -casein and  $\alpha$ -lactalbumin were very similar to those reported by other researchers. They either used the method of Chou and Fasman (Loucheux-Lefebvre et al., 1978), or their own method (Lim, 1974b).

In summary, the main objective of this study to computerize the method of Chou and Fasman (1978a, 1978b) was attained. Extra modifications of the program will be made when additional data or new set of rules (incorporating long-range interaction and energy minimization factors) are published by Chou and Fasman or other researchers. So far most of the predictive methods do not always ensure high predictive accuracy and caution should be given to the prediction of unknown proteins. Nevertheless considering the cost and the lengthy and complex operations involved in the X-ray technique, the predictive algorithms still remain a valuable tool for access to the complicated organization

of proteins while awaiting for confirmation by X-ray analysis. Furthermore, the accuracy of the predictive methods may be improved by combining them with CD or ORD techniques which constitute an additional means to solve ambiguous cases of overlapping  $\alpha$ - and  $\beta$ -areas. The percentage of each conformation in proteins can be obtained using these techniques.

## APPENDIX

### How to Use the Programs

After converting the entire protein sequence into a series of corresponding numbers, the following set of cards must be prepared as input data for the program of helix,  $\beta$ -sheet and  $\beta$ -turn prediction. The first card of the set gives the total number of amino acid residues of the protein in question (NN) and the number of data cards (N). Each of those data cards is composed of 16 numbers or amino acid residues, except the last data card which may or may not be filled with 16 numbers. The following format has been used for NN and N: (6X, 14, 6X, 14).

An example of how the first card looks like for a protein of 164 amino acid residues (NN = 164 and N = 11):

Column	1	6	10	16	20
	1	6	4	1	1

The protein sequence is reported on the subsequent cards (16 data per card) whose format has arbitrarily been chosen as 16 I5. In other words, each of the 16 numbers will occupy five columns on a current IBM card of 80-column width. To keep all the numbers right justified, the one-digit data should be located at columns 5xn ( $n = 1, 2, 3, 4, \dots, 16$ ), and the two-digit ones should start at  $(5n-1)$  columns. A typical data card may look like:

.	.	.	.	8	.	.	.	1	2	.	.	.	1	4	.	.	3	.	.	.	9	.	.	.	1	2	.
1				5				10					15				20				25				30		

An echo print of the input data in the prediction output enables the detection of any typographical error.

In summary, in order to use the programs for helix, sheet, and turn prediction, one has to enter the protein sequence in the form of an "introductory" card (which provides the total number of amino acids and the total number of data cards) followed by the actual data cards (16 data per card).

In addition to the protein sequence, extra information concerning the positions of the overlapping helices and sheets are necessary for the utilization of the

overlapping program. For this reason, the last data card of the protein sequence will immediately be followed by a second set of cards which consists of:

- an "introductory" card of the same format similar to the first one (6X, I4, 6X, I4). The two numbers in question are the total number of values giving the positions of the overlapping helices and  $\beta$ -sheets (it will always be a multiple of four because pairs of helices and  $\beta$ -sheets are involved in the procedure), and the total number of data cards (16 data per card).

- for convenience, keep the format of 16 I5 (5 columns for each datum) for the data cards carrying the information on the positions of the different pairs of overlapping helices and  $\beta$ -sheets. On each card, the boundary values of helices and  $\beta$ -sheets were arranged according to the following ways:

	H1	S1	H2	S2	H3	S3	
Column	1	5	10	15	20	25	30

H1 : N-boundary of the helix starting from H1 to H2

S1 : N-boundary of the  $\beta$ -sheet starting from S1 to S2

H2 : C-boundary of the helix H1-H2

S2 : C-boundary of the  $\beta$ -sheet-S1-S2

H3 : N-boundary of the helix starting from H3 to H4

Hence the relative positions of helices and  $\beta$ -sheets alternate with each other. An 80-column card can contain up to eight pairs of values.

In summary, in order to use the overlapping program, two sets of cards must be prepared. The first set provides the computer with the information on the protein sequence and the second set, which immediately follows the first, contains data on the relative positions of the overlapping helices and  $\beta$ -sheets. For convenience, the same type of format is used in each set of cards.
